Quick Guide to Interactions Evaluation System

Interaction Probability Guide

I. PROBABILITY OF CLINICALLY SIGNIFICANT INTERACTION:

1. Certain
2. Probable
3. Possible
4. Plausible
5. Improbable
6. Unknown

II. TYPE AND CLINICAL SIGNIFICANCE OF INTERACTION:

✗	Potential or Theoretical Adverse Interaction of Uncertain Severity
✗✗	Minimal to Mild Adverse Interaction—Vigilance Necessary
✗✗✗	Potentially Harmful or Serious Adverse Interaction—Avoid
⟐	Impaired Drug Absorption and Bioavailability, Negligible Effect
⟐⟐	Impaired Drug Absorption and Bioavailability, Precautions Appropriate
⟐⟐⟐	Impaired Drug Absorption and Bioavailability, Avoidance Appropriate
⟐	Adverse Drug Effect on Herbal Therapeutics, Strategic Concern
⟐	Adverse Drug Effect on Nutrient Therapeutics, Strategic Concern
⟐≈≈	Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management
⟐≈≈	Drug-Induced Adverse Effect on Nutrient Function, Supplementation Therapeutic, Not Requiring Professional Management
⟐⟐	Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate
⊕✗	Bimodal or Variable Interaction, with Professional Management
⊕	Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management
⊕⊕	Beneficial or Supportive Interaction, with Professional Management
⊕⊕⊕	Beneficial or Supportive Interaction, Not Requiring Professional Management
≈≈	Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management
≈≈≈	Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management
≈⟐⟐	Drug-Induced Nutrient Depletion, Supplementation Contraindicated, Professional Management Appropriate
☼	Prevention or Reduction of Drug Adverse Effect
☼	Prevention or Reduction of Herb or Nutrient Adverse Effect
?	Interaction Possible but Uncertain Occurrence and Unclear Implications

III. STRENGTH AND QUALITY OF SOURCE EVIDENCE:

- ● Consensus
- ◉ Emerging
- ○ Preliminary
- ▽ Mixed
- □ Inadequate

Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on his or her own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Authors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

To those who have inspired us,
who have welcomed us,
who have taught, and supported us,
in our challenges, growth, shortcomings, and successes;

Those with whom we share our lives and work,
with whom we play, create, grow, and endure,
as we evolve together,
in our understanding, appreciation, and respect for one another;

Those who come to us, who trust and challenge us,
who ask difficult questions and want honest responses,
who honor us with the challenge and privilege of serving them
in their healing and self-discovery;

That we may care for each and all, including ourselves,
just a little bit better,
working together in a sincere effort
toward healing, truth, and peace
in every interaction.

Foreword

Dietary supplements are among the most commonly used complementary and alternative medical therapies in the United States, with sales reportedly exceeding $20 billion in 2005. Newspapers, magazines, and the mass media feed our curiosity for new supplements and ways to manage our health on a daily basis. New dietary supplement formulations flood the shelves of pharmacies, health food stores, retail chains, and Internet outlets. Consumers want to know what works and are willing to pay for products that may make them feel better. However, consumers are also growing frustrated with inconsistencies in product quality and perceived lack of regulatory oversight. Surveys indicate that health care professionals are both interested in learning about, and concerned over the widespread use of, dietary supplements. This is not surprising given the contradictory scientific data and provocative titles in medical journals linking supplements with dangerous adverse events and lack of efficacy. Although many supplements are safely used by the public, there is little question that the complex chemistry of botanicals and multi-ingredient formulations may have profound effects, both beneficial and harmful, on our human physiology.

Dietary supplements marketed in the United States before passage of the Dietary Supplements Health Education Act (DSHEA) in 1994 are not required to demonstrate safety or efficacy, an a priori belief that since these products were already in the marketplace, one could assume a certain level of safety. The assumption that these products are safe and free from adverse effects may lead to excessive dosing, concomitant use with prescription and over-the-counter (OTC) medications, and failure to disclose supplement use to health care providers. According to a large, federally sponsored survey, approximately 28 million Americans are taking dietary supplements with their prescription medications, and 69% of them have not told their primary care provider. As a physician who is also an herbalist, I find that patients generally feel comfortable talking to me about their use of supplements and alternative therapies. Yet, even with my training, I constantly brush up against the edge of my knowledge and experience when a patient asks if taking ginkgo, ginseng, saw palmetto, hawthorn, coenzyme Q10, magnesium, L-carnitine, multivitamin, and a Chinese herbal formulation called *xin li dru kang wan* will interact in any way with his quinapril, amiodarone, clopidrogel bisulfate, simvastatin, and esomeprazole! A difficult question for anyone to answer, but even more for those without any formal training in natural products and limited to the typical 12- to 15-minute patient encounter. As was shown with St. John's wort, however, herb-drug interactions can occur and can be very serious.

It would be easy to assume that if adverse events and interactions with drugs were really a problem, it would be glaringly apparent given the number of people using these products. However, as Chair of the United States Pharmacopeia Dietary Supplements Information Expert Committee, I can attest to the difficulty in determining and establishing safety for many of the dietary supplement ingredients in the marketplace. Many botanicals and nutritional supplements lack detailed pharmacokinetic and pharmacodynamic data. The adverse event reporting systems that are currently in place for drugs are woefully inadequate for monitoring dietary supplement products, given the vast number of complex and unique formulations in the marketplace and the variety of names used on the label (i.e., Latin binomial, common, foreign language). This makes it almost impossible to enter, retrieve, or analyze information from electronic databases when an adverse event is suspected. Unlike prescription and OTC medications, it can be difficult to ascertain if the adverse event was caused by the ingredient(s) declared on the label, or actually resulted from the accidental or intentional adulteration, substitution, or contamination of the product with a toxic botanical, heavy metal, or pharmaceutical agent. Accurate identification of the dietary supplement is essential for determining causality; however, the point of contact for most serious adverse events is generally a physician who has neither the training nor the funds for collecting, submitting, and paying a laboratory with expertise in analyzing complex botanical or supplement products. This further complicates evaluation of adverse event reports in the medical literature, because product identity is seldom verified. In most cases, the evidence for causality is based primarily on the fact that the supplement cannot be excluded, rather than clear evidence of toxicity. And yet, in the absence of better pharmacological data and an optimal adverse event reporting system, case reports remain a necessary, if problematic, mechanism for monitoring safety.

With the primary emphasis on adverse interactions, the topic of beneficial interactions has received little attention. It is well recognized that statin medications deplete coenzyme Q10 in the body. Preliminary evidence suggests that administering 50 to 100 mg per day of the supplement may reduce the myopathies that are reported by about 20% of patients using this class of lipid-lowering medications. A growing body of evidence supports the administration of glutamine during chemotherapy to prevent neuropathy, whereas selenium was shown to reduce the nephrotoxicity associated with cisplatin. Low serum folate levels decrease the effectiveness of antidepressant medications. An integrative approach would utilize therapies that reduce or mitigate the adverse effects of medications deemed necessary for the patient whenever possible.

It is within this climate that I enthusiastically welcome this book, a collaboration written by experienced clinicians within the fields of conventional, integrative, and natural medicine for health professionals who wish to counsel their patients effectively on the safe and beneficial use of dietary supplements. As the title suggests, this book addresses herb-drug interactions, nutrient-drug interactions, and drug-induced nutrient depletions in a clinically oriented, integrative manner. The authors demonstrate an appropriate balance between recommendation and risk based on the overall strength of the scientific evidence and their own clinical experience. The text is well referenced, balanced, and objective, and the use of icons and summary tables allows the clinician to quickly identify areas of potential risk, as well as potential benefit. This book is a major contribution to the field of integrative medicine and an invaluable resource to practitioner and researcher alike.

Information Expert Panel

Preface

We are in the midst of a critical historic juncture in the evolution of medicine. Three major currents are influencing the practice of medicine, the science underlying its methodology, and the relationship between caregiver and patient. First, a significant proportion of patients are exercising greater levels of self-education and self-care, requesting greater opportunity for informed decision making and often demanding a realignment of the usual power relationships in conventional medicine. Second, the emergence of personalized medicine, particularly but not only in the form of genomics, pharmacogenomics, and nutrigenomics, offers the promise of tailoring efficacy while decreasing adverse effects in a manner that offers a modern scientific approach to individualization of care beyond generic pathology and lowest-common-denominator generalizations. Third, the now well-established recognition of medical pluralism mandates greater communication and collaboration between health care providers of various medical traditions from diverse cultures and philosophies, methodologies and therapeutics. Together, these factors give a profoundly transdisciplinary impetus to the development of enhanced clinical strategies synthesizing the science of medicine and the art of healing in a process-oriented approach to the individual patient.

Within the context of these converging influences, the issues arising from the potential interactions between conventional drug therapies and herbal and nutritional therapies present both a challenge and an opportunity. The challenge involves unanticipated adverse drug reactions (ADRs). The opportunity involves the potential for enhancing the depth and breadth of the mainstream medical model, ultimately improving the success of clinical outcomes. After more than two decades of complementary and "alternative" medicine ("CAM") and subsequent optimistic portents of an era of "integrative medicine," the average practitioner surveying the medical landscape for substantive changes in the clinical care model usually sees only glimmers of vision, moments of inspiration, and select ideal cases. Such aspirations may be suitable for some, but most clinicians would be content simply with effective tools for understanding other disciplines, how their patients are using them, and the implications when mixing pharmaceutical medicines and other modalities. Nevertheless, our patients are using a diverse array of medical approaches, and we all are entering a world of transdisciplinary care and personalized medicine, complexity models of physiology, and unprecedented access to information. In this context, the discovery of new synergies and unparalleled collegial collaboration offer the promise of enhanced patient empowerment and novel clinical strategies. Ultimately, we must always keep in mind that our first and only loyalty can be to our patients and their health, even if it forces us to grapple with the unfamiliar and acknowledge the unconventional.

PURPOSE AND FUNCTION

The present work derives from the clinical needs of practicing health care professionals who have been compiling, analyzing, and publishing assessments on interactions for two decades. Interactions between drugs and nutrients first became a subject of review and education in 1988 during the development of the *Integrative BodyMind Information System (IBIS)* database. On publication of that reference tool, clinicians increasingly requested deeper coverage of interactions issues involving nutrients and herbs, in response to widespread and growing use of such products by their patients and clinicians' desire to integrate such agents into their therapeutic repertoire. In 1997, exhortations from physicians and educators precipitated a dedicated focus on interactions issues in a clinical context and catalyzed development of the *Interactions* software database, subsequently published in 2000. That reference work essentially functioned as the first edition of the research and writing that has evolved into the present publication. Through that experience and several years of input and feedback from health care professionals and educators around the world, as well as inquiries from an online reporting and resource website, the models, methods, and tools applied in the creation of this publication were developed and refined. In particular, a year of intensive investigation, dialogue, and debate produced the pioneering system of interaction characterization, literature evaluation, and clinical probability applied in reviewing, compiling, and assessing the relevant scientific and medical literature. Thus, the current volume represents the indirect outcome of almost 20 years of work and 10 years of direct efforts.

Interactions between pharmaceutical drugs and "natural" products such as nutrients and herbs constitute an area of immediate concern and growing awareness wherever patients are receiving health care and members of the public are engaged in self-care through use of these substances. Many patients naively assume that nutrient and herbal products are "natural" and that this somehow implies they are "safe." More disturbing is the acknowledged fact that many patients often withhold disclosure of nutrient and herbal intake or use of nonconventional care from their conventional health care providers. This combination suggests the need for deep inquiry and analysis into the doctor-patient relationship and the coordination of medical care. In the meantime, however, clinicians need a guide to working with patients using nutrients and herbs and guidelines for crafting their interventions to coordinate these elements. This book is most directly intended to serve this need among health care professionals, educators, and students throughout the whole range of medical professions. The depth of coverage, the emphasis on research, and the focus on practical implications address the needs of this professional audience. Secondarily, this information will be of benefit to individuals in other professions, ranging from librarians to retail staff, faced with questions from the general public regarding these issues.

An overview of the presently available literature reveals the predominance of two types of print and electronic publications covering this subject matter: those intended for the professional market and those intended for a consumer/patient audience. The same data may also be disseminated differently for use by both audiences. In both cases, most publications can fairly be characterized as lacking in depth and incomplete or overreaching in conclusions.

The professional literature tends to assume that patients using nutrients and herbs ("dietary supplements") are doing so without supervision of health care professionals trained and experienced in the therapeutic application of nutritional and botanical therapies. Lack of disclosure by patients also tends

to be the case, and greater awareness, frank discussion, and informed decision making in these areas are necessary for effective clinical management as well as patients' perception of respect for their choices. Similarly, especially in complex and chronic conditions, the use of multiple providers from several different health care disciplines is increasingly common. Professionals in all disciplines can increase clinical efficacy and patient safety through open dialogue and collegial (peer-to-peer) collaboration. However, interactions literature is often prepared by health care professionals without training or experience in nutritional and botanical therapies. Therefore, the advantages of purposefully combining, strategically sequencing, or deliberately avoiding such interventions are usually not addressed in a comprehensive and practical way. In addition, the interactions reference texts and guides developed for consumers are limited in depth, often avoid critical issues, and sometimes prey on readers' fears by exaggeration and headline hyperbole. Furthermore, the commercial context of their use frequently presents an apparent conflict of interest, especially when provided as aids in product selection in a retail setting. Similarly, these guides are presented as online educational tools appended to broader coverage of "alternative medicine" within the context of medical, pharmaceutical, or insurance websites. Either situation implies significant constraints as to thoroughness, rigor, and efficacy because caution is justifiably the operative premise. The issue of apparent conflict of interest and possible bias must always be considered in a setting funded and presented by commercial interests, both for what is said and what is avoided. Inherently, the scope, thoroughness, and standards of evidence tend to be different for consumer education (or promotional) publications than for professional publications because of the vast divergence in educational level, operational needs, and responsibility. Overall, the literature available to most of the general public, whether magazines, books, friends and family, or the Internet, tends to avoid recommendation of these agents at therapeutic doses or in a manner that might be construed as treating diagnosed conditions.

By contrast, in this book we explore many methods of using nutritional and herbal interventions not only as "dietary supplements" but also as components of comprehensive, transdisciplinary therapeutic strategies. This approach diverges fundamentally from typical drug interactions databases marketed for physicians, especially those for handheld devices, that list telegraphic warnings (often unsubstantiated) about "supplements" without context or qualification. Where concomitant administration of nutrients and herbs might harm a patient or significantly interfere with predictable effects of conventional medications, the priority of ensuring patient safety is established throughout the text by providing cautions and suggesting modifications based on scientific literature and clinical experience.

METHODOLOGY AND STRUCTURE

The methodology applied in developing this publication involved two steps. First, input was gathered from among the authors and other clinicians, as well as pharmacists and educators, as to potential interactions they were seeing in clinical practice and of substantive clinical relevance, particularly potential risk or observed therapeutic value. Second, available reference works on interactions, including drug-drug interactions literature, were reviewed for scope, depth, methodology, and presentation. This method ensures that we incorporated the best of all approaches, building on those from our own experience, and avoiding or countering those methods and characteristics that lead to poorly founded, overreaching, or misleading conclusions. Ultimately, the team that produced this book was determined to make realistic assessment of clinical relevance and evidence quality its foundation. Only a product that would meet the standards of what we would feel confident using in our own practices would be acceptable for publication. Thus, the research and editorial team consists of practicing health care professionals trained in therapeutic nutrition, botanical medicine, pharmacology, and pharmacognosy with experience on a daily basis in general family practice and specialty care, with an emphasis on internal medicine, oncology, and hematology. This text is therefore itself a result of collaboration among practicing experts from different modalities that is emblematic of the transdisciplinary collaboration that ultimately is required to understand and manage drug-nutrient and drug-herb interactions. This fact alone distinguishes this text from other publications that claim to cover the topics but present one-sided, theoretical, or partial approaches that necessarily lack the transdisciplinary insight and clinical relevance of this collaboration. Perhaps most importantly, our authors are deeply enmeshed in collaborative care on a daily basis, bringing together health care professionals from multiple disciplines and combining therapies from multiple modalities.

In areas where the available resources appeared to be limited, immature, or flawed, the authors systematically addressed three primary needs. First, the lack of a multidisciplinary approach inherent in the existing literature leads to the common tendency, for example, to assert potential interactions imputed from assumed pharmacological theory, without any corroboration from clinical experience with the interacting agents. Other than research into certain well-known drug-induced nutrient depletion patterns, direct clinical trials of adequate power are nearly absent from literature pertaining to drug-herb and drug-nutrient interactions. Overall, the primary source evidence tends to be delayed and reactive, fragmented, or tangential to other research objectives, or simply unapparent to those not trained and experienced in these fields. Consequently, many interactions supported by readily available evidence are simply not described in most texts. Also, many interactions based on substandard or preliminary evidence are given more weight than they deserve. In such cases, contextualization and "debunking" of the putative or alleged interactions often result from the necessary "reality check." This problem also derives from overreliance on secondary literature (e.g., reviews, meta-analyses) and derivative material in topical publications. Second, no previously available text, including our first effort, incorporates sufficient detail to assess effectively the quality of the original data; the strengths and limitations of the study design, size, and duration; or the characteristics or even the dose, form, or other critical particulars of the agents involved. Third, *clinical relevance* and *therapeutic implications* need to be the primary goal of analysis of all interactions.

In light of these many factors, this text relies primarily on evidence from clinical trials whenever possible, using reasonable extrapolations from human research as secondary evidence and relegating animal studies or in vitro experiments to a supportive role. Published case reports are assessed based on the strength of their relevance, detail, and quality. Extrapolations can be reasonable or not. Our in-depth examination of the published literature revealed that the available secondary and derivative literature contains at worst an abundance of confusion and at best a lack of clarity on decisive facts, such as proper identification of a nutrient or herb and the plant part used, naturally occurring nutrients or whole herbs versus synthetic forms or

extracts, doses outside the range of those considered safe and clinically effective, diverse modes of administration, and distinctive or even divergent characteristics of subject populations. In particular, the repeated citation of a poor-quality case report, irrelevant finding, or flawed research in multiple publications suggests superficial recycling of citations by secondary authors without full text review of original sources or critical analysis of conclusions. The pervasive interchanging as equivalents of *Ephedra* (the plant) and ephedrine (a pharmaceutical alkaloid) provides a stark illustration of this problem and its reverberations, despite the presumed good intentions of those making the assertions. In contrast, this text notes if studies use forms of an agent that experienced practitioners would shun, or doses too high for safety or too low for therapeutic efficacy. Perhaps most important is the recognition that uninformed administration of agents, or combinations of agents, in a manner wholly detached from the logic, methodology, or standards and guidelines of appropriate clinical practice and historical context from which they are derived, does not constitute an "adverse event" or "interaction."

A significant gap often exists between the research literature and clinical practice in regard to the origins and form of many agents studied in the scientific literature. Not all nutrients or botanically derived preparations can accurately be described as "natural" medicines; many do not appear in nature and are more accurately placed in the province of "pharmaceutical preparations" rather than herbs or nutrients as traditionally understood or historically practiced. Thus, a gradient can be articulated spanning pharmaceutical nutrients (e.g., dl-alpha-tocopherol, i.e., racemic synthetic vitamin E), isolated preparations of naturally occurring nutrient and botanical constituents, foods and herbs in whole or minimally modified forms (with inherent diversity and variability of constituents), and nutrients and herbs in combinations or formulae (with even greater complexity). Often the isolated constituents and synthetic preparations or mixed isomers used in research studies contrast sharply with the forms (whether naturally occurring or crafted in accordance with traditional methodologies) typically used by practitioners trained and experienced in nutritional and botanical therapeutics. Moreover, the issues affecting interactions analysis are confounded by the recurrent paradox observed in innumerable papers on broader topics in which authors voice contradictory assumptions and conclusions; first, that whole-food sources are safer and more effective than, and generally preferable to, nutrients (or herbal) constituents in pill or tablet form, but second, that foods, herbs, nonstandardized extracts or isolates, or multicomponent formulae do not fit the methodology of study designs oriented to assessing single-agent pharmaceutical interventions. The resulting statements that naturally occurring and synthetic forms are equivalent, and recurrent findings that food (or herbal) sources provide benefits not found in synthetic supplemental or extracted forms, at least not in those specific forms studied, suggest that naturally occurring forms, identical in origin, to food (or plant) sources may be the missing link. Further, authors of research papers, and even more so those who read abstracts or press releases and then write articles on these papers for the professional and lay press, often fail to discriminate between studies using naturally occurring forms, dosage levels, and modes of administration typical in experienced clinical practice and studies using isolates or synthetic variants. Consequently, ill-founded extrapolations and unsubstantiated conclusions and warnings often result that diverge from the actual research findings and even more so from real-world clinical implications. In general, it might be stated that foods are a common preference among practitioners emphasizing nutritional therapies in their clinical practice. However, the therapeutic efficacy of food sources can be limited by several critical factors, including difficulty in achieving necessary dose thresholds of specific nutrients or constituents on a consistent basis because of volume of food sources required, low rates of compliance in the regular consumption of such required doses of necessary food items, and, in more recent decades, declining nutrient quality of commercially available foods.

Similarly, just as there is a large divergence between primary literature and the secondary literature of reviews and meta-analyses, an even greater separation exists between primary sources and editorial news coverage in both professional publications and popular press, as well as in educational materials and tools available to the typical patient/consumer. In particular, three primary limitations appear on analysis. First, the nature of study populations is often not defined, particularly with reference to critical distinctions between healthy subjects and those with diagnosed conditions. The related factors, such as genetic risk and pharmacogenomic variability, gender and age, health status, and socioeconomic vulnerabilities, are only considered on rare occasions. Second, critical factors in study design, such as cohort size, dose, form, duration of administration, and other potentially confounding influences, can significantly alter outcomes and the interpretation of findings. In many cases, these variables would be significant enough to create major divergences in assessing conclusions because characteristics of a given study could plausibly alter effects, but such characteristics were not mentioned or factored into the analysis and conclusions. Third, certain health care professionals, most notably naturopathic physicians and herbalists of the Euro-American, Chinese–East Asian, and Ayurvedic traditions, employ botanical formulations and nutritional therapeutics as a primary clinical intervention. Whether in these settings or in multidisciplinary integrative approaches, the use of multiple agents within a therapeutic strategy is typical practice, and especially in herbal medicine, single agents are rarely expected to provide the properties, potency, or personalization that a compound formula provides. Such treatment strategies are very difficult to assess adequately using research models or methodologies that assume single-agent interventions, which are uncommon in patients with chronic diseases and complex cases.

The methodology applied in this text emphasizes that supplementation of nutrients (and rarely, nutritive use of herbs) in healthy populations is distinct from unsupervised, concomitant use of nutrient support in individuals concurrently taking prescription drugs (especially those with known nutrient-depleting effects) and from purposeful coadministration of nutrients or herbs with conventional drugs within the context of clinical management by health care professionals applying integrative principles. Therefore, the organization of these interactions monographs involves a spectrum of categories, including "avoidance," "benefit," and "management."

By incorporating summary tables as well as in-depth analysis of each interaction analysis, our text provides a useful combination of brevity and thoroughness by presenting an accurate overview as well as answering needs for deeper access to substance and detail. We refer to this publication as a "comprehensive" reference work because our goal is to articulate the subject in a broad and practical manner, not merely to catalogue available data without reference to origins, therapeutic context, patterns of usage, and clinical implications. In response to feedback from users of the previous software publications and in pursuit of strategic design goals, the current text not only increases the breadth and depth of the topics under

consideration, but more importantly also applies a systematic method of analysis and presentation aimed at enhancing the clinical utility of the reviewed information and subsequent analysis. The structure and presentation of each monograph are designed to enable rapid review through summary analysis and coded characterizations of the character, significance, and evidence quality of each substantiated interaction, while also providing greater depth with a thorough review of evidence, mechanisms, and evolution of the scientific literature on the subject.

Each monograph provides basic information on physiology and function of the given nutrient or herbal agent, followed by a summary of established interactions and a review of clinically relevant data that contextualizes the discussion of interactions with specific drugs, including known or potential therapeutic uses and historical/ethnomedicine precedent, deficiency symptoms, dietary sources, nutrient preparations, typical therapeutic and supplemental dosing, laboratory assessment, and safety profile, with nutrient adverse effects, contraindications, and precautions and warnings. The Strategic Considerations section of each monograph discusses the broader clinical role of the particular agent, emphasizing implications of interactions, and further assesses the clinical relevance of the available data, patterns of interactions, and contentious or unresolved issues; this section also presents broad clinical reviews for substances for which substantive interactions evidence is lacking. Each review of a particular interaction dyad is divided into those with substantive evidence, primarily focusing on clinical trials and qualified case reports, and those relying on preliminary, speculative, and/or questionable data. Within each interaction pair, the pharmaceutical agent, and/or drug class, is introduced by generic name(s) and a summary characterization regarding type(s) of interaction(s) involved, quality of the evidence base, and estimated probability of clinical relevance, followed by subsections presenting mechanism(s) of action, evidence and practical clinical implications, suggestions, and cautions.

Presenting the development of evidence chronologically and thematically places emphasis on critical factors such as study design, number and characteristics of subjects, study duration, form, and dosage. Data from in vitro experiments and animal research are primarily used to examine possible mechanisms of action and to elucidate or qualify evidence from human research. In general, the standards applied in evaluating the strength of evidence are less demanding than those appropriate to evaluation of clinical trial relevance. Furthermore, patient safety is emphasized as the highest value, with a focus on optimizing outcomes while minimizing adverse effects. Overall, given the emerging state of interactions literature, the threshold of inclusion applied in weighing the available evidence is often of a lower standard than ideal, and conclusions are often qualified as such, with the oft-repeated recommendation that "further research through well-designed and adequately powered clinical trials is warranted." Specific citations are appended to each monograph, and a separate file listing Reference Literature underpinning the overview presentations for each nutrient monograph is available.

The *default bias* often displayed in the medical literature assumes that interactions involving herbs and nutrients result in adverse effects. Not only are such outcomes merely one of several possible effects, but such reports are also often of substandard quality in the professional literature and are typically caricatured and misrepresented in the popular press. In assessing the quality of evidence, we have appreciated the taxonomy articulated by Fugh-Berman and Ernst (2001) for the review and assessment of report reliability in the area of herb-drug interactions. As noted in their meta-analysis, the data used in making claims of interactions are frequently inadequate and unreliable. Thus, these authors concluded that more than two thirds of published reports reviewed were "unevaluable" and graded only 13% as "well-documented." They also noted that, in contrast to most drugs that contain a single pharmacological agent, most herbal products in use, and thus likely to be involved in possible interactions, tend to contain a variety of pharmacologically active constituents. The typical use of multiple herbs within a formulation further complicates the possibilities of ascribing causal relationships.

The literature of nutrient-drug interactions is typically not much better in quality than that of herb-drug interactions, with the possible exception of research into drug-induced nutrient depletions. Generally, the research cited is limited by several factors: inadequate patient history; presence of concurrent conditions or pathologies; involvement of one or more medications (particularly those with known interactions or adverse effects); lack of adequate recording of such comedications; failure to adequately describe, assay, or otherwise document alleged interactors; incomplete chronology or consideration of time relation of intake among substances; and incomplete consideration of alternative explanations for adverse effects. The need for improvements in the methodology, gathering, and analysis of reports and research of interactions involving herbs and nutrients will benefit all concerned and enable distinctions among harmful, beneficial, and bimodal interactions and clarify the frequency, intensity, and risk parameters influencing such events. Our conscious intention in assessing data is to tilt toward safety and emphasize conservative, nontoxic interventions. The development of this text has also emphasized avoidance of unreasonable and poorly founded extrapolations, especially speculative construction of "backwards interactions" based on tenuous assumptions. For example, asserting that because an herb may relieve symptoms assumed to derive from estrogen deficiency, the herb inherently will adversely interact with agents intended to elevate estrogen levels; or when a nutrient or herbal preparation demonstrates a beneficial effect on glycemic control, it is somehow interpreted as adversely "interacting" with hypoglycemic medications. In fact, however, such effects often represent a therapeutic synergy worth investigating.

Awareness of narrow therapeutic index, titration in response to gradual introduction or withdrawal of any agent, and individualized assessment and evolving interventions stand as the recurrent issues and key operative watchwords in safe and effective implementation of interactions in a clinical setting. Overall, developing methods for approaching potential interactions can help health care professionals avoid inherently dangerous situations; minimize, neutralize, or counter risks and potential adverse effects or impaired therapeutic responses; and engineer increased therapeutic potency through additive, synergistic, or strategic combinations.

Many of the limitations in the scientific literature relating to interactions reflect and parallel those in the broader study of herbal and nutritional therapies in general. The scientific literature available to those attempting to assess the probability and clinical significance of interactions among various agents is inherently incomplete and inclined to be reactive. Whether in the area of drug-drug interactions or those involving nutrients or herbs, the instances of purposeful research into adverse interactions are rare. Case reports and circumstantial findings tend to dominate the literature and are of highly variable quality, with the clear majority qualifying as incomplete and unreliable. Further, although the scientific study of combined drug and

nutrient therapies is emerging, and study of drug-induced nutrient depletions is occasionally commanding attention (again, usually in reaction to accumulating reports of adverse outcomes), the literature investigating drug-herb interactions is in a highly preliminary, and often woeful, state. Again, unqualified case reports tend to dominate the headlines, and only recently have experienced practitioners of herbal medicine become involved in designing clinical trials or evaluating case reports. Notably, most discussions of herbs in the conventional literature involve single herbs, and if being used for treatment, then only using a generic, pathology-focused treatment model, when in fact experienced health care professionals almost always prescribe herbs in formulae that are modified to match peculiar individual patient characteristics and that evolve over time in response to changes in the patient's condition. Similarly, the dosages, clinical indications, prescribing methodology, preparation methods, and even plant parts used in most published trials often reflect little on the professional practice of herbal medicine. In other words, the two groups are usually talking about different things, and the designs of most studies have limited relevance to clinical practice of European, American, or East Asian schools of herbal medicine. Thus, we see a surge in discussion of the use of St. John's wort for depression, when a poll of professional herbal prescribers before such papers would have revealed no consistent use of the plant for that condition as a broad psychiatric diagnostic category; perhaps for melancholy and head injuries, but not "depression." Even more disturbing are studies using parts of plants never used or rarely used by herbalists or in doses at grossly different levels of potency than typical in clinical practice. Similar issues arise when looking at studies of vitamins, minerals, or other nutrients where single-agent interventions using forms usually avoided by professional prescribers, and often at doses considered ineffectual, produce insignificant outcomes. "Well, what would you expect; that's why we don't do it that way," is the usual response from experienced botanical/nutritional practitioners. The major consequences of such ill-conceived research are wasted money and resources and lost opportunities at evolving scientific knowledge and collegial collaboration.

The secondary literature discussing interactions involving herbs and nutrients amplifies and distorts the problems with the primary source material. Again, "news" tends to be hyperbolic and inflammatory and information delayed, reactive, and overrun with incestuous overuse of poorly qualified and superficially analyzed or incomplete reviews of the primary literature; consequently the conclusions are often poorly founded and hasty, of questionable clinical relevance, and misleading in their therapeutic implications. "The devil is in the details," and more often than not, no one bothered to look into the details. Although not nearly as "glamorous" and headline producing as adverse events and dangerous interactions, the areas of drug-induced nutrient depletions and integrative interventions combining drugs, nutrients, and/or herbs represent the bulk of substantive interactions material. Beyond simply correcting problematic interactions resulting from ignorance and lack of communication, these potential avenues of purposeful interactions management also constitute the most promising opportunities for the development of scientific knowledge capable of delivering the clinical interventions most likely to result in successful outcomes. Again, we see the necessity of distinguishing between supplemental use of nutrients, especially vitamins and minerals, on a broad level for undifferentiated populations and the clinical application of botanical and nutritional agents as therapeutic interventions in their own right or as part of multicomponent strategies. The quantity and quality of clinical trials focusing on, or at least taking note of, interactions will grow as researchers in conventional medicine become more conversant with nutrient and herbal therapies and engage practitioners experienced in such modalities in study design. All these observations emphasize the need to develop tools to facilitate submission of clinical data with complete and pertinent details to high-quality case reports of herb-drug-nutrient interactions, with the active cooperation of all parties involved. High-quality case reports can form the basis for meaningful clinical research and allow the emergence of informed and clinically relevant pharmacovigilance.

Grappling with drug-drug interactions is well known for its difficulties, and the emerging field of drug-nutrient and drug-herb interactions introduces many other complications, as mentioned. Because interactions involving drugs are commonplace and can be dangerous, those involving nutrients and herbs need not seem particularly unusual. Most notoriously, as one noted PharmD commented in conversation: "We just assume that warfarin interacts with everything." Drug-drug interactions are known for variability based on dose, timing, gender, hepatic function, and other drug clearance parameters. Reliably predicting interactions involving more than two agents, of any type, inherently invokes greater uncertainty, and any declarations other than probability are best viewed with skepticism. As a result, throughout the interactions literature, including that covering drug-drug interactions, there is often an implicit understanding that such interactions are strictly pharmacodynamic or pharmacokinetic and thus completely within the province of pharmacology. On close examination, however, such assumptions often unravel as it becomes apparent that interactions operate at many levels, and that firm distinctions are elusive and assurances of a complete mechanism of action may be hasty. Interestingly, many combinations described as interactions are not really *interactions* in the narrow technical definition. Although some may be "interactions" in some broader definition, a large proportion of adverse events derive from situations more accurately described as "contraindications" or "inappropriate prescriptions" (e.g., excessive additive effects; contrary actions; effective but inappropriately sequenced interventions; patients too young, compromised, or otherwise inappropriate for a certain agent[s] at the given dose).

Within the interactions literature, scant attention has been paid to the methodology by which interactions are analyzed. Borgert and associates (2005) noted in this connection that the "commonest approach was the no method approach." In general, there is insufficient quantitative dose-response data in herb and nutrient interaction studies to meet rigorous criteria for the accurate demonstration of supra-additive and subadditive effects of different dose levels for a given pair of agents.

THE INTERACTIONS UNIVERSE

The evaluation schema and detailed definitions and standards used in this text are provided in the following Interactions Evaluation Guide. The primary emphasis of this taxonomy is to establish an operational characterization of each interaction pair based on clinical priorities. In summary, the type and clinical significance of each known or potential interaction are parsed according to several variables: pharmacokinetic, pharmacodynamic, or clinical/strategic; adverse, beneficial, or bimodal (bidirectional); prevention or reduction of adverse effects; compensatory or protective response to probable depletions; negligible, cautionary, or avoidance levels of probable effects; and suitability for self-care or necessity of professional management. The levels of probability of clinically significant interaction are

graded as "1. Certain," "2. Probable," "3. Possible," "4. Plausible," "5. Improbable," or "6. Unknown." In a parallel assessment, the available and reviewed evidence is evaluated according to strength and quality: "Consensus," "Emerging," "Preliminary," "Mixed," or "Inadequate." The overall position of each interaction pair within this taxonomy is clearly data dependent, and when the available data suggested ambiguity or conflict, a final assignation was established by review and agreement of the entire editorial team.

In this text, all interactions are considered as potentially operating on several levels within the genomic variability and physiology of individual patients, their behavior and local environment, the clinical strategy and therapeutic relationship(s), and among practitioners. These multiple levels may be represented as a set of concentric circles (see figure).

Interactions Universe

Within this "interactions universe," multiple interventions are more often the rule than the exception, and interactions may be influenced by several different levels; as always, these effects may vary based on patient characteristics and the timing relationship between different interventions. Some interactions may be significantly affected by pharmacogenomic variability, with those involving warfarin, statin drugs, or folic acid being prime examples. In other cases, by shifting the perspective to clinical strategy, what may appear superficially as an interaction may simply be a clinical contraindication; that is, the therapeutic intent of one agent is antagonistic to the other agent, and these would generally be avoided in combination. More subtly, concomitant use of two agents may be characterized as "divergent" or "distracting," in which the action of a secondary or adjuvant therapy could theoretically reduce the action of the primary agent and thereby reduce overall therapeutic efficacy. A similar interaction pattern might be described as "dissonant" when two interventions are potentially appropriate but often can be incompatible in their action or mode of administration. Likewise, from a strategic perspective, some agents in pairs or in clusters, particularly when applied in a logical sequence, may act in a "consonant" manner. Thus, two agents given simultaneously may provide minimal benefit but administered sequentially may enhance therapeutic outcomes through strategic synergy. Two examples of such patterns are seen in the relationship between antibiotics and probiotic flora and, in a more complex form, between chemotherapy and antioxidants. Further, as recognition of herbs and nutrients as therapeutic agents, rather than mere supplements, grows, so does the need for expanding study of interactions between and among herbs and nutrients. Classical herbal traditions all have guidelines regarding synergies and contraindications for coadministration; such a methodology is inherent to formula building. However, research is only coming into the light in regard to such phenomena as the potential adverse effects on healthy intestinal bacterial flora from herbs with direct antibacterial activity, as opposed to indirect immune-enhancing activity. Once again, we see the need to place all substances with known or potential pharmacological activity on a level playing field using objective research design and integrative clinical approaches.

The complexities of these various influences on drug activity are rarely discussed in the literature with regard to resultant "interactions" and possible clinical implications. For example, clinicians of many modalities might recommend exercise, but how often do they consider the potential impact of exercise on drug metabolism? Might not a sudden increase in physical activity significantly change clearance of certain drugs as much as or more than many common nutrients or herbs? Similarly, in an era when every patient (except those on warfarin) is advised to "eat more fruits and vegetables," how can we calculate the impact of a significant change in dietary habits, especially for the better? Do we want to discourage patient initiative and motivation? Here, for example, one might consider the use of pomegranate juice in the patient with a family history of prostate cancer, or high intake of vegetables in someone with a family history of vascular disease. The recent finding that pomegranate juice, like grapefruit juice, inhibits the 3A4 isotype of cytochrome P450 enzymes involved in the metabolism of many pharmaceuticals, adds another level of complexity to prescribing and pharmacovigilance. Further, when the recommendation of dietary fiber and healthy oils is almost universal, doesn't every clinician need to advise patients about the known pharmacokinetic effects on drug metabolism of increasing fiber (which can bind many medications) or of eating more fish or olive oil, with the unknown implications of the effects of lipids on simultaneously consumed drugs? In considering these possibilities, we realize the limitations of scientific knowledge and clinical experience regarding pharmacokinetics of dietary intake, which does not even take into account the wide, pharmacogenomically determined variability among patients in the activity of hepatic enzymes and other systems of detoxification.

CLINICAL IMPLICATIONS

The questions raised here and throughout this text challenge the attentive reader to reconsider drug activity within the full context of therapeutic strategy and patient outcomes. Simply put, is it a higher priority to manage therapies for the sake of the patients or for the stability of their drug levels? Ultimately, the question arises: when do we counsel patients to avoid healthy behavior on the basis of the possible risk of disrupting predictable drug levels? Even with such cautions and qualifications, can we be certain this is really obtainable? How does such an approach address interindividual biochemical and metabolic variability? These issues have been discussed in nutrition therapeutics for decades (e.g., Roger Williams, PhD, discoverer of pantothenic acid and father of the concept of "metabolic individuality") and are foundational to the methodology of many of the so-called alternative medical traditions. For example, after emphasizing to patients the importance of the modern mantra of "eat right and exercise," how do we accept the paradox of telling "warfarinized" patients with cardiovascular disease to refrain from eating green vegetables, while also asserting repeatedly that food sources of nutrients are inherently superior to pharmaceutical supplemental sources?

Most experienced health care professionals understand that many "disruptive" behaviors (in terms of medication levels) are not really "problematic" in an absolute sense, and that simply refraining from such behaviors is not the answer. In fact, the patient who abruptly stops using a nutrient or herb, drops

something from the diet, or radically changes habits out of fear and ill-informed warnings is actually at greater risk from sudden changes. Carried to its extreme, might we not recommend to patients that they sit on the couch and eat only nonnutritive food so as best to maintain stable drug levels? Do we want our patients to imitate the in vitro experiments that we so often caution ourselves not to extrapolate so freely into human physiology? Thus, for example, with patients receiving oral anticoagulants, it would be more desirable, both from a health perspective and in terms of building patient rapport, if we could work with them on increasing healthy foods in their diet, teaching them to maintain a stable intake of dietary vitamin K, while monitoring their INR and titrating it with the appropriate warfarin dosage to maintain the desired clinical effect.

In reviewing the broad literature relevant to interactions between drugs and natural products, four key factors seem paramount and decisive to safety and efficacy: doctor-patient communication and trust; therapeutic index and rapidity of response; monitoring, feedback, and titration; and the urgent need for high-quality research and well-documented case reports together with communication and collaboration. Moreover, the overview of all the findings involving such interactions strongly suggests that other than a minority of clearly dangerous and contraindicated combinations of agents, most interactions are therapeutically advantageous when managed properly, and some portion are between these two polarities, where they pose clinically significant risks only when frank discussion and full disclosure are lacking and corrective measures are not implemented. In some cases, nutritional and herbal therapies may impair activity of a drug by promoting healthy physiological functions (our primary goal) and thereby increase metabolism of stressful or toxic substances, including many drugs. Thus, in these circumstances, the issue is not necessarily incompatibility, but rather lack of coordination and inappropriate timing, such as separation of bile sequestrant intake from the ingestion of fat-soluble nutrients, which tend to be depleted by such a drug, or separating intake of an immune-supportive nutrient such as zinc from antibiotics when the two might chelate when ingested simultaneously.

Although some observations and recommendations in this text may appear unfamiliar to some medical practitioners, the material used is inherently conservative, and the clinical suggestions are designed to be both pragmatic and clinically oriented, with an emphasis on objectivity and evidence, safety and efficacy. Apart from research into certain well-known drug-induced nutrient depletion patterns, direct clinical trials of adequate power are nearly absent from literature pertaining to drug-herb and drug-nutrient interactions. The scant number of reports of well-qualified and clinically significant adverse events suggests that dangers may be less than some have anticipated or declared, especially given the widespread use of herbs and nutrients and the overlap with medication intake. Moreover, research directed at the potential value of the anecdotal evidence available in qualified case reports strongly suggests that these could be a resource of premier value, given the complexities of interactions and the metabolic idiosyncrasies of patients.

Drug-induced nutrient depletion patterns constitute a significant proportion of drug-nutrient interactions. In these situations, awareness of interference with physiological functions of key nutrients or simple decline in available nutrient levels contributes directly or indirectly to known adverse drug effects and offers simple and safe interventions for reducing adverse effects, increasing patient comfort and compliance, and improving therapeutic efficacy and clinical outcomes. Research in this area was largely established in professional discourse by Daphne A. Roe, MD, who focused on such phenomena, particularly in geriatric patients, more than three decades ago. Growing awareness of nutrient use by patients and interest in nutritional therapies within conventional medicine suggest that this body of scientific literature will expand in coming years.

In essence, the issue of interactions presents physicians and other health care professionals with the challenge of working as allies, treating all interventions as options to be evaluated as tactics with a potential to enhance the therapeutic strategy. Thus, we may come to reframe the term "alternative medicine" not as "unconventional" or "competing" but rather as a range of options within a comprehensive repertoire to be considered in light of the patients' risks, needs, and history, as well as their preferences and values, motivation and compliance. Furthermore, effective clinical practice requires more flexible approaches, given the limitations of predictive models, especially when we question whether any model can accurately comprehend and predict the outcomes if more than two factors interact in a patient whose natal pharmacogenomic individuality has been modified by a lifetime's layers of stressors, trauma, and supports. These complexities suggest the need for an evolving and customized response in providing medical care, especially when treating chronic disease, in which some generic elements of treatment intertwine with some highly individualized aspects, and all components shift through phases of the clinical strategy and are crafted to optimize multiple interventions. The nature of the therapeutic relationship and its central role in such a setting emphasize the primacy of establishing and maintaining trust and frank open communication, the ability to be supportive and challenging, especially regarding diet and other lifestyle factors, and the need to be nonjudgmental, flexible, and responsive.

These issues point to patient self-care and utilization of multiple health care professionals from different modalities or specializations as central but often-ignored factors in the clinical reality of drug-herb and drug-nutrient interactions. In discussions of diverse approaches to health care and medicine, two distinct but often-related issues often become confused and inappropriately intermingled.

First, patients are using a wide range of medical treatments, ingesting unsupervised and untested permutations of substance combinations, and experimenting with both ancient and novel techniques and behaviors for enhancing wellness and treating disease. Since the early 1990s, conventional medicine has become increasingly aware of the patterns of utilization of health care services provided by health care professionals other than medical physicians (MDs), as well as use of nonconventional therapies by MDs. Likewise, the emerging educational, legal, and professional infrastructures of accredited educational institutions, professional associations, and licensing laws reveal the continued growth of naturopathic physicians, chiropractors, acupuncturists, massage therapists, medical herbalists, and others. Providing safe and effective clinical care in this environment requires knowledge, mutual respect, communication, and collaboration among health care providers working with individual patients, recognizing, affirming, and utilizing their choices, instincts, experiences, and intuitions. These issues become even more complex when patients have ready access to previously unavailable medical information and demand a partnership based on informed decision making. Professionals may have difficulty accepting that each patient, especially patients with chronic disease, holds this final responsibility and control and that health care providers are simply participants in this critical aspect of the patient's life and personal evolution.

Demographic data indicate that higher educational and income levels are associated with the use of natural medicine and alternative therapies. Whether acting from healthy initiative or desperation, these patients deserve respect in their health care choices and support in obtaining coherent medical care. Self-care is a strong tradition within American, English, and other cultures. Whether Culpepper or the Thomsonian and Hygienic movements, individuals, families, and communities have long fought for their right to continue their traditions of care that predate professional medicine. Although potentially challenging to our authority as educated health care professionals (and to the time constraints of daily practice), education and initiative, informed decision making, and self-empowerment can be our greatest allies in promoting health, preventing illness, and treating disease, with proper timing and strategic coordination. Here, must we not defer to the obvious necessity and professional duty to build trust based on honesty and full disclosure? Enabling frank discussions can provide the most reliable means of respecting patients' choices and satisfying their needs within a context of communication and mutual respect, collaboration and coordination among an integrative team of health care professionals.

This brings us to the second broad and often-unstated issue deeply involved in adverse events and interactions involving patients utilizing the services of multiple health care providers. Short of learning many types of medicine directly, clinicians of every type, whether conventional MDs, practitioners of natural medicine traditions, or practitioners from indigenous medical traditions, can benefit from cultivating collegial alliances with professionals from the diverse health care traditions that their patients utilize, as a means of developing practical familiarity and experience in cross-referrals. Each of these schools of medicine possesses its own respective models, techniques, and tools, and each derives from unique circumstances of history, demographics, and culture. Although simply the result of a lack of opportunity in some cases, ignorance of other health care systems often results from indefensible reliance on ill-founded rumors and inherited prejudices. Rarely does an MD really know the particulars of the chiropractic profession, or vice versa. Likewise, many practitioners of nutritional therapies have little substantive training in herbal medicine, and vice versa, to say nothing of the huge differences among European phytotherapy, American botanical medicine, and Chinese herbal tradition. Unfortunately, besides the notable exception of numerous pharmacists, our patients sometimes have a broader view of the numerous medical options in their repertoire than their health care providers, and that knowledge base is often far wider than deep. None of these parochial attitudes and behaviors serves the interest of our patients or respects their choices and values. Our responsibility as health care professionals is to serve our patients' needs, have access to information regarding the substances they choose to ingest and the procedures they find beneficial, and build collaborative relationships with providers experienced in those approaches, regardless of whether we agree with or support those choices. Ultimately, is any other option professionally ethical, clinically responsible, or therapeutically effective?

Reports of adverse events or interactions involving nutritional therapies or botanical agents almost universally derive from situations of patient self-medication, usually without disclosure or coordinated planning by the health care providers, and often involve faulty preparation, adulteration, contamination, or other departures from typical responses to known interventions. In contrast, substantive reports of adverse events or interactions regarding nutritional therapies or botanical agents prescribed, administered, and supervised by health care professionals trained and experienced in the respective therapies are virtually nonexistent. The few exceptions typically represent interventions considered within the standards of care but subsequently determined to be inappropriate to specific patient populations or in particular dosages or preparations. Thus, MDs, naturopathic physicians, and qualified herbalists have rarely been involved in situations of adverse reactions or interactions with prescribed nutritional or herbal treatments; in fact, they usually are enthusiastic advocates of scientific research through well-designed trials that might ensure safety, clarify indications, and enhance efficacy.

Based on our education, training, and clinical experience and strongly influenced by the process of compiling and analyzing the material in this text, we offer the following final thoughts. First, the issue of interactions involves not only avoiding unnecessary risks, but also recognizing unforeseen opportunities. The greater promise in integrative medicine lies not in the use of naturally occurring agents, such as an herb, food, or nutrient, to treat standard diagnoses in place of pharmaceutical agents, nor in the benefits of expanding the clinical repertoire of conventional medicine, but in rendering its medicines more effective, especially in combination with innovations in pharmacogenomics, systems physiology, and new research methodologies. More profoundly, the very movement of engaging with transdisciplinary approaches and their underlying models offers all practitioners and providers, conventional or otherwise, an inseparable corollary to the restructuring of their practice, the potential for transformation and expansion of their own consciousness, and an openness to a greater vision of the mysterious and miraculous in medicine.

INTERACTION PROBABILITY GUIDE

I. Probability of Clinically Significant Interaction

Interactions are by definition probable events. As with any statistical variable, meaningful prediction must be based on knowledge of the numerator and denominator.

Probabilities assigned to the interactions in the text are based on the following criteria of combined likelihood and clinical relevance.

1. Certain

Interaction occurrence is definite. Available research and clinical experience both indicate that purposeful coadministration is likely to provide increased therapeutic effect in beneficial interactions. With adverse interaction, concomitant use is definitely to be avoided, even when under the active care of an appropriately trained and experienced health care professional. In most cases, however, it is inadvisable to make sudden changes in usage if the individual's medical condition has been stable.

2. Probable

There is relatively high probability of this interaction occurring, all other factors being equal. Conservative practice implies considering these interactions operationally as definite, unless there are compelling reasons to the contrary. Available evidence or clinical experience indicates that purposeful coadministration may enhance therapeutic intervention. With adverse interaction, concomitant use is generally to be avoided, except when under the active care of an appropriately trained and experienced health care professional. In most cases, however, it is inadvisable to make sudden changes in usage if the individual's medical condition has been stable.

3. Possible

There is variable probability of this interaction occurring, depending on specific circumstances. Operationally, the probability of the interaction may be relatively low for most individuals; however, interindividual and intraindividual variation in probable occurrence of the interaction is likely, depending on multifactorial circumstances, including atypical dosages, certain preexisting medical conditions altering pharmacokinetic or pharmacodynamic parameters, particular risk associated with life stage susceptibilities, and pharmacogenomic and biochemical variability.

4. Plausible

Interaction of plausible, but not proven, likelihood. Although the mechanism and rationale of this interaction appear reasonable based on current knowledge, the available evidence is inadequate to support a conclusive judgment as to the likelihood of its occurrence or the variables influencing the character of such an interaction. However, potential clinical significance of the interaction may warrant careful consideration within integrative therapeutic strategies. This may be based on currently accepted clinical practices among appropriately qualified professionals in botanical and nutritional therapeutics, despite lack of currently available published evidential support.

5. Improbable

This interaction is unlikely to occur in most individuals, all other factors being equal. When taken at commonly used dosages for appropriate medical conditions as prescribed by health care professional(s) trained and experienced in botanical and/or nutritional therapeutics, the probability of clinically significant interaction occurring appears to be minimal.

6. Unknown

Data are contradictory, inconclusive, or insufficient to assign probability status.

INTERACTION TYPE AND CLINICAL SIGNIFICANCE GUIDE

II. Type and Clinical Significance of Interaction

Generally applicable principles:

- If the individual's prior medical condition has been stable, *any* changes to the therapeutic regimen involving addition or withdrawal of nutrients, botanicals, or pharmaceuticals should not be made abruptly. Transitions in protocols are de facto potential foci for interaction instability that may, if ignored, significantly affect intended therapeutic outcomes.
- Individuals vary in response to any pharmacological agent because of individual biochemical or pharmacogenomic variability, as well as health status and medical conditions.
- Professional management implies supervision by collaborating health care professionals with appropriate training in nutritional and/or botanical therapeutics within an integrative medical framework.

✗ Potential or Theoretical Adverse Interaction of Uncertain Severity

Interaction is theoretically possible based on known pharmacological characteristics of each substance. Inadequate information is currently available to determine clinical significance of potential risk. Pending conclusive research, close supervision and regular monitoring by a health care professional are warranted for any concomitant use.

✗✗ Minimal to Mild Adverse Interaction—Vigilance Necessary

Interaction represents a low to moderate risk, but potential severity warrants supervision of patient during concomitant use. Concomitant use is therapeutically feasible within the context of multidisciplinary collaboration, along with supervision and monitoring by health care professional(s) trained in conventional pharmacology and experienced with clinical herbal medicine and/or therapeutic nutrition.

✗✗✗ Potentially Harmful or Serious Adverse Interaction—Avoid

Interaction represents a significant to severe risk of adverse effect and should be avoided. Concomitant use should be deliberately avoided outside the context of close supervision and regular monitoring, including laboratory monitoring wherever feasible, by health care professional(s) trained in conventional

pharmacology and experienced with clinical herbal medicine and/or therapeutic nutrition.

◇ Impaired Drug Absorption and Bioavailability, Negligible Effect

Interaction is adverse but of minimal clinical significance. Nonetheless, modification of dosage, timing, or mode of administration may reduce potential for adverse effects of interaction.

◇◇ Impaired Drug Absorption and Bioavailability, Precautions Appropriate

Interaction is of mild to moderate severity. Modification of dosage, timing, or mode of administration will reduce adverse effects of interaction.

◇◇◇ Impaired Drug Absorption and Bioavailability, Avoidance Appropriate

Interaction has clinically significant adverse effects. Concomitant use should be avoided, especially outside the context of close supervision and regular monitoring by health care professional(s) trained in conventional pharmacology and experienced with clinical herbal medicine and/or therapeutic nutrition. Modification of dosage, timing, or mode of administration may contribute to minimizing severity in cases in which benefit of concurrent administration outweighs risks.

◇ Adverse Drug Effect on Herbal Therapeutics, Strategic Concern

Interaction in which drug may interfere with therapeutic effect of herbal prescription because of the drug's pharmacological properties. Alterations in drug dosage, timing, or other factors may prevent, ameliorate, or compensate for adverse effects of or interference with herbal therapeutics and optimize therapeutic effect, with appropriate clinical management within an integrative therapeutic strategy, without compromising therapeutic efficacy of either intervention.

◇ Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern

Interaction in which drug may interfere with therapeutic effect of nutrient prescription because of the drug's pharmacological properties. Alterations in drug dosage, timing, or other factors may prevent, ameliorate, or compensate for adverse effects of or interference with nutritional therapeutics and optimize therapeutic effect, with appropriate clinical management within an integrative therapeutic strategy, without compromising therapeutic efficacy of either intervention.

◇≈≈ Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management

Interaction in which standard-practice use of pharmaceutical agent will usually interfere with normal physiological nutrient function because of predicted drug action. Appropriate coadministration of nutrient, with appropriate clinical management within an integrative therapeutic strategy, will counter adverse metabolic effects of drug on nutrient and may optimize therapeutic effect without compromising therapeutic efficacy of pharmaceutical intervention.

◇≈≈ Drug-Induced Adverse Effect on Nutrient Function, Supplementation Therapeutic, Not Requiring Professional Management

Interaction in which standard-practice use of pharmaceutical agent will usually interfere with normal physiological nutrient function because of drug action. Appropriate concomitant supplementation with (or coadministration of) nutrient will counter adverse metabolic effects of drug on nutrient and may optimize therapeutic effect without compromising therapeutic efficacy of pharmaceutical intervention. Clinical management is usually not required.

◇◇ Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate

Interaction in which prescription pharmaceutical agent intentionally interferes with normal physiological nutrient function through predicted drug action. Nutrient dietary intake is typically restricted and supplementation or administration contraindicated to optimize therapeutic effect and avoid compromising therapeutic efficacy of pharmaceutical intervention.

⊕✗ Bimodal or Variable Interaction, with Professional Management

Interaction is inherently neither beneficial nor adverse, unless ignored. Based on known pharmacological characteristics of each substance (or reasonable extrapolations therefrom), interaction is theoretically possible. Depending on the specific clinical contextualization (patient, population, diagnosis, setting) and practitioner training and experience, the interaction may be deliberately utilized by an appropriately trained and experienced health care professional for increasing clinical efficacy with appropriate clinical management within an integrative therapeutic strategy. Although clinically significant in certain circumstances, this interaction may be of only minor significance in other contexts.

Note: In situations in which "Bimodal" is assigned to an interaction dyad in the text, the possible variations are also listed.

⊕ Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management

Beneficial interaction is theoretically possible based on known pharmacological data. However, inadequate substantive data exist currently to determine clinical significance of potential benefit. Coordinated use with appropriate clinical management within an integrative therapeutic strategy may theoretically increase therapeutic efficacy. Pending conclusive research, concomitant use may warrant close supervision and regular monitoring by a health care professional.

⊕⊕ Beneficial or Supportive Interaction, with Professional Management

Interaction in which intentional therapeutic use of nutrient or botanical preparation concomitantly with drug therapy can provide additive or synergistic effect and increase therapeutic efficacy for most individuals when taken at appropriate dosages with professional supervision and monitoring as needed. Some individuals may derive greater benefit because of medical conditions or individual pharmacogenomic and biochemical variability. Coadministration can be therapeutically efficacious within the context of multidisciplinary collaboration and supervision by health care professional(s) trained in conventional pharmacology and experienced with clinical herbal medicine and/or therapeutic nutrition.

⊕⊕⊕ Beneficial or Supportive Interaction, Not Requiring Professional Management

Interaction in which concurrent administration can generally be considered safe for patient self-care. Based on available

evidence, it is improbable that the therapeutic benefit of additive or synergistic interaction or nutritive support has the potential to induce an undesired and possibly adverse additive or interference effect, although discussion and communication with prescribing physician are advised.

≈≈ Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management

Interaction in which appropriate use of nutrient, given clinical management within an integrative therapeutic strategy, can prevent or counter nutrient depletion caused by drug without compromising therapeutic efficacy for most individuals when taken at commonly used dosages. Concomitant use therapeutically efficacious within the context of multidisciplinary collaboration and supervision by health care professional(s) trained in conventional pharmacology and experienced with clinical therapeutic nutrition.

≈≈≈ Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management

Interaction in which simultaneous use can generally be considered safe for patient self-care. Based on examined evidence, appropriate therapeutic use of nutrient adjunctively with drug therapy likely to provide correct drug-induced nutrient depletion pattern and improve therapeutic outcomes for most individuals, without interfering with drug efficacy, when taken at appropriate dosages. Based on available evidence, it is improbable that the therapeutic benefit of additive or synergistic interaction or nutritive support has the potential to induce an undesired and possibly adverse additive or interference effect, although discussion and communication with prescribing physician are advised.

≈◇◇ Drug-Induced Nutrient Depletion, Supplementation Contraindicated, Professional Management Appropriate

Interaction in which prescription medication intentionally interferes with normal physiological nutrient metabolism and may produce nutrient depletion pattern through predicted drug action. Nutrient dietary intake is typically restricted and supplementation (or coadministration) contraindicated to optimize therapeutic effect and avoid compromising therapeutic efficacy of pharmaceutical intervention. Concomitant use is generally contraindicated for most individuals. In some unusual circumstances, nutrient might be prescribed under appropriate parameters of dosage, timing, and duration, with clinical management and monitoring within the context of multidisciplinary collaboration and supervision by health care professional(s) trained in conventional pharmacology and experienced with therapeutic nutrition.

☼ Prevention or Reduction of Drug Adverse Effect

Interaction in which intentional coadministration of nutrient or herb concurrently with drug therapy within an integrative therapeutic strategy can prevent, reduce, or counter adverse drug effects without compromising therapeutic efficacy for most individuals when taken at appropriate dosages, under professional guidance.

☼ Prevention or Reduction of Herb or Nutrient Adverse Effect

Interaction in which appropriate use of medication is intended to prevent, reduce, or counter adverse nutrient or herb effects in conditions characterized by nutrient overload, exogenous toxicity, and metabolic derangement, without inducing clinically significant nutrient deficiency pattern or obstructing the role of herbal prescription for appropriate individuals when taken at therapeutic dosages. Concomitant use is contraindicated unless specifically determined as therapeutically efficacious within the context of multidisciplinary collaboration and supervision by health care professional(s) trained in conventional pharmacology and experienced with therapeutic nutrition.

? Interaction Possible but Uncertain Occurrence and Unclear Implications

Interaction is of uncertain character, significance, and predictability of occurrence, reflective of inconsistent and/or inadequate evidence. Prudence dictates avoiding concomitant use while assuming neither risk nor benefit until more data become available. Pending further clinical research findings, it is prudent to avoid concomitant use outside the context of close supervision and regular monitoring by health care professional(s) trained in conventional pharmacology and experienced with clinical herbal medicine and/or therapeutic nutrition.

STRENGTH AND CHARACTER OF SOURCE EVIDENCE GUIDE

III. Strength and Quality of Source Evidence

The source material for each topic is evaluated using the following composite indicators to offer an assessment of the overall character of the literature reviewed for that nutrient-drug or herb-drug pair.

● Consensus

Interaction demonstrated by a converging consensus of clinical experience, research literature, and known pharmacology, including significant findings from published clinical or preclinical human studies of strong design, size, and relevance; well-documented and consistent case reports; and established pharmacokinetic and pharmacodynamic data.

◉ Emerging

Interaction supported by emerging pattern of clinical experience, research literature, and known pharmacology, including human studies of adequate design, size, and relevance; limited but consistent, well-documented case reports; unpublished papers and presentations; and probable pharmacokinetics or pharmacodynamics.

○ Preliminary

Interaction suggested by preliminary data, involving fragmentary or partial evidence; reports derived from anecdotal clinical experience, preliminary research literature, or general pharmacological principles; research findings based on animal or in vitro experimental studies; or human studies characterized by inadequate design, size, and significance; limited or incomplete case reports; or extrapolations from pharmacokinetic or pharmacodynamic data.

▽ Mixed

Interaction proposed on the basis of partial, contradictory, or otherwise inconclusive evidence, including from single sources; unsubstantiated or incomplete case reports; inappropriate or methodologically flawed studies; or nonsignificant data.

□ Inadequate

Interaction proposed using obsolete, discredited, speculative, or otherwise inadequate or inappropriate evidence from derivative or secondary sources, including conjecture or unjustified extrapolation, inappropriate or flawed methodology, or studies of questionable relevance.

Aloe

Botanical Name: *Aloe vera* (L.) Burm.
Pharmacopoeial Name: Aloe vera gel.
Synonym: *Aloe barbadensis* (Mill.).
Common Names: Aloe gel, aloe vera gel.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Chemotherapy and radiotherapy associated with mucositis ⊕/☼	Aloe gel may ameliorate chemotherapy-induced oral and gastrointestinal mucositis.	Use prophylactically and symptomatically during chemotherapy with agents known to induce mucositis.
Wound care, surgery ⊕/⊕	Aloe gel incorporated into conventional dressings improves healing in wound care settings.	Commercial hydrogel dressings available.

HERB DESCRIPTION

Family

Aloaceae (formerly in Liliaceae).

Related Species

Aloe ferox Mill., *A. africana* Mill., *A. spicata* Baker., *A. perryi* Baker.; the *Aloe* genus has more than 300 species. *Aloe vera* has been widely hybridized in commerce, and cultivars are the primary source of the gel.

Habitat and Cultivation

Native to Africa, widespread in cultivation throughout subtropical regions in North and South America, West Indies, and East Asia; the cactuslike aloe is also a popular houseplant.

Parts Used

Aloe gel is a mucilaginous, colorless liquid derived from the central parenchymatous cells of the fresh leaves of aloe.

Note: Aloe gel and aloe latex are completely distinct remedies. The anthraquinone-containing dried juice, a yellow-orange latex, or sap exuded from the outer or pericycle (vascular bundles) area of the leaf, is often known as "Cape aloe" or "Curacao aloe." Some traditional cultures have used the root as a medicine, but this is not a current Western usage. Aloe latex can be considered with the Rhamnacae species such as cascara (*Rhamnus purshiana* DC), the buckthorns (*R. frangula* L. and *R. cathartica* L.), as well as senna leaf and fruits (*Cassia senna* L.) and rhubarb root (*Rheum palmatum* L.). All these species contain closely related anthraquinone glycosides that dominate their pharmacology, particularly the pronounced laxative and purgative activity associated with these herbs.

Common Forms

100% Fresh gel and freeze-dried concentrates, typically 4.5:1 concentrate, equivalent to 11.25 mg/mL of acemannan.
Standardized Extracts: Preparations based on acemannan (acetylated mannose polysaccharide) obtained by hydroethanolic extraction from the inner leaf gel. Multiple proprietary products are available, including Carrysyn (73% acemannan, Carrington Laboratories).

Note: "Aloe juice" is not a pharmacopoeial term; it describes varied products sold commercially that contain diluted gel. These products may contain only small amounts of the active gel constituents and may incorporate added thickeners such as pectins and starch. These juice products are usually anthraquinone free.

HERB IN CLINICAL PRACTICE

Overview

Aloe vera gel, the clear, colorless mucilage from the central parenchyma of the leaf, is primarily known for promoting topical healing of burns, wounds, incisions, frostbite, ulcers, and related inflammatory problems. The gel is also widely incorporated into natural cosmetic and skin care products. Modern research interest has focused on identifying the active polysaccharide components of the gel and investigating their potential immunomodulatory properties as biological response modifiers.[1] Internal applications are also of interest, such as for inflammatory bowel disease, and a positive trial in active ulcerative colitis patients is available.[2,3]

Proprietary aloe extracts based on hydrogel are available in professional and consumer markets. These are either stabilized by means of rapid pasteurization or freeze-dried as a soluble powder; both forms contain standardized amounts of the main active polysaccharide (acemannan). Professional products are available in a variety of applications for wound care, burn treatment, diabetic care, general first-aid dressings, and management of radiation and chemotherapy adverse effects. Limited clinical evidence supports these applications, although promotion of wound healing appears to be better supported by the available data than burn treatment.

In the United States, popular dietary supplement products combining freeze-dried acemannan with other ingredients are "network marketed" as "glyconutritionals." These are promoted as nonspecific immunostimulants, often with wide-ranging therapeutic claims, including for the treatment of cancer and human immunodeficiency virus (HIV). Evidence for such claims is not substantial at this time and is partly extrapolated from non–peer-reviewed data supplied to the U.S. Patent Office based on in vitro or uncontrolled animal studies using parenteral routes of administration.[4]

Aloe gel and its derivative products are not officially approved for internal medical use, although some proprietary topical hydrogel products have been approved by the U.S. Food and Drug Administration (FDA). The botanical literature emphasizes the anthraquinone herb rather than the gel. The World Health Organization (WHO) monograph series includes both remedies separately, but this is the exception.[5] Comprehensive literature reviews relating to recent immunological research on the gel are unavailable, although there are surveys of the data up to the late 1990s.[6] The available clinical trial evidence on aloe gel extracts was systematically reviewed in 1999 by Vogler and Ernst.[7]

Historical/Ethnomedicine Precedent

Aloe leaf has been in recorded use for centuries, with documentation by Dioscorides, Pliny, and Galen, as well as in traditional Ayurvedic and Chinese medicine. The gel was allegedly used by Cleopatra for cosmetic skin enhancement, but Europeans became more familiar with uses of the gel from African tribes and subsequently planted specimens of *Aloe* spp. throughout their colonies, which became rapidly naturalized in subtropical zones. Aloe spread in the United States, especially Florida, where it was used by the Seminole people for healing burns and stings. The gel remains in widespread popular folk use; currently it is often kept as a houseplant, with a leaf cut to obtain fresh gel as treatment for sunburn, thermal burns, insect bite, and other first-aid needs.

Known or Potential Therapeutic Uses

External/Topical: Treatment of abscesses, burns, surgical incisions, wounds, ulcers (oral, leg), dermatitis, and psoriasis.
Internal: Antiviral (HIV/herpes simplex virus [HSV]), dysglycemia, inflammatory bowel disease, immunomodulation, peptic ulcer preventive, ulcerative colitis.

Key Constituents

The gel is more than 97% water by weight. The solid matter is approximately 65% carbohydrate, predominantly in the form of a long-chained, polydispersed, beta-(1,4)-acetylated mannan (acemannan).[8,9] Sterols, organic acids (especially oxalate), and various amino acids make up the remainder. Novel dihydrocoumarins have recently been described.[10] Naturally occurring enzymes are present in the fresh gel, and pasteurization is necessary to stabilize the gel to prevent enzymatic degradation.

Therapeutic Dosing Range

Fresh Juice Concentrate: 25 mL up to four times daily.
Standardized Extracts: 500 to 800 mg-equivalent acemannan daily.

INTERACTIONS REVIEW

Strategic Considerations

The WHO monograph on aloe gel does not ascribe any interactions involving the herb.[5] The anthraquinone-containing *Aloe* latex is not considered here, but the reader should refer to the Cascara monograph for some interactions typical of the anthraquinone-containing botanicals.

In the setting of externally applied medications, aloe interactions are limited to various combination preparations, using the hydrogel as a vehicle with related materials (e.g., algal gums, synthetic hydrogels) or as an ingredient of creams and ointments in combination with anti-inflammatory agents.

The topical effects of the gel are thought to be the result of several mechanisms.[11,12] Anti-inflammatory effects have been established experimentally in the treatment of adjuvant arthritis, paw edema, frostbite, and diabetic ulceration in animal models,[11,13-15] as well as in human mucosal $CaCO_2$ cells in vitro.[2] The mechanisms involved are probably multifactorial and include inhibition of prostaglandin synthesis, antioxidant quenching of free radicals, and bradykinin inhibition, as well as promotion of connective tissue development, inhibition of collagenase (and metalloproteinase) activity, and stimulation of cell-mediated immunity.[14,16-21] Research at Carrington Laboratories has established that the pectins present in aloe vera gel are efficient stabilizers of peptides, which constitute a large class of tissue growth factors and immunomodulators, and may explain some of the observed activities of the plant gel (by increasing the half-life of peptide cytokines and growth factors).[22]

Since the 1930s, when aloe gel was first investigated for the topical treatment of "roentgen dermatitis," there have been persistent attempts to establish its efficacy for topical treatment of ultraviolet B (UVB) and x-ray radiation burns, although with consistently mixed results.[23] Recent animal tests have been positive,[24] but the only randomized controlled clinical trial available failed to show any benefit of the gel against placebo on chest wall and breast irradiation in 108 breast cancer patients.[25] Another oncological use is in chemotherapy-induced mucositis, although only oral (aphthous stomatitis) treatment has received substantial evidential support, and a proprietary aloe hydrogel product has been FDA approved for aphthous ulcer treatment.[26]

Internal use of the gel has been examined in relation to potential antiviral and immunostimulating effects for HIV patients, as well as for glycemic regulation in diabetic patients. Neither of these indications is well supported, nor are they in current general use clinically by practitioners of natural or botanical medicine. Suggestions of potential synergistic interactions with antivirals and antidiabetic agents are discussed later (see Theoretical, Speculative, and Preliminary Interactions Research). A recent United Kingdom trial established positive support for the use of aloe gel internally for ulcerative colitis.[2,3] Wide variation in commercial and proprietary processing methods, leading to products with differing activities, may underlie much of the conflicting results in clinical trials in various applications of "stabilized" *Aloe vera* products. The only relatively uniform activity would be from fresh gel obtained from freshly harvested aloe leaves, which are, however, logistically difficult to use in studies.

One recent, small, crossover-design human trial found a significant effect of aloe on the pharmacokinetics of vitamin C and vitamin E absorption. When single doses of the vitamins were consumed orally with 2 oz of aloe gel or whole-leaf extract, absorption of both the water-soluble and fat-soluble vitamins were significantly slowed, leading to longer half-life in plasma. The authors suggested that aloe could be used to complement the absorption of these nutrients.[27]

Data on the effects of aloe gel on drug-metabolizing enzymes and transporters are not available.

HERB-DRUG INTERACTIONS

Chemotherapy and Radiotherapy Associated with Mucositis, Including Bleomycin, Fluorouracil/5-FU, and Methotrexate

Including Bleomycin (Blenoxane), cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox), docetaxel (Taxotere), doxorubicin (Adriamycin, Rubex), etoposide (Eposin, Etophos, VePesid, VP-16), fluorouracil (5-FU; Adrucil, Efudex, Efudix, Fluoroplex), gemcitabine (Gemzar), irinotecan (camptothecin-11, CPT-11; Campto, Camptosar), methotrexate (Folex, Maxtrex, Rheumatrex), paclitaxel (Paxene, Taxol).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
4. Plausible

Evidence Base:
✗☐ Inadequate

Effect and Mechanism of Action

Inflammation of the oral mucosa (mucositis) induced by chemotherapeutic agents or ionizing radiation may be reduced by topical application of aloe vera gel.

The interaction is unsupported by published direct evidence but is based on established pharmacology and empirical clinical practice.

Research

Mucositis can be a dose-limiting toxicity of certain chemotherapies (notably 5-FU) and not only compromises normal physiological function, but also can present a portal to systemic infection complications in granulocytopenic patients following secondary infection.[28] An acemannan-containing product has been licensed by the FDA for aphthous stomatitis, although clinical trial evidence for the efficacy of aloe in this setting is equivocal.[26,29] There is also some experimental evidence for the efficacy of aloe gel as a cytoprotective agent for gastrointestinal (GI) mucosa, in addition to moderate gastric acid inhibition activity.[2,30-32] Radiation oncology has also investigated aloe gel as a topical preventive against adverse effects and one trial tested the effects of aloe gel in head and neck radiotherapy for prevention of oral mucositis; although a positive effect was noted, it was not statistically significant.[33] Preclinical and clinical studies on radiation-induced dermatitis and mucositis prevention by aloe gel have been conducted but, to date, have failed to demonstrate convincing benefits of aloe in symptom reduction.[23,34-36]

Finally, aloe gel has been shown in vitro to exhibit hematopoietic activity, which lends additional, if indirect, support to its use in combination with conventional cancer treatments.[37]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Topical oral wash ("swish and swallow") formulations containing aloe gel, often combined with agents such as glutamine and licorice extracts, have been employed empirically by practitioners using botanical/nutritional approaches to reduce chemotherapy-induced mucositis and stomatitis and are associated with anecdotal reports of symptom reduction. The antiviral and antifungal effects of aloe gel, along with its putative immunostimulatory and hematopoietic effects, lend additional circumstantial support to aloe gel as a choice of remedial agent for oral mucositis in this setting. Although the indirect GI mucositis also caused by chemotherapeutic drugs is, to some extent, a different issue clinically from oral mucositis, the same general approach with aloe gel has been used for prophylaxis of this GI toxicity. Further data and clinical trials are required to establish whether the anecdotal combination treatment is efficacious.

Surgery and Other Wound Care

Evidence: Polyethylene oxide sheet dressing (Vigilon).
Extrapolated, based on similar properties: Hydrogel dressings.

Interaction Type and Significance

⊕/⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
2. Probable

Evidence Base:
▽ Mixed

Effect and Mechanism of Action

Addition of aloe vera gel to polyethylene oxide hydrogel dressings may improve abrasive wound healing in the context of professional wound management. The extent and significance of the benefit of combining aloe gel with conventional dressings are unknown.

Research

Polyethylene oxide is a cross-linked hydrogel containing 96% water that is supported on a low-density mesh of polyethylene sheet for dressing wounds with limited epidermal involvement, such as dermabrasions, minor burns, and pressure ulcers. One clinician-researcher reported that the addition of aloe vera gel to this dressing format increased dermabrasion wound-healing rates.[38,39] Another surgical report from an obstetrical practice, however, suggested that application of aloe vera gel actually delayed the healing of surgical wounds, with complications of healing in 21 women.[40] A small trial compared the effects of an aloe vera hydrogel to a non–aloe-containing hydrogel in the healing rates of pressure ulcers and found no significant differences between the preparations.[41] Oral surgical aloe hydrogel products have shown some efficacy on molar extraction sites.[42]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Despite the general evidence for promotion of wound healing by aloe vera gel, further studies are needed before recommending its use in any situation other than uncomplicated, superficial wounds. Evidence from specialized wound care settings remains inconclusive, and although skilled wound care management is available in these contexts, the use of aloe vera gel for intensive wound care requires professional monitoring.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Antivirals: Acyclovir and Related Purine Nucleoside Analog Antivirals; Zidovudine/AZT and Related Reverse-Transcriptase Inhibitor (Nucleoside Analogs and Nonnucleosides) Antiretroviral Agents

Evidence: Acyclovir (Zovirax), zidovudine (azidothymidine, AZT, ZDV, zidothymidine; Retrovir).
Extrapolated, based on similar properties: Zidovudine combination drugs: abacavir (ziager), zidovudine, and lamivudine

(Combivir); abacavir (ziager), lamivudine, and zidovudine (Trizivir); didanosine (ddI, dideoxyinosine; Videx), dideoxycytidine (ddC, zalcitabine; Hivid), lamivudine (3TC, Epivir), stavudine (D4T, Zerit), tenofovir (Viread).

A preliminary in vitro study examined the potential synergistic effects of acemannan with both azidothymidine (AZT) and acyclovir on human U1 cells infected with HSV-1 and HIV-1. The investigators found a synergistic antiviral effect in which suboptimal drug doses, when combined with acemannan, produced significant antiviral effects. The authors suggest this should be further investigated as a possibly beneficial clinical interaction for HIV/AIDS patients because the mechanisms of the drug and herb were considered to be mutually exclusive.[43] Only one subsequent trial has investigated the effect of the combination in HIV patients and found no effect of acemannan on CD4 count decline compared with the control groups, which included coadministration with AZT over 48 weeks of treatment.[44]

Glyburide and Related Sulfonylurea Hypoglycemics

Evidence: Glyburide (glibenclamide; Diabeta, Glynase, Glynase Prestab, Micronase, Pres Tab).

Extrapolated, based on similar properties: Acetohexamide (Dymelor), chlorpropamide (Diabinese), glimepiride (Amaryl), glipizide (Glucotrol, Glucotrol XL), tolazamide (Tolinase), tolbutamide (Orinase, Tol-Tab); combination drugs: glipizide and metformin (Metaglip), glyburide and metformin (Glucovance).

Aloe has been attributed with mild antidiabetic activity and is often listed as such in surveys of hypoglycemic medicinal plants.[45,46] Vogler and Ernst's review[7] concluded that aloe may be useful as an adjunctive treatment in diabetes, but the studies were limited in number and methodologically poor, and their conclusion is controversial. The possible use of different plant parts (i.e., latex, gel) further confounds interpretation. A human trial with glyburide comedication has not been replicated,[47] although its findings have been cited as evidence of an aloe gel–glyburide interaction.[48] One negative human study failed to show hypoglycemic effect of the juice, and an animal study demonstrated an actual hyperglycemic action of the gel.[49,50] Animal studies suggest that antioxidant activity may exert indirect antidiabetic effects.[51,52] The use of aloe in any form for glycemic control of type 1 or type 2 human diabetes is not common current clinical practice, at least not in Western botanical medicine. This is therefore a speculative interaction postulated by reverse extrapolation from a nonestablished pharmacological effect.

Hydrocortisone and Related Topical Corticosteroids

Evidence: Hydrocortisone 17-butyrate, acetate, probutate, or valerate (hydrocortisone topical; Acticort 100, Aeroseb-HC, Ala-Cort, Ala-Scalp HP, Allercort, Alphaderm, Bactine, Beta-HC, Caldecort Anti-Itch, Cetacort, Cort-Dome, Cortaid, Cortef, Cortifair, Cortizone, Cortone, Cortril, Delacort, Dermacort, Dermarest, DriCort, DermiCort, Dermtex HC, Epifoam, Gly-Cort, Hi-Cor, Hydro-Tex, Hytone, LactiCare-HC, Lanacort, Lemoderm, Locoid, MyCort, Nutracort, Pandel, Penecort, Pentacort, Proctocort, Rederm, S-T Cort, Synacort, Texacort, Westcort).

Extrapolated, based on similar properties: Alclometasone (Aclovate, Modrasone), amcinonide (Cyclocort), beclomethasone, betamethasone dipropionate/valerate (betamethasone topical; Alphatrex, Beta-Val, Betaderm, Betanate, Betatrex, Diprolene AF, Diprolene, Diprosone, Luxiq, Maxivate, Teladar, Uticort, Valisone), clobetasol (clobetasol topical; Cormax, Dermoval, Dermotyl, Dermovate, Dermoxin, Eumosone, Lobate, Olux, Temovate, Temovate E, Topifort), clobetasone (Eumovate), clocortolone (clocortolone pivalate topical; Cloderm), desonide (DesOwen, Tridesilon), desoximetasone (Topicort, Topicort LP), desoxymethasone, dexamethasone (Aeroseb-Dex, Decaderm, Decadron, Decaspray), diflorasone (Apexicon, Florone, Maxiflor, Psorcon), diflucortolone (Nerisona, Nerisone), fluocinolone (Derma-Smoothe/FS, Fluonid, Synelar, Synemol), fluocinonide (Fluonex, Lidex, Lidex-E, Lonide, Vanos), fludroxycortide (flurandrenolone), fluocortolone (Ultralan), flurandrenolide (Cordran, Drenison), fluticasone (Cutivate), halobetasol (Ultravate), halcinonide (Halog), mometasone (Elocon, mometasone topical), triamcinolone, (Aristocort, Triderm, Kenalog, Flutex, Kenonel, triamcinolone topical); triamcinolone and nystatin (Mycolog II).

A single animal study used rodent paw models of inflammation to compare the effect of topical hydrocortisone acetate alone and in combination with aloe hydrogel. The combination was found to be more efficacious than the synthetic steroid alone at reducing edema and inflammation in this model.[53] This combination is frequently reported as a (beneficial) interaction; however, the combination does not appear to be used at all in practice and, although theoretically plausible, remains clinically undemonstrated at present and appears to be overstated.

Sevoflurane

Sevoflurane

A single perioperative incident of excessive bleeding was attributed to preoperative aloe consumption.[54] In fact, the anesthetic sevoflurane is a potent inhibitor of platelet aggregation, and the procedure was biopsy of a hemangioma. In this case it seems unlikely that the excessive hemorrhage could be reliably attributed to aloe consumption. Isoflurane is suggested as a preferred anesthetic to sevoflurane in situations with high risk of perioperative bleeds.[55] No other reports of aloe and bleeding or enhanced anticoagulation have been made.

The 55 citations for this monograph are located under Aloe on the CD at the back of the book.

Astragalus

Botanical Name: *Astragalus membranaceus* (Fisch.) Bunge.
Pharmacopoeial Name: Radix astragali.
Common Names: Astragalus, milk vetch root, Huang-Qi.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Acyclovir Purine nucleoside analog antivirals ⊕	Astragalus promotes T helper cell type 1 (Th1) immunity. Possible additive antiviral activity, against herpes simplex virus type 1 (HSV-1). Experimental support only; interaction not established clinically.	Consider coadministration during drug therapy for HSV family viruses.
Aldesleukin Recombinant interleukin-2 (rIL-2) ⊕/☼	Astragalus may synergistically increase effects of rIL-2. Experimental evidence only; interaction not clinically established.	Theoretically, coadministration may enhance therapeutic outcome of IL-2 treatment.
Cyclophosphamide Myelosuppressive chemotherapy ☼/⊕⊕/⊕✗	Astragalus promotes myelopoiesis; may protect white blood cell (WBC) counts during chemotherapy with cyclophosphamide, platinum agents, or other myelosuppressive chemotherapies. In nonmalignant disease applications, theoretically an adverse interaction.	Coadminister and continue after myelosuppressive chemotherapy until WBC count normalized; used with related herbs in formula.
Interferon alpha (IFN-α) ☼/⊕	Astragalus increases endogenous IFN; can be used to support IFN therapy or potentiate drug, allowing reduced drug dose and increased tolerability. Empirical clinical support; no trial evidence.	Consider coadministration in chronic viral conditions treated with IFN.
Thrombolytics ⊕	Astragalus increases fibrinolytic capacity by promoting tissue-type plasminogen activator (tPA). Astragalus may additively support fibrinolytic drug therapies. Interaction not clinically established.	Consider use in hyperviscosity or high-risk thrombotic patients with appropriate drugs.

HERB DESCRIPTION

Family

Fabaceae.

Related Species

Astragalus membranaceus var. *mongholicus* (Bunge).

Habitat and Cultivation

Perennial member of the legume family, native to Northern China, Mongolia, and Siberia and now under organic cultivation in the United States. The genus contains more than 400 species. Wild "locoweeds" (various *Astragalus* spp.) are a common livestock forage food. Gum tragacanth is derived from a related species, *A. gummifer*.

Parts Used

Radix (root).

Common Forms

Dried Sliced Root: Often soaked, then pressed or flattened; variant preparation may be honey-roasted in Chinese medicine.
Powdered Root: For decoction, liquid extracts and tablets.
Tincture and Fluid Extracts: 60% to 70% ethanol; usually include a water-extraction phase for polysaccharides, then preserved in ethanol.
Standardized Extracts: Several preparations are available. There is no consensus on marker compounds for standardization at this time; individual manufacturers' preparations may vary.

HERB IN CLINICAL PRACTICE

Overview

Astragalus has been used for more than 2000 years in Chinese medicine and is one of several important materia medica imports into Western botanical medicine. The herb is primarily used in Western herbalism as an immunomodulating agent and for cardiovascular disease. Interest in the herb as an adjunct to chemotherapy in oncological settings is increasing, but a recent Cochrane review found limited evidence of value for astragalus decoctions in improving adverse effects of chemotherapy in colorectal cancer patients.[1] Another, more recent meta-analysis reviewed trials in which astragalus was combined with platinum agents in non–small cell lung cancer; evidence showed that the combination may provide increased effectiveness in terms of tumor response, reduced toxicity of the chemotherapy, survival time, or performance status.[2]

Most available scientific literature is published in Chinese and has not been directly accessed for this survey. Much of the experimental data on astragalus are based on isolated polysaccharide fractions, either in vitro or by intraperitoneal administration in vivo. Extrapolation from this data to human oral consumption of powdered crude herb or liquid extracts may not be appropriate, particularly with regard to dosage. Chinese clinical trials usually use the herb in combination formulae with other herbs, such as ginseng, dang gui, poria, and rhemannia, because this is the typical manner of clinical administration. The available data have been used to discuss the interactions later.

Astragalus, as with other East Asian herbs incorporated into the Western materia medica relatively recently, is not monographed by the German Commission E, European Scientific

Cooperative on Phytotherapy (ESCOP), or World Health Organization (WHO). Astragalus does have an *American Herbal Pharmacopoeia* monograph,[3] and the literature has been reviewed by McKenna et al.[4] and Wagner et al.[5] Bensky et al.[6] provide an authoritative review, and Chen and Chen[7] relate traditional Chinese uses to conventional pharmacology.

Historical/Ethnomedicine Precedent

Chinese uses include spleen *(Pi) qi* tonification, lung *(Fei) qi* tonification, and "securing the exterior"; promoting pus discharge and growth of new tissue and providing immune support. These features may contribute to a number of different biomedical pathological conditions. Astragalus is traditionally used in Chinese medicine in combination formulae for a wide range of conditions, from the common cold to chronic renal failure.[7]

Known or Potential Therapeutic Uses

Cardioprotection (anti-ischemic, fibrinolytic, antioxidant); immunostimulation (reversal of leukopenia, myelosuppression); general prophylaxis of infection, stress, hypertension, certain viral infections (coxsackieviruses B2 and B3, parainfluenza type 1, viral myocarditis, Japanese endocarditis, HSV-1), nephritis, nephropathy, oxidative stress psoriasis, prostatic hypertrophy, and Takayasu arteritis.

Key Constituents

Polysaccharides (astragalans or astragologlucans); triterpene saponins (astragolides I-VII); isoflavones and other flavonoids; amino acids, minerals, essential oils, and phytosterols.

Therapeutic Dosing Range

Dried Root: 10 to 15 g daily; by decoction, maximum 120 g in Chinese medicine.
Hydroethanolic Extracts: 10 to 20 mL daily (based on 1:1 equivalent).

INTERACTIONS REVIEW

Strategic Considerations

Astragalus is used in Western botanical medicine as a tonic, adaptogenic, immunomodulating herb with negligible toxicity. It is myeloprotective, with added cardioprotective, hepatoprotective, and antioxidant properties, which make it a potentially useful adjunct in contexts involving immunosuppression, whether through disease processes, such as human immunodeficiency virus (HIV) and chronic fatigue immune dysfunction syndrome (CFIDS), or drug induced, such as myelosuppressive chemotherapies for the treatment of malignancies and immunosuppression in allograft patients. Recent research on the cardiac properties of the herb may help expand the Western use of astragalus beyond the narrow confines of "immunomodulation."[9,10]

Astragalus use with pharmaceutical immunosuppression (i.e., allograft patients) may be theoretically problematic, but there are no reports of adverse interactions arising from its use in this context. Combination with immunosuppressants may be regarded as contraindicated in practice. Several interactions described later are based on pharmacodynamic effects of the herb on immune parameters. These interactions are not generally supported by published clinical trials; however, strategic coadministration of the herb in some of the therapeutic contexts described is anecdotally established practice among some practitioners of botanical and integrative medicine.

Effects on Drug Metabolism and Bioavailability

There is currently no evidence of interactions resulting from the effects of astragalus on drug-metabolizing systems. A rodent study examining the hepatoprotective effects of astragalus saponins against acetaminophen-induced toxicity found a significant increase in hepatic cytochrome P450 (CYP) levels after astragalus administration.[11] Although studies are lacking, clinically significant pharmacokinetic interactions have not been reported to date.

HERB-DRUG INTERACTIONS

Acyclovir and Related Purine Nucleoside Analog Antivirals

Evidence: Acyclovir (Zovirax).
Extrapolated, based on similar properties: Purine nucleoside analog antivirals; famciclovir (Famvir), ganciclovir (Cytovene), valciclovir (Valcivir, Valcyclovir, Valtrex).

Interaction Type and Significance
⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action
A synergistic pharmacodynamic interaction increases the antiviral efficacy of the drug. Astragalus has established activity against a number of viruses in experimental and in vivo environments. Mechanisms remain to be clarified, but in general, T helper cell type 1 (Th1) cytokines and cell-mediated immune responses are enhanced by astragalus extracts.

Research
Zuo et al.[12] demonstrated a potentiation of acyclovir against herpes simplex virus type 1 (HSV-1)–infected mice when combined with astragalus that was greater than the effects of either agent alone, when measured by reduced mortality and extended survival time.

Integrative Therapeutics, Clinical Concerns, and Adaptations
Coadministration or pretreatment with astragalus may be useful as a possible adjunct to pharmaceutical antiviral therapies, based on limited available evidence. The interaction remains to be confirmed by clinical studies.

Aldesleukin (IL-2)

Interleukin-2 (IL-2), recombinant interleukin-2 (rIL-2); Proleukin.

Interaction Type and Significance
⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
3. Possible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

The coadministration of astragalus and rIL-2 may produce a synergistic pharmacodynamic interaction. Astragalus extracts enhance several aspects of Th1-mediated immunity. Interleukin-2 immunotherapy is used to enhance cell-mediated immunity. Astragalus appears to potentiate IL-2 synergistically, which is one plausible mechanism of its ability to increase Th1 (cell-mediated) over Th2 immune activity.

Research

Co-incubation of lymphokine-activated killer (LAK) cells with astragalus F3 (fractionated extract) polysaccharide (55 μg/mL) achieved the same "tumor cell kill" when combined with 100 units/mL of IL-2, as did untreated LAK combined with 1000 units/mL of IL-2, suggesting a tenfold potentiation.[13] In a related study by the same group using LAK cells from patients with acquired immunodeficiency syndrome (AIDS), measured activity against melanoma cell lines increased tenfold when IL-2 was combined with astragalus F3, allowing a 50% reduction in effector/target cell ratio.[14,15] Similar results of tenfold potentiation with the F3 fraction and IL-2 with murine renal cell carcinoma have been reported.[16]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Patients undergoing low-dose cytokine therapy using IL-2 may benefit from concurrent use of astragalus extracts or combinations, allowing a lower dose of IL-2 to be used and thus reducing potential adverse effects of the immunotherapy. Astragalus tends to favor Th1 over Th2 through additional mechanisms and may be considered a useful synergist in this therapeutic context. Direct clinical evidence for the interaction is not available.

Cyclophosphamide and Related Myelosuppressive Chemotherapy, Especially Alkylating Agents

Evidence: Cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox).

Extrapolated, based on similar properties: Busulfan (Myleran), carboplatin (Paraplatin), chlorambucil (Leukeran), cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), dacarbazine (DIC, DTIC, DTIC-Dome, imidazole carboxamide), ifosfamide (Ifex, Mitoxana), mechlorethamine (Mustargen, nitrogen mustard), melphalan (Alkeran), oxaliplatin (Eloxatin), phenylalanine mustard (Melphalan), pipobroman (Vercyte), streptozocin (Zanosar), temozolomide (Temodar), thiotepa (Thioplex), uracil mustard (uramustine).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**
⊕/✗ **Bimodal or Variable Interaction, with Professional Management**

Probability:
2. Probable

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Astragalus reduces the effects of cyclophosphamide-induced suppression of cell-mediated immunity, increasing white blood cell (WBC) counts in chemotherapy-induced leukopenia and neutropenia, and is lymphoproliferative at splenic and bone marrow levels. In the context of cyclophosphamide treatment of nonmalignant disease, the interaction is theoretically adverse, although properly speaking, this is a "contraindicated" combination.

Research

Several studies using cells from human cancer and healthy control patients in graft-versus-host (GVH) reaction models suggest that astragalus polysaccharide extracts promote cell-mediated immunity and reverse cyclophosphamide-induced immunosuppression.[13,17,18] Water extracts increase phagocytosis in carbon clearance tests, stimulate splenic lymphocyte proliferation, and increase tumor necrosis factor alpha (TNF-α) and interleukin-6 (IL-6) production by macrophages.[19] Proliferative effects on bone marrow stem cells and peripheral WBCs was observed after intraperitoneal (IP) administration of astragalus in mice.[20] Rodent macrophages were activated by astragalus polysaccharide in vitro, partly through nuclear factor kappa B (NF-κB) activation.[21] Clinical trials with intravenous (IV) astragalus polysaccharide coadministered with chemotherapy have been reported in the Chinese literature with positive results on outcome, versus chemotherapy alone, in terms of survival as well as quality-of-life measures.[22,23]

Clinical Implications and Adaptations

The astragalus-cyclophosphamide interaction has been classified as adverse by some authorities, presumably in the context of cyclophosphamide used in autoimmune disease treatment rather than cancer therapy.[24] Astragalus extracts may be incorporated into integrative protocols designed to support patients undergoing any myelosuppressive chemotherapies. Combination formulae are typically used in these applications, and experimental evidence indicates that such combinations may be more efficacious than the single herb against cyclophosphamide immunotoxicity.[25] Lymphopenia also occurs frequently in cancer patients, before, during, and after chemotherapeutic interventions, and correlates with decreased immunocompetence. To the degree that astragalus and other botanicals can support lymphocyte counts in such patients, these agents may be of clinical benefit, although controlled trials are required to demonstrate efficacy.

Interferon Alpha (IFN-α)

Interferon Alpha (IFN-α): Alferon N, Intron A, Roferon-A.

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Astragalus increases endogenous interferon (IFN) production by leukocytes and thus may potentiate the effects of therapeutic recombinant interferon (rIFN) administration. It is not established whether this is an additive or synergistic effect. Preliminary clinical support is available.

Research

An experimental study compared administration of a combination of recombinant IFN-2α with astragalus in a cell culture model of HSV-1–infected diploid human cells. The combination exhibited greater antiviral activity than the rIFN alone.[26] In a human trial, healthy volunteers were given 8 g/day of astragalus. After 2-week and 2-month periods of administration, blood levels of IFN were significantly elevated compared

with controls.[27] The effect of IFN in treatment of 235 patients with chronic viral cervicitis was potentiated by astragalus, the combination being more effective as topical treatment than either IFN or astragalus alone. Interferon and astragalus combinations were superior to either agent alone against the human cold in a human trial using topical nasal spray application. Duration of symptoms was reduced significantly.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Astragalus is known to have antiviral activity and to increase cell-mediated immunity. It is not clear to what extent augmentation of IFN levels underlies these effects; coordinated use of astragalus extracts may potentiate or synergize with IFN treatments (e.g., for viral hepatitis).

Thrombolytic Agents

Parenteral alteplase, recombinant (Activase); anistreplase (Eminase); reteplase, recombinant (Retavase); streptokinase (Streptase); urokinase (Abbokinase, Abbokinase Open-Cath).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Astragalus extracts increase fibrinolysis and improve rheological characteristics of whole blood. Coadministration with various forms of antithrombotic therapy may be supportive, although clinical evidence is unavailable.

Research

Astragaloside IV fractionated extracts increased fibrinolytic potential of human umbilical vein endothelial cells in culture. The effect was mediated by upregulation of tissue-type plasminogen activator (tPA) expression and downregulation of plasminogen activator inhibitor (PA-I).[28] Increased PA-I activity relative to tPA and urokinase-type plasminogen activator (uPA) activity strongly correlates with cardiovascular morbidity and mortality. Reduced fibrinolytic capacity is a major cardiovascular disease risk in younger men. PA-I type 1 (PAI-1) is a risk factor for recurrence of myocardial infarction (MI), and high PAI-1 levels predict a first MI in middle-aged men and women.[29-31]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Astragalus extracts may be supportive of strategies aimed at prophylaxis and treatment of thrombosis in at-risk populations. There are no reports that astragalus extracts adversely interfere with normal hemostasis or interact adversely with typical anticoagulant drugs, which generally do not act through tPA. Combination with natural fibrinolytic agents such as Wobenzyme, nattokinase, and lumbrokinase may be appropriate in integrative protocols targeting hypercoagulable states.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Aminoglycoside Antibiotics

Amikacin (Amikin), gentamicin (G-mycin, Garamycin, Jenamicin), kanamycin (Kantrex), neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin), netilmicin (Netromycin), paromomycin (monomycin; Humatin), streptomycin, tobramycin (AKTob, Nebcin, TOBI, TOBI Solution, TobraDex, Tobrex).

A combination of astragalus and *Lu Han Cao* (Herba Pyrolae) was injected into guinea pigs subsequently administered intraperitoneal (IP) aminoglycosides, and the combination was found to prevent toxicity and nephrotoxicity.[32] Chen and Chen[7] overstate this as an interaction. Because the formula included another herb ingredient and parenteral administration, it should not be extrapolated to astragalus alone in oral administration without further supporting data.

Oral Hypoglycemic Agents and Insulin

Buformin (Andromaco Gliporal, Buformina), chlorpropamide (Diabinese), glimepiride (Amaryl), glipizide (Glucotrol; Glucotrol XL), glyburide (Glibenclamide; Diabeta, Glynase, Glynase Prestab, Micronase, Pres Tab), insulin (animal-source insulin: Iletin; human analog insulin: Humanlog; human insulin: Humulin, Novolin, NovoRapid, Oralin), metformin (Dianben, Glucophage, Glucophage XR); combination drugs: glipizide and metformin (Metaglip), glyburide and metformin (Glucovance); tolazamide (Tolinase), phenformin (Debeone, Fenformin), tolbutamide (Orinase, Tol-Tab).

A traditional Chinese use of astragalus combinations includes effects that would be recognized in modern pharmacology as lowering blood glucose.[7] There is also some experimental support for this theoretical interaction using streptozocin-induced rodent models of diabetes. It has been suggested that this implies a potential adverse interaction with oral hypoglycemics, a speculation that has no foundation, and if anything is contrary to the known effects and uses of the herb in this context. Data even suggest that insulin sensitivity may be increased by the herb.[33] Astragalus is also potentially beneficial in preventing diabetic cardiomyopathy.[34]

The 34 citations for this monograph are listed under Astragalus on the CD at the back of the book.

Bilberry

Botanical Name: *Vaccinium myrtillus* L.
Pharmacopoeial Names: Myrtilli folium, Myrtilli fructus.
Common Names: Blueberry, bilberry, whortleberry, huckleberry.

HERB DESCRIPTION

Family

Ericaceae.

Related Species

There is considerable bioregional diversity of wild blue-fruited *Vaccinium* spp., whose berries are very similar nutritionally and medicinally to the official species, *V. myrtillus* L. (e.g., in the U.S. Pacific Northwest alone, *V. ovatum* Pursh., *V uliginosum* L., *V. occidentale* Gray., *V ovalifolium* Smith., *V deliciosum* Smith., *V. membranaceum*, Dougl.). Horticultural cultivars are also common.

Parts Used

Fruit (berries); the leaf, a separate remedy, has been used in traditional herbal medicine but currently is not widely used.

Common Forms

Leaf: Dried leaf (infusion), dried-leaf hydroethanolic extract.
Berry (Fruit): Dried whole fruit; hydroethanolic tincture and liquid extracts; standardized extract (Myrtocyan, Tegens, MirtoSelect) in capsule form containing 25% anthocyanidins, with 36% anthocyanosides.

INTERACTIONS REVIEW

Strategic Considerations

Bilberry is currently best known for the properties of the anthocyanidin (Greek *antos*, "flower," and *kyanos*, "blue") and proanthocyanidin content of the fruit (berries). Anthocyanidins and proanthocyanidins are naturally occurring polyphenolic flavonoids widely present in berries and other fruit, also responsible for the blue-red pigmentation in many flowers and fruits. The chemistry and biological activities of the anthocyanidins and anthocyanins (aglycones and glycosides, respectively) have been extensively studied; the representative compound is cyanidin and its glycosides.[1,2]

Although the phytomedical literature on bilberry is dominated by the pharmacology of the anthocyanins and proanthocyanins and their glycosides, these are present at a level of only 0.1% to 0.25% in the fresh fruit. The catechin (tannin) content of the fruit, however, is actually an order of magnitude higher, 5% to 10%. This implies that standardized extracts that are widely used in commerce represent a highly concentrated product, and the safe therapeutic dose range is wide, from 120 to 480 mg standardized extract per day (equivalent to upper dose of ~500.0 g fresh, or ~100.00 g dry, berry/day). At these dose levels, bilberry concentrated extracts can be considered as a "phytonutriceutical" product, better classified with other concentrated flavonoid supplements, such as quercitin, rutin, and the oligomeric proanthocyanidins (OPCs). Resveratrol and the related compound pterostilbene may also be present in significant quantities in the concentrated extracts. Pterostilbene appears to have hypocholesterolemic properties mediated by its binding affinity to the peroxisome proliferator activated receptor (PPAR) and shares some of the chemopreventive and antioxidant characteristics of resveratrol.[3,4]

The German literature describes use of 10% dried bilberry fruit decoction as a safe supportive treatment of nonspecific diarrhea, including pediatric cases, and for topical inflammations of the mouth and throat, including oral candidiasis.[5-8] These uses are not widespread in North American clinical practice and are unlikely to invoke interactions with pharmaceutical agents.

The concentrated extracts, enriched in anthocyanins, have a range of pharmacological actions, including antioxidant, chemoprotective, vasoprotective, antiulcer, anti-inflammatory and antiatherogenic, antiaggregatory, and ophthalmic effects. Clinical evidence supports their use in peripheral vascular disorders (e.g., venous insufficiency, capillary fragility) and in ophthalmic disorders. Recent reviews of these data include the therapeutic monograph from the European Scientific Cooperative on Phytotherapy (ESCOP)[9] and a survey by McKenna et al.[10] Data relating to berry and fruit polyphenols and cancer chemoprevention has been reviewed by Prior and Joseph.[11] Experimental data demonstrating direct anticancer effects of anthocyanins is emerging.[12] In clinical practice, concentrated bilberry extracts are most likely to be used for disorders of microcirculation, and the specific advantage of the anthocyanins is their affinity for ophthalmic neurovasculature; conditions such as optic neuritis of multiple sclerosis, macular degeneration, glaucoma, and diabetic retinopathy are often the key prescribing indications.

Interactions between standardized bilberry extracts and pharmaceutical drugs have received minimal study. A single study reported a reduction in platinum compound toxicity without compromise to antitumor efficacy in an Ehrlich tumor rodent model using oral anthocyanins at 300 mg/kg coadministered with cisplatin.[13] No English translation of this report has been published, and the platinum interaction has not been confirmed by other studies or clinical reports and is not reviewed further here.

Pharmacokinetic data suggest that human intestinal flora are essential for hydrolysis of the glycoside form to the anthocyanin and proanthocyanin aglycones.[14-16] This suggests that iatrogenic reduction in microflora populations induced by antibiotics may reduce the bioavailability of the bilberry polyphenols, although evidence for this is not available.

Effects on Drug Metabolism and Bioavailability

Effects of bilberry extracts, or anthocyanins and proanthocyanins, on drug metabolism have not been well studied. Chemopreventive effects of fruits and berries have been examined in a few studies examining the mechanism of these effects, including possible inhibition of cytochrome P450 (CYP) 1A1 and 2E1 xenobiotic (aryl hydrocarbon carcinogen)–metabolizing enzymes.[17-20] The data are inconclusive but suggest low or minimal effects on these enzymes. Resveratrol, present in small amounts in bilberries, may inhibit CYP1B1, but this is not a significant drug-metabolizing cytochrome in humans although it is overexpressed in hormone-dependent tumor tissue.[21] Recent experimental evidence suggests that bilberry extracts

potently inhibit organic anion-transporting polypeptide B (OATP-B), which is an intestinal transporter responsible for mediating absorption of several drugs.[22] The flavonoid fraction of bilberry seems likely to be the active inhibitory component, but the in vivo significance of this inhibition remains to be established. Pharmacokinetic interactions between bilberry extracts or ingredients have not been reported.

HERB-DRUG INTERACTIONS

Antiplatelet Thromboprophylactics

Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin), ASA, caffeine, and propoxyphene (Darvon Compound), ASA and carisoprodol (Soma Compound), ASA, codeine, and carisoprodol (Soma Compound with Codeine), ASA and codeine (Empirin with Codeine), ASA, codeine, butalbital, and caffeine (Fiorinal); cilostazol (Pletal), clopidogrel (Plavix), dipyridamole (Permole, Persantine), ticlopidine (Ticlid); combination drug: ASA and extended-release dipyridamole (Aggrenox, Asasantin)

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability:
5. Improbable

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

Aspirin (ASA) is a well-documented antiplatelet agent acting through inhibition of cyclooxygenase production of thromboxane A_2 (TXA_2). Ticlopidine interacts with glycoprotein IIb/IIIa to inhibit adenosine diphosphate (ADP)–induced fibrinogen binding to activated platelets and has been used for prevention of thrombosis when aspirin is poorly tolerated. Because of reports of hematological adverse effects associated with ticlopidine, clopidogrel is currently the preferred antiplatelet agent in such cases. As with ticlopidine, clopidogrel (Plavix) is an irreversible antiplatelet drug operating via ADP receptor antagonism. The potential interaction is therefore an additive pharmacodynamic increase in antiplatelet activity. Such an additive effect may theoretically increase the likelihood of bleeding disorders related to disturbances of primary hemostasis.

Research

Preliminary in vitro evidence suggested that concentrated anthocyanidins can inhibit platelet aggregation, probably by a decrease in cyclic adenosine monophosphate (cAMP) or an inhibition of TXA_2 formation at the platelet level.[23,24] A later study examined the effect of standardized bilberry extract in 30 healthy adults for 30 and 60 days, at an oral dose of 160 mg three times daily (tid). The subjects were divided into three groups: extract alone, extract combined with vitamin C (1000 mg tid), or vitamin C alone. Platelet aggregation was studied in vitro in relation to ADP- and collagen-induced stimulation. The bilberry extract/vitamin C group had a higher level of inhibition of aggregation than either the bilberry or the vitamin C group. Aggregation returned to baseline 120 days after treatment discontinuation.[25]

Integrative Therapeutics, Clinical Concerns, and Adaptations

If thromboprophylaxis is being affected by use of aspirin, there is at least a theoretical benefit in using bilberry extracts, not only to enhance the antiplatelet effects, but also because bilberry anthocyanidins have been shown (in rodent models) to be inhibitory of experimental chemically induced gastric ulceration, and to promote ulcer healing.[26,27] However, combining deglycyrrhizinated licorice (DGL) with aspirin in such cases may be a more cost-effective and reliable way of reducing the nonsteroidal anti-inflammatory drug (NSAID)–induced mucosal irritation and bleeding. Patients taking chronic high doses of concentrated bilberry extracts in combination with pharmaceutical antiplatelet agents should be advised to report any symptoms of peripheral bleeding such as epistaxis or susceptibility to bruising, but the effect of dietary intake is likely negligible. This hypothetical interaction is probably of marginal clinical significance.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Oral Hypoglycemic Agents and Insulin

Buformin (Andromaco Gliporal, Buformina), chlorpropamide (Diabinese), glimepiride (Amaryl), glipizide (Glucotrol; Glucotrol XL), glyburide (Glibenclamide; Diabeta, Glynase, Glynase Prestab, Micronase, Pres Tab), insulin (animal-source insulin: Iletin; human analog insulin: Humanlog; human insulin: Humulin, Novolin, NovoRapid, Oralin), metformin (Dianben, Glucophage, Glucophage XR); combination drugs: glipizide and metformin (Metaglip), glyburide and metformin (Glucovance); tolazamide (Tolinase), phenformin (Debeone, Fenformin), tolbutamide (Orinase, Tol-Tab).

Traditionally, bilberry leaf was used as an antidiabetic tea before the ready availability of insulin for management of blood sugar levels. This use was emphasized in German phytotherapy and is discussed at length by Wichtl.[6] However, as pointed out by Weiss,[5] bilberry leaf, in common with other herbal infusions touted as antidiabetic teas, does not afford a clinically significant degree of glycemic control, and bilberry leaf infusions are not in general use by diabetic patients. Bilberry leaf is "unapproved," according to the Commission E monograph, because of lack of evidence for the antidiabetic function. One study of a rodent model of streptozotocin-induced (STZ) diabetes suggested that a short-term drop in blood glucose was seen compared with nondiabetic control animals after acute oral doses of bilberry leaf at a rate of 3.0 g/kg for 4 days (equivalent to cumulative human dose of ~840 g dried leaf).[28] Extrapolations from this study that infer interactions with insulin or hypoglycemic agents are unwarranted, given the excessive dose used and the lack of clinical use of the leaf in modern Western botanical medicine.

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar), warfarin (Coumadin, Marevan, Warfilone).

Some secondary sources have speculated that, because of the in vitro antiplatelet actions previously discussed, interactions may occur between concentrated bilberry extracts and warfarin or related "vitamin K antagonist" oral anticoagulants, as well as antiplatelet drugs.[29-31] Although some foods (e.g., avocado) have been reported to interact with warfarin, without a direct effect on vitamin K, the mechanisms of these interactions remain unclear. Combining antiplatelet and anticoagulant medications can result in increased risk of bleeding in certain individuals, so it remains a theoretical possibility that chronic coadministration of very high doses of bilberry extract with warfarin could result in an increased risk of bleeding. However, this remains a speculative extrapolation, without supportive data.

The 31 citations for this monograph are located under Bilberry on the CD at the back of the book.

Black Cohosh

Botanical Name: *Cimicifuga racemosa* (L.) Nutt.
Pharmacopoeial Name: Rhizoma cimicifugae racemosae.
Synonym: *Actea racemosa* L.
Common Names: Black cohosh, black snakeroot, macrotys (historical).

SUMMARY

Drug/Class Interaction Type	Mechanism and Significance	Management
Androgen blockade LHRH antagonists Antiandrogens ☼/⊕	Black cohosh reduces drug-induced vasomotor adverse effects. Established effect in women, but only anecdotal support for the interaction in men.	Coadminister with professional management and monitoring.
Hormone replacement therapy (HRT) Estrogens/progestins ☼/⊕⊕	Black cohosh supports reduced HRT doses, or tapered withdrawal by reducing symptoms associated with climacteric.	Consider adoption, especially for HRT withdrawal.
Tamoxifen, Raloxifene (SERMS) ⊕⊕/☼	Black cohosh reduces drug-induced climacteric symptoms, may synergize with SERM antitumor effects in estrogen receptor–positive cancer.	Consider coadministering with professional management.

LHRH, Luteinizing hormone–releasing hormone; *SERMs*, selective estrogen response modulators.

HERB DESCRIPTION

Family

Ranunculaceae.

Related Species

None; blue cohosh (*Caulophyllum thalactroides* L.) is a different species botanically and medicinally. Asian varieties sold as *sheng ma* may be derived from *Actea foetida* or *Actea dahrica* and are not interchangeable.

Habitat and Cultivation

Native to eastern North America; 95% of black cohosh is wildcrafted, and the impact of annual harvests of 600,000 to 700,000 pounds (1998) on the viability of wild populations is a cause for concern.

Parts Used

Rhizome and roots.

Common Forms

Dried: Powdered rhizome and root.
Tincture: 1:3 to 1:10 60% alcohol-dried.
Fluid Extract: 1:1 60% to 90% alcohol-dried.
Standardized Extracts: Commercial extracts standardized to 2.5% triterpene glycosides are available. Clinical trials have largely been based on Remifemin, a proprietary isopropanolic formulation available as liquid and tablet form equivalent to a 1:1 g/mL fluid extract, or BNO 1055, an ethanolic extract sold as Klimadynon/Menafem. (See constituents discussed later for labeling of 27-deoxyactein marker compound.)

Note: Herbal practitioners may use fresh herb material, but this is not common in commerce.

HERB IN CLINICAL PRACTICE

Overview

Modern use of black cohosh is dominated by its perception as a remedy for various symptoms associated with menopause. In 1989 the German Commission E approved its use for dysmenorrhea, premenstrual discomfort, and neurovegetative ailments associated with menopause. Increasing concern about the adverse effects of conventional hormone replacement therapy (HRT), coupled with clinical trial support for menopausal applications and promotion of standardized European isopropanolic preparations of black cohosh, has led to a narrowing of focus on the herb as a gynecological remedy, especially for menopausal issues. Therapeutic monographs of the herb include those by the British Herbal Medical Association (BHMA),[1] German Commission E,[2] and more recently by the World Health Organization (WHO),[3] *American Herbal Pharmacopoeia*,[4] and European Scientific Cooperative on Phytotherapy (ESCOP).[5]

Contrary to initial research assumptions of its "estrogenic" properties, recent studies on black cohosh suggest that it is in fact antiestrogenic. Lacking any phytoestrogenic isoflavone constituents, newer data have demonstrated dopaminergic and serotonergic receptor binding. Ongoing developments in estrogen receptor molecular biology continue to add to the complex emerging picture. The traditionally known affinities of black cohosh for the nervous and musculoskeletal systems, its cardiovascular effects, and the broad scope of its gynecological indications (which extend far beyond the specific issue of climacteric symptoms) increasingly appear to have an underlying basis in the neuroendocrine pharmacology of the herb, although this awaits full elucidation.

Historical/Ethnomedicine Precedent

Black cohosh was used by Native Americans for general malaise, various gynecological conditions, kidney ailments, malaria, rheumatism, sore throat, and snakebite.[6] The early

colonists also used the herb, reputedly for menorrhea, uterine disorders, nervous disorders, lumbago, snakebite, and various infectious conditions, including malaria.[7] *Cimicifuga* was a primary remedy for the Eclectic physicians, who termed it "macrotys." The Eclectics used different forms of the herb, including fresh and dried extracts and a "resinoid" concentrate. This was employed for a wide range of neuromuscular, gynecological, and obstetrical conditions, including neuralgia, headache, rheumatism, false labor, labor, postpartum pain, "partus preparator" (to encourage natural contractions during labor), mastitis, atony of the uterus, and amenorrhea, as well as for a variety of nervous system disorders, including chorea, convulsions, delirium tremens, nervous excitability, spasmodic cough, and pertussis. Interestingly, Eclectic use included male urogenital conditions such as orchalgia and spermatorrhea as well as infections such as smallpox.[8-10] Grieve includes the indication of St. Vitus' dance (Sydenham's chorea) in children.[11] Boericke[12] emphasized depression as a key mental indication for *Cimicifuga* as a homeopathic medicine.

Known or Potential Therapeutic Uses

Antirheumatic, antispasmodic, uterine tonic; treatment of climacteric symptoms and ovarian insufficiency, especially associated with iatrogenically induced menopause; mild depression, especially associated with cyclical or climacteric changes; fibromyalgia.

Key Constituents

Triterpene glycosides: More than 20 identified, including 23-epi-26 deoxyactein, which is often incorrectly labeled as "27-deoxyactein" on commercial standardized product labels.[13]

Flavonoids: Early reports of the presence of the phytoestrogenic isoflavones formononetin and biochanin A have not been substantiated by recent analytical data and are not present in the standardized isopropanolic extract Remifemin.[14,15]

Aromatic acids: Hydroxycinnamic acid esters of fukiic and piscidic acid; fukinolic and cimicifugic acids, along with ferulic isoferulic and caffeic acids.

Novel polyphenolics have recently been described.[16]

Other components include up to 20% resin ("cimicifugin").[17]

Therapeutic Dosing Range

From 0.2 to 4.0 mL/day (1:1 equivalent) hydroethanolic extracts.

Recent clinical trials using isopropanolic extracts average a modest daily dose of 40 to 80 mg-equivalent dried herb.

INTERACTIONS REVIEW

Strategic Considerations

Black cohosh therapeutic monographs typically do not identify any drug interactions.[2,3,5] The herb appears to be relatively safe and is well tolerated with minimal toxicity at therapeutic doses.

A recent comprehensive safety review by Low Dog et al.[18] analyzed uncontrolled reports, postmarketing surveillance, and human clinical trials of more than 2800 patients involving black cohosh. The trials demonstrated a low incidence (5.4%) of adverse events, of which 97% were minor, and none resulted in discontinuation of therapy. No severe events were attributable to the herb. The authors concluded that black cohosh was safe when used for menopausal symptoms and is a safe alternative for women in whom estrogen therapy is contraindicated.[18] However, both this and other safety reviews[19] mainly examined isopropanolic extracts as used in clinical trials, and the data do not necessarily apply to traditional preparations, which are often used at higher doses. According to the manufacturers of Remifemin, animal tests suggest that higher equivalent doses, up to 500 times the 40-mg oral dose of isopropanolic preparations, are well tolerated over 6 months.

Despite the apparently benign toxicity of the herb according to clinical trial data, there have been persistent anecdotal reports of hepatotoxicity linked to black cohosh consumption. A recent National Institutes of Health (NIH) workshop discussed such reports and concluded that at present, hepatoxicity has not been conclusively demonstrated, although vigilance, including liver function monitoring, may be appropriate when higher doses are used.[20,21]

The absence of published interactions data and reports requires integrative practitioners to make the best possible assessments about potential interactions in light of the known pharmacology of the herb. Given increasing concerns about the risks of breast cancer associated with female HRT, arguably one of the more common clinical settings for use of the herb is the coadministration of black cohosh with HRT. Related concerns are potential interactions between black cohosh and drugs used for other aspects of menopause, such as the bisphosphonates for osteoporosis.

Hormone-dependent malignancies are another important area where drug-herb interactions must be considered. Premenopausal patients with reproductive malignancies are likely to experience more severe menopausal symptoms, especially vasomotor effects, as a result of chemotherapy-induced menopause than are postmenopausal patients.[22,23] The use of HRT in either population is contraindicated because of the proliferative activity of estrogens and the increased risk of renewed tumorigenesis.[24,25] The possible efficacy of black cohosh for symptom relief in these populations has not been the subject of systematic long-term studies, although some data are available; nevertheless, anecdotally the use of black cohosh is widespread in this setting.[26] The potential interaction between adjunctive tamoxifen and black cohosh in this population has been subject of small number of preclinical and clinical investigations.[27-30] (See SERMs later.)

Related adjuvant endocrine pharmacotherapies, such as aromatase inhibitors, including the more selective third-generation drugs, are restricted in use to postmenopausal patients.[24] Black cohosh does not contain the isoflavones with known in vitro aromatase inhibition (e.g., red clover, soy) and has no known aromatase inhibitory activity. Currently, no data relate coadministration of black cohosh with aromatase inhibitors.

Women for whom estrogen therapy is contraindicated and those with a history of estrogen-dependent malignancies should avoid black cohosh, according to some sources.[31] Recent studies on the pharmacology and clinical effects of black cohosh have been reviewed by Borrelli et al.[32,33] The current consensus is that the herb is primarily antiestrogenic, with receptor-binding tests negative for alpha or beta estrogen receptor (ER), and that it lacks estrogenic effects on uterine tissue.[34-40] Despite the predominant evidence for nonestrogenicity, as evidenced by assays on immortal ER-positive lines such as the MCF7 (breast) and Ishihara (endometrial) cell lines, data on cell proliferation are conflicting, with a few

studies suggesting proliferation at low doses, although not at higher doses.[41-44] In contrast, a recent poster report suggested that MMT-neu transgenic rats (in which mammary tumors develop through spontaneous activation of the HER-2/neu oncogene), when treated with equivalent oral doses of isopropanolic black cohosh, show increased metastatic progression to the lung at necropsy.[45] However, the black cohosh–treated animals did not differ from controls in latency or incidence of mammary tumor formation. Publicity about this poster report suggesting that black cohosh is unsafe for breast cancer patients would appear premature given that the weight of emerging evidence is against proliferative effects of the herb.[46] Further evidence is needed to establish safety definitively, and use of black cohosh in oncological settings should be restricted to health care professionals with appropriate clinical expertise in the use of botanicals in reproductive malignancies.

Evidence that both serotonergic and dopaminergic pathways may be involved in the mediation of some of the clinical effects of black cohosh on menopausal symptom reduction is gathering weight from initial experimental studies on serotonin receptor binding of the extract.[47] Borrelli et al.[33] hypothesized that serotonin may account for the apparent low-dose estrogenic effects, and this hypothesis has also been adopted by experienced researchers in the field such as Jarry et al.[48] Significantly, recent clinical evidence exists for the effectiveness of selective serotonin reuptake inhibitors (SSRIs; e.g., paroxetine, venlafaxine, fluoxetine) in reducing hot flashes in breast cancer patients.[49-51] Circumstantial support for this theory is also found in ER research which suggests possible activation effect of ER transcription by serotonin.[52]

The ER itself is an intensive focus of ongoing study, and the complexities of coactivation factors and pharmacogenomic variation within the alpha and beta receptor subtypes continue to expand the picture.[53-55] The complexity of ER biology may account for some of the earlier contradictory research findings; for instance, the biphasic nature of dose-response curves exhibited by estrogens and phytoestrogens has been studied as an example of the general phenomenon of *hormesis* (biphasic or U-shaped dose response curves), adding a further explanatory dimension to the multifactorial mechanisms involved.[56,57]

In clinical practice, combination prescriptions of herbs are often employed, but these are rarely studied in trials. An exception is a recent positive trial of the paired combination of St. John's wort *(Hypericum perforatum)* and black cohosh for climacteric symptoms.[58] The study indirectly lends further support to the thesis that menopausal symptoms are caused by neurotransmitter imbalances, given the known pharmacology of St. John's wort, which is devoid of phytoestogenic effects. (See St. John's Wort monograph.)

Overall, the pharmacodynamics of black cohosh are complex and not fully understood. The focus on menopause may have detracted from wider considerations; for example, black cohosh compounds are chemoprotective against menadione-induced deoxyribonucleic acid (DNA) damage.[59] The model of black cohosh emerging from current research in many ways is more coincident with the traditional picture of the remedy as a neuroendocrine rather than a hormonal agent.

Effects on Drug Metabolism and Bioavailability

Pharmacokinetic interactions between black cohosh and prescription drugs have not been recorded to date. Preliminary clinical data suggest a potential for interactions with drugs metabolized by cytochrome P450 2D6 (CYP2D6), following a probe drug study with desobriquin on 12 healthy volunteers by Gurley et al.[60] This study failed to find any effect of black cohosh extracts on CYP1A2, CYP2E1, and CYP3A4, despite significant inhibition of CYP2D6. The preparation was a commercial black cohosh extract standardized to 0.2% triterpene glycosides administered at 1090 mg orally twice daily for 28 days. An in vitro study tested separate black cohosh triterpene compounds for inhibitory activity against recombinant CYP3A4 oxidation of nifedipine. Separate isolated triterpenes demonstrated moderate IC_{50} (median inhibitory concentration) effects, but the whole extract demonstrated a notable inhibition, with IC_{50} of 0.027 mg/mL. The authors suggested potential for interactions with 3A4-metabolized drugs; however, this conflicts with the available clinical evidence from Gurley's group, who established that black cohosh extracts had no effect in vivo on the 3A4 substrate midazolam.[61]

Drugs metabolized by CYP2D6 include important tricyclic antidepressants, SSRIs, antipsychotics, stimulants (e.g., risperidone), analgesics, and tamoxifen. CYP2D6 is a narrow-band (high-affinity) low-throughput cytochrome, and many of the drugs metabolized by 2D6 can also be oxidized by 3A4. Polymorphisms of 2D6 are well known, and "poor metabolizers" have been shown to exhibit higher adverse effect levels with several drugs that are 2D6 substrates. Genotyping of patients for whom for prescription of 2D6 substrate drugs is indicated has been proposed as advisable.[62] Coadministration of black cohosh with drugs that are substrates of 2D6 should be avoided, or related drugs that are not 2D6 substrates should be selected, but interactions with 3A4 substrates are unlikely.

Modulation of drug transporters by black cohosh has received little study. Gurley et al.[63] found no effect of the herb (40 mg/day for 14 days) on digoxin pharmacokinetics, suggesting a negligible action on P-glycoprotein (P-gp). An experimental model of the human organic anion-transporting polypeptide B (OATP-B) revealed a moderate inhibitory effect on estrone-3-sulfate uptake after black cohosh addition; however, the number of known OATP-B substrates in humans is limited at present, although it does include DHEA-S and estrone.[64]

HERB-DRUG INTERACTIONS

Androgen Blockade Chemotherapies

Chemotherapy, antiandrogens: Bicalutamide (Casodex), cyproterone (Androcur, Cyprohexal, Cyprostat, Cyproteron, Procur, Cyprone, Ciproterona, Cyproteronum, Neoproxil, Siterone), flutamide (Chimax, Drogenil, Euflex), nilutamide (Anandron, Nilandron).

Chemotherapy, estrogens: Diethylstilbestrol (DES; Stilphostrol).

Chemotherapy, luteinizing hormone–releasing hormone (LHRH) agonists: Goserelin (Zoladex), leuprolide (Eligard, Lupron, Lupron Depot, Viadur), triptorelin (De-capeptyl Trelstar, Trelstar LA).

Chemotherapy, gonadotropin-releasing hormone (GnRH) receptor antagonists/LHRH antagonists: Aberelix, etrorelix (Cetrotide), ganirelix (Antagon).

5α-Reductase inhibitors: Dutasteride (Avidart, Avodart, Avolve, Duagen, Dutas, Dutagen, Duprost), finasteride (Propecia, Proscar).

Steroid/androgen synthesis blockade: Ketoconazole (Nizoral).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:
4. Plausible

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

Androgen deprivation combining one or more endocrine agents (or orchiectomy) in prostate cancer patients leads to well-documented adverse effects of hot flashes and loss of libido in more than 50% of patients. Black cohosh extracts may reduce vasomotor symptoms in patients with androgen deprivation.

Research

To date, research into the effects of black cohosh on vasomotor symptoms has been in women undergoing menopause, whether the natural climacteric or chemically or surgically induced. (See later discussion of interactions with HRT and SERMs.)

Reports

Currently, there are no published reports on the use of black cohosh for adverse effects of androgen blockade, although a recent general review of the subject by Moyad[65] highlights the pressing need for research on this topic.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Although the clinical efficacy of black cohosh in reducing hot flashes is not always consistent, interest in the use of the herb remains high among menopausal women and is a focus of ongoing research. On the other hand, information regarding use of lifestyle and integrative strategies or alternative therapies for andropausal symptoms is scarce. The spectrum of clinical and laboratory abnormalities associated with androgen deprivation therapy has been characterized as "androgen deprivation syndrome" (ADS) by prostate oncologist Strum, who suggests that ADS is an accelerated and exaggerated form of male menopause (andropause) involving a spectrum of possible symptoms, including mental and emotional changes and bone and joint pain.[66] The traditional indications of black cohosh for depression and rheumatic conditions, as well as its effects on vasomotor symptoms, suggest that its consideration is appropriate in the context of integrative oncological management of prostate cancer patients experiencing ADS, and clinical investigation is warranted.

Hormone Replacement Therapy (HRT): Estrogen-Containing and Synthetic Estrogen and Progesterone Analog Medications

HRT, estrogens: chlorotrianisene (Tace); conjugated equine estrogens (Premarin); conjugated synthetic estrogens (Cenestin); dienestrol (Ortho Dienestrol); esterified estrogens (Estratab, Menest, Neo-Estrone); estradiol, topical/transdermal/ring (Alora Transdermal, Climara Transdermal, Estrace, Estradot, Estring FemPatch, Vivelle-Dot, Vivelle Transdermal); estradiol cypionate (Dep-Gynogen, Depo-Estradiol, Depogen, Dura-Estrin, Estra-D, Estro-Cyp, Estroject-LA, Estronol-LA); estradiol hemihydrate (Estreva, Vagifem); estradiol valerate (Delestrogen, Estra-L 40, Gynogen L.A. 20, Progynova, Valergen 20); estrone (Aquest, Estragyn 5, Estro-A, Estrone '5', Kestrone-5); estropipate (Ogen, Ortho-Est); ethinyl estradiol (Estinyl, Gynodiol, Lynoral).

HRT, estrogen/progestin combinations: Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); conjugated equine estrogens and norgestrel (Prempak-C); estradiol and dydrogesterone (Femoston); estradiol and norethindrone, patch (CombiPatch); estradiol and norethindrone/norethisterone, oral (Activella, Climagest, Climesse, FemHRT, Trisequens); estradiol valerate and cyproterone acetate (Climens); estradiol valerate and norgestrel (Progyluton); estradiol and norgestimate (Ortho-Prefest).
HRT, estrogen/testosterone combinations: Esterified estrogens and methyltestosterone (Estratest, Estratest HS). (See also Estrogen Replacement Therapy [ERT] later.)

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Black cohosh extracts have been demonstrated to reduce several menopausal discomforts, especially vasomotor symptoms such as hot flashes and night sweats, through nonestrogenic mechanisms for which female HRT is also prescribed. Coadministration can be used to assist drug withdrawal, to reduce drug dosage or form of drug administration, or to decrease exposure to undesirable levels of exogenous estrogen.

Research

There is no research directly analyzing the effects of combining HRT and black cohosh, and the majority of clinical trials preclude use of HRT as an inclusion criterion, comparing the effects of black cohosh alone to placebo. Coadministration data are generally confined to survey information (see Reports), although two German open-label trials that included coadministration groups (Petho 1987, Warnecke 1985) were cited in McKenna et al.[67] but were unavailable for review; apparently these trials did not demonstrate significant interactions or adverse effects.

Reports

Recent survey data on menopausal women in Western countries reveal extensive use of dietary, botanical, and nutritional supplements for menopausal complaints.[68-71] Significant proportions of survey participants admitted to concurrent use of HRT with herbal therapies for menopause, ranging from 16% in the San Francisco Bay area survey by Kam et al.[69] to 46% in the Seattle area survey by Newton et al.[70] (n = 886). Black cohosh was the third most popular supplement used (after soy extracts and ginkgo). Almost all participants believed the natural therapies used were beneficial.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Changing perceptions of menopause (which is increasingly seen as a normal life cycle transition for which "natural" and folk remedies are more appropriate than mainstream medical interventions), coupled with increasing concern about the risks of breast cancer associated with female HRT, has led to widespread self-prescribed use of black cohosh (among other agents) as a "replacement" for HRT.[72] Practitioners familiar with botanical therapies use black cohosh in formulations to assist tapered withdrawal from HRT. It is also used to facilitate transition from combination regimens of conjugated estrogens

and synthetic progestins to lower doses of "safer" bioidentical HRT protocols using estriol and natural progesterone, or Bi-est or Tri-est compounded hormonal formulations (i.e., estrone, estradiol, and estriol compounded formulations). Black cohosh is rarely used alone in this context, but rather is used as one ingredient of formulae addressing the specific pattern of the individual case. Use of laboratory test data of urinary 2α-/16α-hydroxyestrone ratio as a screening test is advisable to determine incorporation of related interventions affecting estrogen metabolism in postmenopausal women; the 2α-substituted estrogen metabolites have much less tumor-promoting activity than those with 16α-substituted structure. Typical associated complementary interventions include the dietary consumption of brassicaceous vegetables, use of soy isoflavones and indole-3-carbinol supplements, and lifestyle factors such as physical exercise and weight reduction, all of which favor the shift from the 16α-hydroxylation to the 2α-hydroxylation pathway.

Selective Estrogen Response Modulators (SERMs)

Raloxifene (Evista), tamoxifen (Nolvadex), toremifene (Fureston).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Black cohosh extracts reduce vasomotor adverse effects associated with SERMs and may synergize with the antiproliferative effects of these agents in the adjuvant setting for ER-positive breast cancers.

Research

The mechanism of this interaction is not currently understood, although the reduction of hot flashes is unlikely to be directly mediated through ER effects. Preliminary evidence for enhancement of the antiproliferative effects of tamoxifen by black cohosh in MCF-7 (estrogen-dependent breast cancer) cells was demonstrated by Bodinet and Freudenstein,[27] who found significant inhibition of proliferation by the extract alone and a synergistic increase when combined with tamoxifen. Nisslein and Freudenstein[30,73] found similar synergistic effects with tamoxifen for both mammary and endometrial cancer lines in rodent models; in the endometrial model the effects did not result in increased tumor growth or metastasis, either with black cohosh alone or with the black cohosh–tamoxifen combination.

Two trials have examined the effects of black cohosh on tamoxifen-induced hot flashes. Jacobson et al.[29] used isopropanolic black cohosh extracts at 40 mg for 60 days in placebo/tamoxifen, black cohosh/tamoxifen, black cohosh/no tamoxifen, and placebo/no tamoxifen groups. They studied incidence and severity of hot flashes and sampled changes in follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels before and after treatment. The decline in hot flashes was 27% over baseline, but differences between the black cohosh and placebo groups were only significant in the degree of reduction of sweating. This contrasts with a more recent study by Hernadez Munoz and Pluchino,[28] who compared the use of tamoxifen alone (20 mg/day) to the same dose combined with 20 mg of ethanolic standardized black cohosh extract daily, administered for 12 months in 136 breast cancer survivors age 32 to 52 years. Almost half the intervention group were free from hot flashes, and the incidence of severe hot flashes was 24% in the intervention group and 73.9% in the usual-care (tamoxifen-only) group. Pockaj et al.[74] conducted a survey of black cohosh use among menopausal women with hot flashes, 13 of whom had a history of breast cancer or were taking tamoxifen or raloxifene, and found that a significant number had reduced symptoms and that no adverse effects of the herb were noted.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Endocrine therapy with tamoxifen remains a standard adjuvant approach in ER-positive breast cancer for both premenopausal and postmenopausal women, despite issues of tumor flare, development of drug resistance, and a range of adverse effects. Adverse effects of tamoxifen include hot flashes, vaginal bleeding and discharge, and a range of central nervous system (CNS) symptoms, such as mood changes, irritability, and depression. In addition, tamoxifen increases the risk of endometrial cancer and blood clots because of its estrogen-like activity, although it also lowers blood lipid levels and enhances bone density for the same reason.

Practitioners experienced in the use of botanical medicines in integrative cancer care settings may consider black cohosh (along with the isoflavone and lignan phytoestrogens) as potential supportive agents for reduction of hot flashes induced by tamoxifen. Furthermore, the experimental data suggest a potential improvement in anticancer efficacy for the combination. Large-scale clinical trials of these agents (vs. placebo) in combination with endocrine therapies are needed to evaluate fully the potential effects of such combination therapies. (See also Androgen Blockade Chemotherapies earlier.)

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Estrogen Replacement Therapy (ERT)

Warnings about black cohosh causing "estrogen excess" with ERT have been made by Miller.[75] This suggestion is not only speculative, but also in conflict with the known pharmacology of the herb. (See previous sections on HRT with estrogens and estrogen/progestin combinations.)

Iron

It has been suggested that black cohosh extracts may deplete iron from supplemental sources because of the tannin content of the herb.[76] Black cohosh rhizome and roots are not excessively tannin rich, and circumstantial evidence for the interaction is absent, so this interaction can be regarded as wholly speculative.

The 76 citations for this monograph are located under Black Cohosh on the CD at the back of the book.

Cascara

Botanical Name: *Rhamnus purshiana* DC.
Pharmacopoeial Name: Cortex rhamni purshianae.
Synonym: *Frangula purshiana* (DC) A. Gray ex J.C. Cooper.
Common Names: Cascara, cascara sagrada.

HERB DESCRIPTION

Family

Rhamnaceae.

Related Species

Alder buckthorn, *Rhamnus frangula* L. (syn. *Frangula alnus*, Miller.), buckthorn, *Rhamnus catharticus* L.

Parts Used

Dried bark (aged at least 1 year, stored in dark).

Common Forms

Dried bark: Powdered or cut for decoction.
Fluid Extract: 1:1 25% alcohol.[3]
Other liquid and solid preparations.

INTERACTIONS REVIEW

Strategic Considerations

Cascara bark is a major representative of the anthraquinone-containing herbs that are principally used for short-term relief of constipation. The anthraquinone-containing laxative group of botanicals traditionally includes related Rhamnaceae species such as the buckthorns (*Rhamnus frangula* L. and *R. catharticus* L.), senna leaf and fruits (*Cassia senna* L.), rhubarb root (*Rheum palmatum* L.), and aloe latex (*Aloe ferox*, Miller). The different crude drugs in this group have a large medical and commercial application as stimulant laxatives for the preparation of patients for radiological or colonoscopic procedures, softening of stool before anorectal surgical procedures, and treatment of constipation linked to drug-induced or lifestyle causes. In traditional botanical medicine, cascara and its relatives have long been used for short-term treatment of constipation, with a more recent history of folk use in herbal cancer treatments (e.g., the Hoxsey formula).

The widespread availability of both over-the-counter (OTC) and dietary supplement preparations containing stimulant laxatives has emphasized the problem of adverse effects from laxative abuse, with public education through cautionary product labeling suggesting restrictions for duration of use and contraindications for consumers.[2] Most of the professional literature echoes this concern. Cascara bark was approved for constipation by the German Commission E[3] and is the subject of monographs by the British Herbal Medical Association (BHMA),[1] World Health Organization (WHO),[4] and most comprehensively by the European Scientific Cooperative on Phytotherapy (ESCOP).[5]

A distinction should be made between appropriate therapeutic use of cascara and related botanicals and the uncontrolled, self-prescribed consumption of these agents by certain individuals. These latter, for psychological reasons, either consider normal bowel movement frequency to be unhealthy or compulsively exhibit behaviors classified in the eating disorder group of diagnoses (i.e., bulimia, anorexia, binge eating) and use purgation (and/or vomiting) as a self-imposed means of eliminating ingested food. Although such abuse exists, preoccupation with the purgative aspects of these herbs and their anthraquinone constituents is only one concern to integrative practitioners. A broader consideration of the activity of these botanicals in light of recent research suggests therapeutic applications in other fields, such as cancer chemotherapy.

Recent findings have revealed that the earlier concept of all stimulant laxatives acting through gut motility mechanisms is oversimplistic. Multiple mechanisms are involved, including almost every aspect of active and passive electrolyte transport, such as sodium/potassium-adenosinetriphosphatase (Na^+, K^+-ATPase), cyclic nucleotides, protein kinase C, calcium (Ca^{++}) dependence, autocoids or neurotransmitter release, increased mucosal permeability, and histological damage.[6-11] Furthermore, it has become clear that significant differences exist between the mechanism of action of the different agents; for example, senna does not stimulate platelet-activating factor (PAF) or inducible nitric oxide synthase (iNOS), as occurs with cascara.[6,8]

In the field of cancer biology, hydroxyanthraquinone agents such as emodin, once considered to be potentially carcinogenic, have more recently been studied for a variety of antiproliferative effects, mediated by inhibition of both nuclear factor kappa B (NF-κB) and tyrosine kinase.[12,13] These results have particular impact on HER-2/neu overexpression, as discussed later in the context of cascara's possible therapeutic combination with herceptin. Parenthetically, it should be noted that a significant number of conventional chemotherapeutic agents, notably doxorubicin, idarubicin, epirubicin, and mitoxantrone, are all anthraquinone derivatives. Interestingly, drug resistance to these agents may be reduced by plant-based polyphenols, including aloe-emodin, probably by inhibition of NF-κB.[14] Experimental studies with whole-herb extracts are rare, and most available data derive from studies using isolated anthraquinone ingredients such as emodin and aloe-emodin, and extrapolations to whole-plant effects must be qualified.

Pharmacokinetic interactions involving modification of drug absorption resulting from decreased transit times induced by cascara administration should not be overlooked. Stockley[15] reports only one such interaction between quinidine and a senna preparation in which quinidine AUC (area under curve) levels were reduced to 25% of baseline 12 hours after administration of a dose of Liquedepur. This is in contrast to the German Commission E, who proposed potential for interactions between all laxative herbs and antiarrhythmic drugs because of electrolyte disturbances (hypokalemia) rather than drug depletion from reduced bioavailability. The onset of enhanced bowel motility and the formation of soft or semisolid stool after administration of anthraquinone laxatives are known to lag 6 to 8 hours after ingestion, a result of the bowel flora hydrolysis of anthrone conjugates into the active aglycone drug form.[16] The extended delay should be taken into account if pharmaceuticals with a therapeutically narrow range are already being administered to the patient before

cascara administration. As always, clinical context and goals of coadministration are relevant for evaluating the significance of a potential interaction, and the cautions persistently repeated in relation to these drugs in the botanical literature (possible hypokalemia) are only discussed here in the section Theoretical, Speculative, and Preliminary Interactions Research.

Effects on Drug Metabolism and Bioavailability

Some evidence suggests that the naturally occurring anthraquinones such as emodin and chrysophanol are substrates that may undergo bioactivation into carcinogenic (mutagenic/genotoxic) intermediates through cytochrome P450 1A1 and 1A2.[17] However, in vitro data suggest that they may inhibit the same enzymes.[18,19] Extrahepatic cytochromes, such as CYP1B1 (which is often overexpressed in certain reproductive malignancies), have been experimentally induced by emodin in a human lung cancer cell line.[20] Similar experimental models also suggest inhibitory effects on phase 2 enzymes, including glutathione-*S*-transferase P1 and *N*-acetyltransferase.[21,22] These effects may be due to inhibition or downregulation of transcription factors NF-κB and activating protein 1 (AP-1).[22,23] At present, the pharmacokinetic effects of anthraquinone herbs on drug metabolism are not well characterized, but the possibility of clinically significant effects cannot be ruled out.

HERB-DRUG INTERACTIONS

Trastuzumab

Trastuzumab (Herceptin).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **4. Plausible**

Evidence Base: ☐ **Inadequate**

Effect and Mechanism of Action

Anthraquinone constituents of cascara, especially emodin, inhibit proliferation of HER-2/neu–overexpressing cancer cells and may additively interact with the monoclonal antibody, which also inhibits proliferation of HER-2/neu–overexpressing malignancy.

Research

Emodin, an anthraquinone constituent (and metabolite) of cascara, has been demonstrated to have antiproliferative effects, including induction of differentiation and apoptosis, through different mechanisms in several cancer cell lines, including breast, cervical, non–small cell lung cancer (NSCLC), and hepatoma, through a variety of mechanisms.[24-29] As a known inhibitor of the HER-2 tyrosine kinase domain,[30] emodin is particularly effective against HER-2/neu–overexpressing cells, and the continuing work by Zhang et al.[12,31] suggests that several beneficial interactions may occur between emodin and chemotherapy for HER-2/neu–overexpressing malignancies.

The HER-2 proto-oncogene is structurally related to the epidermal growth factor receptor. HER-2/neu is a p185 protein tyrosine kinase receptor and is a major target of antiproliferative drugs. Trastuzumab (Herceptin) is a successful first-generation monoclonal antibody drug that targets the HER-2/neu receptor. Currently, trastuzumab is licensed only for treatment of HER-2/neu–overexpressing metastatic breast cancer in patients with prior chemotherapy failure.[32,33] Gefitinib (Iressa, AstraZeneca) has been approved for treatment of NSCLC in patients who have failed treatment with traditional chemotherapeutic agents.[34] Currently, no studies have directly examined the interaction of trastuzumab and emodin. However, emodin has been shown in vitro to reduce drug resistance of HER-2/neu–overexpressing NSCLC cells to cisplatin, doxorubicin, and etoposide, as well as with paclitaxel in HER-2/neu–positive breast cancer cells.[25,31]

Integrative Therapeutics, Clinical Concerns, and Adaptations

At this time, use of natural tyrosine kinase inhibitors, such as curcumin from turmeric or emodin from cascara and related anthraquinone-containing herbs, is tentatively beginning to be explored in integrative oncological protocols. In practice, effective daily doses to achieve cytotoxicity from emodin have been calculated to be between 160 and 180 mg.[35] An issue with these doses is the possibility of mutagenicity from emodin itself. Despite in vitro tests that suggest mutagenicity, however, this factor has been considered a minimal risk factor in humans.[36-38]

The controversial Hoxsey anticancer formula incorporated several anthraquinone-containing herbs, including those with high levels of emodin. Anecdotally, the strongest support for Hoxsey formula came from breast and some skin cancers, several of which are now known to overexpress HER-2/neu.[39]

In China, other herbs containing emodin have been used in cancer therapy, notably *Polygonum cuspidatum*.[35] Practitioners of integrative oncology use the herb in this setting in botanical formulae for prevention of cancer recurrence, following conventional treatments. It should also be considered as a remedy for opiate-induced constipation in opiate-dependent cancer patients, in whom it might also synergize with certain chemotherapies.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Digoxin and Related Cardiac Glycosides and Antiarrhythmic Drugs

Amiodarone (Cordarone, Pacerone), deslanoside (cedilanin-D), digitoxin (Cystodigin), digoxin (purgoxin; Digitek, Lanoxin, Lanoxicaps), disopyramide (Norpace), dofetilide (Tikosyn), flecainide (Tambocor), ibutilide (Corvert), ouabain (g-strophanthin), procainamide (Procan-SR, Pronestyl), quinidine (Quinaglute, Quinidex, Quinora), sotalol (Betapace, Betapace AF, Sorine).

Potential electrolyte and acid-base disturbances resulting from chronic diarrhea caused by inappropriately prolonged use (or abuse) of cascara extracts was considered by the German Commission E. In their 1984 monograph on cascara, the Commission included a warning about the possibility of adverse interactions with cardiac glycosides, as well as other antiarrhythmic drugs, caused by hypokalemia. This was extended to a possible additive adverse interaction with known potassium-depleting drugs, such as thiazide diuretics and corticosteroids, as well as licorice root.[3] Over time, through force of repetition, this has now become a consensus interactions concern associated with all the stimulant laxative botanicals.

There are no actual clinical reports of this speculative interaction occurring. Therapeutic context should be

acknowledged before general warnings about interactions are given. Laxative abuse is a possible context to consider.

Estimates of the incidence of laxative abuse are scarce. A review of 73 published studies suggested an incidence of approximately 4.0% in the general population, but 14% among bulimic patients.[40] The diagnosis of bulimia predominantly affects females and is rare in older populations likely to be taking antiarrhythmic medication. Also, hypokalemia is a rarely reported adverse effect of laxative use, although decades ago the issue was sporadically noted.[41] A single case report from the psychiatric literature does suggest that two severe episodes of torsades de pointes in a mentally ill woman were the result of electrolyte disturbance from the stimulant laxative bisacodyl.[42] No antiarrhythmics were being used by this patient; however, a preclinical study that examined the effect of coadministered bisacodyl on digoxin serum levels found a significant reduction in serum cardiac glycoside levels compared with controls, which the authors considered a result of absorption losses caused by the laxative.[43]

Beyond the situation of overt or covert laxative abuse, the dangers of a hypokalemia-induced interaction seem remote. *Stockley's Drug Interactions*[15] does not report drug-induced hypokalemia cases from any cause, including stimulant laxatives interacting with cardiac glycosides. As suggested by at least one commentator, these adverse effects are overstated and unlikely to be the basis of a clinically relevant interaction.[44,45] Unless a patient is borderline hypokalemic from potassium-wasting diuretic therapy without potassium supplementation, diarrhea-induced hypokalemia would require at least five voluminous liquid stools per day for several days, which is an improbable consequence of normal therapeutic administration of cascara.

The 45 citations for this monograph are located under Cascara on the CD at the back of the book.

Cayenne

Botanical Name: *Capsicum annuum* L. *var annuum*.
Pharmacopoeial Names: Capsici fructus, capsici fructus acer.
Common Names: Cayenne, chili pepper, red pepper, hot pepper.
Note: Conventionally, "chili" or "cayenne" refers to the hottest varieties, "paprika" to intermediate varieties, and "sweet" or "bell" pepper to the mild, nonpungent types. None are "true peppers" of the Piperaceae, such as black pepper, *Piper nigrum* L.

SUMMARY

Drug/Class Interaction Type	Mechanism and Significance	Management
Acetylsalicylic acid, nonsteroidal anti-inflammatory drugs (NSAIDs), and other ulcerogenic agents ☼/?	Cayenne is ulceroprotective; interaction little used in practice. Superior alternative botanical agents available.	Coadministration unnecessary; use more effective agents.
Enalapril Angiotensin-converting enzyme (ACE) inhibitors ✗	Cayenne may exacerbate ACE inhibitor–induced cough during early coadministration; isolated report.	Monitor, avoid, or reduce drug and herb dose, if feasible.
NSAIDs, oral corticosteroids, antiarthritic medications ⊕⊕⊕	Topical administration may improve symptom relief from anti-inflammatories or enable lower drug doses.	Consider adopting in chronic arthritis patients with escalating medication requirements.

HERB DESCRIPTION

Family

Solanaceae.

Related Species

Capsicum annuum L. var *frutescens*, *Capsicum annuum* L. var *longum*, *Capsicum annuum* L. var *glabriusculum*, (Dunal) Heiser and Pickersgill *Capsicum minimum* (Roxb). Typically, pungent varieties are classed as *C. annuum* and its varieties, whereas the nonpungent peppers are classed as *C. frutescens*.

Habitat and Cultivation

Native to Central America; naturalized to tropical and subtropical zones globally; now cultivated worldwide.

Parts Used

Dried ripe fruit.

Common Forms

Dried: Powdered fruit.
Oleoresin: Crude extract.
Tincture: Typically, 1:10 to 1:20, 60% to 90% ethanol.
Topical: Cream and ointments containing 0.02% to 0.05% capsaicinoids.

HERB IN CLINICAL PRACTICE

Overview

The widespread use of cayenne as a dietary ingredient contrasts with a relative lack of information about the clinical pharmacology of the whole herb. The crude herb extract, capsicum "oleoresin," contains more than 100 different volatile components (many of which are not yet fully characterized) and must be distinguished from isolated capsaicin, which unlike the oleoresin, has been subject to considerable pharmacological research.

Activity of capsaicin and its congeners is responsible for several of the traditional therapeutic effects of cayenne, especially the topical treatment of painful peripheral disorders. Capsaicin has been used extensively in neuropharmacological research, and its vanillyl moiety lent its name to the *vanilloid receptor* (VR). The VR is a chemically and thermally gated cation channel that is opened by heat and closed by capsaicin. Capsaicin activation causes the release of various neuropeptides at the VR, including substance P, which mediates pain sensation in afferent peripheral nociceptive pathways, with recent evidence suggesting additional mechanisms of central noradrenergic activation through the locus coeruleus.[1] The VR is distributed widely in sensory afferent innervation of joints, muscles, and the integumentary, respiratory, digestive, and urogenital systems, as well as in the mucous membranes of the oral cavity and the cornea.[2]

Apart from its irritant effects (well known to police departments), internal use of capsaicin isolate has also been limited by some controversy over the potential mutagenic and tumorigenic toxicities of the compound.[3] Another naturally occurring vanillyl compound, resinferatoxin (RTX), derived from *Euphorbia resinefera*, has been used as a more potent capsaicin analog, therapeutically investigated as an intravesical treatment for incontinence, and is preferred to capsaicin because of a better adverse effects and toxicity profile.[4] Capsaicin itself has been synthesized, and synthetic analogs such as nonivamide (pellargonic acid vanillamide) are also available, sometimes employed as adulterants in capsicum samples.

Therapeutic use of isolated capsaicin and the oleoresin for external use is approved in the United States and several European Union (EU) countries as an ingredient in topical over-the-counter (OTC) preparations for analgesia in various neuralgic and myalgic conditions, with strengths typically

0.02% to 0.05% for creams and ointments. The German Commission E approved capsicum ("Paprika" monograph) for external use only and suggested limits to duration of administration (2 days), which appear to be conservative.[5] Literature reviews of the herb are sparse, except for a recent survey by McKenna et al.[6]

Historical/Ethnomedicine Precedent

Cayenne has been used for thousands of years by Native American and Meso-American peoples (*chili* is the Mayan term for cayenne) and was introduced to Europe following Spanish exploration of the Americas in the fifteenth century CE. Besides its near-universal use as a pungent spice additive to the human diet, cayenne is used in the major systems of traditional medicine, including Ayurveda, Chinese, Kampo, Korean, and African.

Generally, cayenne has been used topically as a rubefacient and counterirritant for arthritis and myalgias and as an analgesic for neuralgias and rheumatic pain. Internally, it has been used as a heating and stimulating remedy for colds and respiratory conditions, colic, and dyspepsia and as a digestive and circulatory stimulant. In Western botanical medicine, cayenne was associated with the popular folk medicine doctrines of Samuel Thomson in the United States in the mid-nineteenth century. "Thomsonian medicine" was based on a primitive energetic system that used cayenne in life-threatening illness "to raise vital heat." Thomsonian medicine later became refined and incorporated into the "Physiomedicalist school" of botanical medicine, which placed less emphasis on "heroic" therapeutic strategies of high doses of cayenne and other stimulants. In traditional Western botanical medicine, cayenne is primarily used internally as a stimulating cardiovascular and digestive tonic and topically as an analgesic.

Known or Potential Therapeutic Uses

External: Arthritis, chilblains, cluster headaches, myalgias, fibromyalgia and rheumatic pains, neuralgias and neuropathies (including diabetic neuropathy, postherpetic neuropathy, shingles, postsurgical neuropathic pain), osteoarthritis, pruritus, psoriasis, rhinopathy.
Internal: Atony of gastrointestinal (GI) tract, chemoprevention, diaphoretic and antipyretic in feverish conditions, noninflammatory flatulent dyspepsia, peripheral circulatory insufficiency, peptic ulcer prophylaxis.

Key Constituents

Pungent "capsaicinoid" principles, 0.5% to 1.5%, consisting principally of capsaicin (8-methyl-6-noneoyl-vanillylamide) and related vanillyl derivatives, dihydrocapsaicin, nordihydrocapsaicin, homohydrocapsaicin, and homocapsaicin.

Cayenne also contains several carotenoids, including carotene, lutein, and zeaxanthin; high levels of vitamins C and A; flavonoids; and steroidal alkaloid glycosides.

Therapeutic Dosing Range

Powdered Dried Herb (cayenne pepper): 30 to 250 mg, two or three times daily.
Tincture: 0.25 to 1.0 mL three times daily; 1:1 equivalent.
Topical: 0.025% capsaicinoid cream applied up to four times daily.

INTERACTIONS REVIEW

Strategic Considerations

The German Commission E monograph for cayenne lists no known interactions, and interactions reports for cayenne are rare.[5] The reason in part may be the rather narrow mainstream patterns of use as a topical analgesic. Synergistic interactions with coadministered analgesic and anti-inflammatory drugs are theoretically possible in this context, and some supportive data on this are available. However, topical herb-drug combinations are not widely employed in current clinical practice (see later discussion of antiarthritic medications). The dose of capsaicinoids in OTC topical preparations varies from 0.02% to 0.05%, applied up to four times daily to the affected area. Therapeutic context is itself apparently a determinant of capsaicin activity; animal experiments suggest that the analgesic effects of the compound are heightened in inflammatory states compared with noninflammatory controls.[7]

Internal prescription of cayenne by practitioners of botanical medicine usually follows traditional prescribing principles; thus cayenne is often incorporated in rather small quantities as an adjunctive ingredient of polypharmacy prescriptions to confer qualities of stimulation, warmth, and dispersion to the principal formula ingredients. The *British Herbal Pharmacopoeia* recommended dose for internal consumption is 30 to 120 mg, thrice daily. Assuming a "high" capsaicin content of approximately 1% capsaicinoids, this would deliver a daily amount of less than 5.0 mg capsaicinoids daily.[8] This is somewhat less than the typical human chronic dietary consumption levels in cultures where cayenne is a principal dietary spice, estimated at approximately 0.5 to 1.0 mg/kg.[2] In this context, interactions that have been extrapolated on the basis of experimental and animal data, involving relatively high levels of isolated capsaicin administered parenterally, are not directly applicable to clinical practice. (See Theoretical, Speculative, and Preliminary Interactions Research.)

Effects on Drug Metabolism and Bioavailability

The effects of dietary levels of cayenne intake on GI motility and secretion theoretically may lead to pharmacokinetic effects on drug absorption through direct actions on gut permeability, gastric acid levels, and intestinal transit times. Early reports suggested that cayenne increases gastric acid secretion, but recent studies do not confirm this.[9] An experimental study with a human ileocarcinoma cell line demonstrated increased cell permeability (tight junction gap increase) on administration of cayenne, although the opposite effect was observed with other spices (e.g., black pepper).[10] Animal evidence is inconclusive, although an ulceroprotective effect has been demonstrated in several studies, possibly related to increased mucous secretion and anti-inflammatory effects.[11-14]

In humans, hot pepper sauce (e.g., Tabasco) appears to slow gastric emptying, but overall orocecal time is unchanged, indicating increased intestinal transit.[15] This corresponds with the empirical observation that diarrhea can result from hot spicy food ingested by individuals who do not consume it regularly. Other evidence suggests a general metabolic stimulation; resting metabolic rate increases after cayenne spice ingestion in a meal, and the simultaneous increases in oxygen uptake, lipolysis, and carbohydrate metabolism may be associated with a degree of beta-adrenergic stimulation.[16,17] Gender differences in these effects have also been recorded.[18,19] Currently, dietary

cayenne studies suggest that absorption of drugs ingested with cayenne-spiced food may be enhanced, regardless of the drug's characteristics. The degree to which this effect may be clinically significant is variable and unpredictable. Furthermore, some experimental data appear to conflict with this general conclusion; in rats, for example, cayenne coadministration appears to reduce the oral bioavailability of aspirin.[20]

Pharmacokinetic effects of capsaicin on drug-metabolizing enzymes have been an area of research interest, partly because of apparently conflicting data on carcinogenicity of the compound from epidemiological and experimental studies. Capsaicin itself is a substrate of hepatic CYP450 2E1, a cytochrome that shares with 1A1 and 1A2 the role of metabolism of potentially carcinogenic aromatic hydrocarbons.[21] Other pathways for capsaicin metabolism have been investigated, including aliphatic hydroxylation.[22] Capsaicin has been reported to be a tumor promoter, carcinogen, and potential mutagen.[23] At the same time, it has also been found to have antigenotoxic, antimutagenic, and anticancer effects.[24,25] More recently, capsaicin has also been found to inhibit nuclear factor kappa B (NF-κB) and to have proapoptotic effects, which support a multimechanism basis for its chemopreventive properties.[26-28]

Capsaicin and dihydrocapsaicin directly inhibit CYP2E1, which has been suggested as a mechanism of its anticarcinogenic effects.[25,29-33] The primary drug substrates of 2E1 include the halogenated aliphatic anesthetics (enflurane, halothane, isoflurane, methoxyflurane, sevoflurane), as well as acetaminophen and ethanol. Ethanol, smoking, obesity, and diabetes all induce 2E1, which is unusual among the CYP450 enzymes in being subject to so many environmental influences. However, capsaicin can also undergo bioactivation.[23,24] The formation of reactive intermediates from capsaicin may also be a result of pan-P450 metabolism of capsaicin, according to a recent study by Reilly et al.,[34] who report that this is an essential part of detoxification of capsaicin rather than bioactivation because the intermediates can be "trapped" by addition of glutathione (GSH), suggesting that they are normally conjugated harmlessly. Overall, current data seem to indicate that capsaicin either can be metabolized as a straightforward detoxification or can be bioactivated, generating intermediates that may have direct or indirect toxicity through pan-P450 enzyme inhibition or covalent adduct formation with hepatic microsomal deoxyribonucleic acid (DNA), depending on the circumstances. Animal experiments suggesting prolongation of pentobarbital- and phenobarbital-induced sleeping times may support the pan-P450 inhibition by reactive intermediates (these agents are multi-P450 substrates, and pharmacokinetic-increased levels would require pan-P450 inhibition).[35]

Preliminary experimental evidence also suggests that capsaicin inhibits P-glycoprotein (P-gp). Drug resistance to vinblastine in a P-gp–overexpressing, multidrug-resistant carcinoma cell line (KB-C2) was significantly inhibited in vitro by capsaicin at 50 μmol.[36] Further data on the effects of capsaicin on drug resistance are needed before clinical extrapolations can be made.

Knowledge of the impact of chronic capsaicin or cayenne ingestion combined with pharmaceuticals on this complex system is clearly incomplete. However, obvious pharmacokinetic interactions resulting from CYP2E1 inhibition have not been reported, with the possibly relevant exception of theophylline (see later).

HERB-DRUG INTERACTIONS

Acetylsalicylic Acid, Nonsteroidal Anti-Inflammatory Drugs (NSAIDs), and Other Ulcerogenic Agents

Evidence: Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin), ASA, caffeine, and propoxyphene (Darvon Compound), ASA and carisoprodol (Soma Compound), ASA, codeine, and carisoprodol (Soma Compound with Codeine), ASA and codeine (Empirin with Codeine), ASA, codeine, butalbital, and caffeine (Fiorinal), ASA and extended-release dipyridamole (Aggrenox, Asasantin).
Extrapolated, based on similar properties: Nonsteroidal anti-inflammatory drugs (NSAIDs):

COX-1 inhibitors: Diclofenac (Cataflam, Voltaren), combination drug: diclofenac and misoprostol (Arthrotec), diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), furbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen), combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen), indomethacin (indometacin; Indocin, Indocin-SR), ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Aleve, Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).

COX-2 inhibitors: Celecoxib (Celebrex).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

? **Interaction Possible but Uncertain Occurrence and Unclear Implications**

Probability: **3. Possible**

Evidence Base: **○ Preliminary**

Effect and Mechanism of Action

Internal administration of cayenne may be protective against drug-induced mucosal ulceration by NSAIDs and related agents. The interaction is likely, but arguably of minimal clinical importance.

Research

Animal studies have provided inconclusive data on the effect of capsaicin on gastric mucosa, either alone or in combination with ulcerogenic agents.[11,13,14,37,38] Early studies suggested that cayenne might increase gastric acid secretion.[9] In more recent human studies, Myers et al.[39] found that red pepper (and black pepper) increased gastric cell exfoliation but had no effect on gastric secretion. Meanwhile, one rodent study found a protective effect against aspirin-induced ulceration in rats.[11] This effect was confirmed in humans in a small preclinical study by Yeoh et al.,[40] who found that 20 g cayenne per day coadministered with 600 mg aspirin daily led to a

significant protective effect against gastric ulceration assessed endoscopically.[40] A study comparing 103 peptic ulcer patients with matched controls examined chili consumption and found that higher chili consumption was significantly associated with lower ulcer incidence.[41] Another study of 84 healthy volunteers found that capsaicin administered in low doses intragastrically was protective against ethanol- and indomethacin-induced mucosal damage when coadministered, but not when the capsaicin was given for 2 weeks before drug administration.[42]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Although this interaction appears to be reasonably established by experimental evidence, the clinical significance is arguably rather low. Internal administration of cayenne at medicinal doses daily to counter aspirin adverse effects seems a relatively unfavorable strategy, given the availability of other herbal agents that are ulceroprotective, anti-inflammatory, and also lack any irritant properties. (See monographs for Aloe and Licorice.)

Enalapril and Related Angiotensin-Converting Enzyme (ACE) Inhibitors

Evidence: Enalapril (Vasotec)

Extrapolated, based on similar properties: Benazepril (Lotensin), combination drug: benazepril and amlodipine (Lotrel), captopril (Capoten), combination drug: captopril and hydrochlorothiazide (Acezide, Capto-Co, Captozide, Co-Zidocapt), cilazapril (Inhibace), combination drug: enalapril and felodipine (Lexxel), combination drug: enalapril and hydrochlorothiazide (Vaseretic), fosinopril (Monopril), lisinopril (Prinivil, Zestril), combination drug: lisinopril and hydrochlorothiazide (Prinzide, Zestoretic), moexipril (Univasc), perindopril (Aceon), quinapril (Accupril), ramipril (Altace), trandolapril (Mavik).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Cough is a known adverse effect associated with ACE inhibitors. Coadministration with cayenne can exacerbate cough symptoms, probably through more than one mechanism. The clinical significance is minimal.

Research

A form of "sensory hyperreactivity" cough induced by capsaicin alone has been described.[43-45] This may be mediated by VRs in the bronchial tree.[46] Vagal afferents that also include vanilloid pathways (C fibers) can be stimulated by capsaicin; however, experimentally this does not appear to cause a cough reflex but induces apnea (in primates).[47] Capsaicin inhalation has also been used to identify a subset of asthmatic patients with chemical sensitivity to inhaled irritants in a controlled manner, providing a degree of exposure management control in sensitive individuals.[48]

The mechanism of ACE inhibitor–induced cough is believed to be related to elevations in bradykinin (ACE is a kininase).[49] Yeo et al.[50,51] conducted a series of small investigations into ACE inhibitor–induced cough and capsaicin with normal and hypertensive patients using enalapril. Skin (delayed-type hypersensitivity, DTH) testing revealed that enalapril cough was associated with bradykinin, not substance P, reactivity. The drug-induced cough lessened over 28 days, and its sensitivity to capsaicin exacerbation also decreased. Adjusting the dose of enalapril downward (5 vs. 20 mg/day) reduced the frequency and severity of cough, but it did not appear to alter consistently the effect of capsaicin on the cough, leading the authors to conclude that there was a wide range of dose-dependent variation in response to capsaicin.[50,51]

Reports

An isolated report is available, with poor documentation standards (i.e., concurrent medications not listed). A 53-year-old woman had been taking an (unidentified) ACE inhibitor for several years without adverse effects, but experienced cough symptoms every time she applied a capsaicin-containing cream (0.075% capsaicin).[52]

Clinical Implications and Adaptations

Differential diagnosis of cough includes possible ACE inhibitor–induced cough. This is reversible on cessation of the drug and will likely diminish over a 28-day period of drug administration. Exacerbation by capsaicin is possible in some individuals, but the interaction is probably of minimal significance. Management strategies are empirical, with cessation or reduction of the herb or drug.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs), Analgesics, Oral Corticosteroids, and Other Antiarthritic Medications

Nonsteroidal anti-inflammatory drugs (NSAIDs):

COX-1 inhibitors: Diclofenac (Voltaren, Cataflam), combination drug: diclofenac and misoprostol (Arthrotec), diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), furbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen), combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen), indomethacin (indometacin; Indocin, Indocin-SR), ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Aleve, Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).

COX-2 inhibitors: Celecoxib (Celebrex).

Acetylsalicylic acid: acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin; combination drugs: ASA and caffeine (Anacin), ASA, caffeine, and propoxyphene (Darvon Compound), ASA and carisoprodol (Soma Compound), ASA, codeine, and carisoprodol (Soma Compound with Codeine), ASA and codeine (Empirin with Codeine), ASA, codeine, butalbital, and caffeine (Fiorinal), ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Corticosteroids, oral: Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol), prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone),

prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).

Interaction Type and Significance
⊕⊕⊕ **Beneficial or Supportive Interaction, Not Requiring Professional Management**

Probability:
1. Certain

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action
Topical capsaicin preparations, when coadministered with antiarthritic medications, can result in increased symptom relief because of substance P modulation by capsaicin. The interaction may be used to reduce the dose of pharmaceuticals to lessen potential drug adverse effects. The interaction is not widely exploited but may be of considerable significance to chronic arthritis patients.

Research
Five controlled clinical trials conducted to date support the use of topical capsaicin preparations for symptom relief in both osteoarthritis (OA) and rheumatoid arthritis (RA). The preparation used most frequently in the trials was Zostrix (GenDerm), containing 0.025% capsaicin administered topically to affected areas four times daily.[53-55] The mechanisms of pain reduction lie in the ability of capsaicin to modulate substance P–mediated nocioceptive pathways (see previous discussion).[53,56,57] The effects are similar to the pain relief mechanisms in other conditions and are not primarily antiinflammatory.[58] The trial conducted by Deal et al.[59] involved both OA (70) and RA (31) patients, who were allowed to continue taking their antiarthritis medications, including NSAIDs, corticosteroids, and analgesics. Analgesic effects of capsaicin are more pronounced in inflammatory states than in normal controls, according to one animal study.[7]

Integrative Therapeutics, Clinical Concerns, and Adaptations
This is a straightforward example of an additive (or possibly synergistic) and beneficial interaction caused by convergent clinical effects operating through different mechanisms (inflammation and nocioception) for drug and herb, respectively. The interaction is apparently benign and noncontroversial and could be recommended to patients interested in either increased levels of symptom relief other than that offered by pharmaceuticals or decreased dose levels of pharmaceuticals to reduce adverse effects.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Antacids

Aluminum carbonate gel (Basajel), aluminum hydroxide (Alternagel, Amphojel); combination drugs: aluminum hydroxide, magnesium carbonate, alginic acid, and sodium bicarbonate (Gaviscon Extra Strength Tablets, Gaviscon Regular Strength Liquid, Gaviscon Extra Strength Liquid); aluminum hydroxide, magnesium hydroxide, and simethicone (Advanced Formula Di-Gel Tablets, co-magaldrox, Di-Gel, Gelusil, Maalox, Maalox Plus, Mylanta, Wingel); aluminum hydroxide, magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); calcium carbonate (Titralac, Tums); magnesium hydroxide (Phillips' Milk of Magnesia MOM); combination drugs: magnesium hydroxide and calcium carbonate (Calcium Rich Rolaids); magnesium hydroxide, aluminum hydroxide, calcium carbonate, and simethicone (Tempo Tablets); magnesium trisilicate and aluminum hydroxide (Adcomag trisil, Foamicon); magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); combination drug: sodium bicarbonate, aspirin, and citric acid (Alka-Seltzer).

Mills and Bone[60] suggest a possible adverse interaction between antacid medications and cayenne resulting from gastroirritant and hypersecretory effects of the herb. Reports of such interactions are lacking, and most data suggest gastroprotective effects follow internal cayenne consumption, with increased mucus and blood flow rather than hyperacidity at the gastric mucosa. Clinically, it is common practice to advise patients with acid-related ulcers to avoid spicy food, and internal administration of stimulants such as cayenne is unusual in GI-sensitive individuals. On balance, this suggested interaction appears entirely speculative.

Anticoagulant and Antiplatelet Medications

Anticoagulants, oral vitamin K antagonists: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar), warfarin (Coumadin, Marevan, Wartilone).
Anticoagulants, heparin, unfractionated (UFH): Heparin (Calciparine, Hepalean, Heparin Leo, Minihep Calcium, Minihep, Monoparin Calcium, Monoparin, Multiparin, Pump-Hep, Unihep, Uniparin Calcium, Uniparin Forte).
Anticoagulants, heparinoids: Danaparoid (Orgaran), fondaparinux (Arixtra).
Anticoagulants, low-molecular-weight heparins: Ardeparin (Normiflo), dalteparin (Fragmin), enoxaparin (Lovenox), tinzaparin (Innohep).
Anticoagulants, thrombin inhibitors, hirudins: desirudin (Iprivask, Revasc), lepirudin (Refludan).
Antiplatelet thromboprophylactics: Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin), ASA, caffeine, and propoxyphene (Darvon Compound), ASA and carisoprodol (Soma Compound), ASA, codeine, and carisoprodol (Soma Compound with Codeine), ASA and codeine (Empirin with Codeine), ASA, codeine, butalbital, and caffeine (Fiorinal); cilostazol (Pletal), clopidogrel (Plavix), dipyridamole (Persantine), ticlopidine (Ticlid); combination drug: ASA and extended-release dipyridamole (Aggrenox, Asasantin).
Blood viscosity reducing agents: Pentoxifylline (Pentoxil, Trental).

Isolated capsaicin has definitively been demonstrated to have some antiplatelet effects in vitro and in animal experiments. The mechanism of these effects is not understood and their relevance to human hemostasis unclear. Some experimental evidence suggests antiplatelet activity of capsaicin may be related to cell membrane fluidization.[61, 62]

Another study has demonstrated a nitric oxide (NO)–releasing effect that is modulated by capsaicin-sensitive afferent neurons, which may implicate the vanilloid pathway.[63] Capsaicin has effects

on at least three stimuli of platelet activation: platelet-activating factor (PAF), collagen, and thromboxane.[64,65] At present, the levels of capsaicin (IC_{50} for collagen-induced in vitro effect was 87 µg/mL), and prolongation of tail bleed times in mice required a dose of 25 mg/kg capsaicin.[66] These levels are more than an order of magnitude higher than typical human doses from therapeutic topical or chronic dietary administration. Some epidemiological data, however, suggest that dietary use of cayenne may be related to lower incidence of thromboses in chronic cayenne consumers. A study comparing 88 Thai subjects to 55 Caucasian Americans found higher fibrinolytic parameters in the latter than in the Thai (cayenne user) group.[67] Finally, traditional herbalist Dr. Christopher[68] recommended cayenne as a hemostatic to stop external bleeding and promote wound healing, and Felter and Lloyd[69] suggest it can also be taken internally as an antihemorrhagic, especially for postpartum bleeding. At present, clinically significant interactions with antiplatelet, fibrinolytic, or anticoagulant medications are unreported and appear improbable.

Cisplatin

Evidence: Cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ).
Extrapolated, based on similar properties: Carboplatin (Paraplatin), oxaliplatin (Eloxatin).

One study using a rodent model demonstrated some reduction in cisplatin-induced nephrotoxicity in animals after single-dose cisplatin when coadministered with intragastric capsaicin.[70] The authors suggested that this was caused by antioxidant mechanisms, because renal glutathione and superoxide dismutase levels rose with the capsaicin treatment. High doses of capsaicin (10 mg/kg) were used, and the applicability of these data to human oncology settings is difficult to establish until more studies are performed.

Monoamine Oxidase (MAO) Inhibitors

MAO-A inhibitors: Isocarboxazid (Marplan), moclobemide (Aurorix, Manerix), phenelzine (Nardil), procarbazine (Matulane), tranylcypromine (Parnate).

MAO-B inhibitors: Selegiline, deprenyl, L-deprenil, L-deprenyl; (Atapryl, Carbex, Eldepryl, Jumex, Movergan, Selpak); pargyline (Eutonyl), rasagiline (Azilect).

Newell et al.[71] suggest a potential adverse interaction between MAO inhibitors and capsaicin, presumably based on extrapolations of "sympathomimetic-like" effects associated with acute cayenne ingestion, such as transient increases in resting metabolic rate. Capsaicin is not an adrenomimetic agent and lacks any direct sympathetic activity; this extrapolation appears to be an overextension of the known pharmacology and is unsupported by clinical reports.

Theophylline/Aminophylline

Theophylline/aminophylline (Phyllocontin, Slo-Bid, Slo-Phyllin, Theo-24, Theo-Bid, Theocron, Theo-Dur, Theolair, Truphylline, Uni-Dur, Uniphyl), combination drug: ephedrine, guaifenesin, and theophylline (Primatene Dual Action).

Two studies by the same investigator examined the kinetics of theophylline and cayenne (dried fruit orally) coadministration. Single-dose coadministration demonstrated an increase in clearance of the drug. However, cayenne pretreatment for 1 week led to decreased levels of the theophylline metabolite 1-methyluric acid (1-MU), suggesting a potential increase in theophylline levels from inhibition of theophylline metabolism.[72,73] Slight increases in theophylline levels are associated with increased adverse effects, which could indicate a potential interaction; however, the effects in humans are unknown and reports unavailable. The author's speculation that xanthine oxidase inhibition is affected by cayenne may or may not be correct. Theophylline is primarily metabolized by CYP1A; however, a secondary pathway of theophylline metabolism by 2E1 exists, and this P450 enzyme is inhibited by capsaicin.[74]

The 74 citations for this monograph are located under Cayenne on the CD at the back of the book.

Dang Gui

Botanical Name: *Angelica sinensis* (Oliv.) Diels.
Pharmacopoeial Name: Angelicae radix.
Synonym: *Angelica polymorpha Maxim. var sinensis* Oliv.
Common Names: Dang gui, dong quai, tang kuei, tang kwei, Chinese angelica.
Note: The phonetic "dong quai" Romanization is not the correct Pinyin transliteration, which is "dang gui." "Tang kuei" is the earlier Wade Giles transliteration, less used today.

HERB CHARACTERISTICS

Family

Apiaceae.

Related Species

In East Asian commerce, several species may be traded as substitutes. *Levisticum officinale* Koch., or lovage, sometimes known as "European dang gui," is a recorded adulterant, not a substitute.

Parts Used

Root; in East Asian traditional medicine, the head, body, and tail of the root are regarded as having different medicinal properties.

Common Forms

Dried: Prepared root, smoke-dried; baked in wine.
Fluid Extract: 1:1 70% ethanol, according to the *Pharmacopoeia of the People's Republic of China (PPRC)*.
Standardized Extract: Liquid or dry extracts may be standardized to ligustilide content (0.8%-1.0%) and to ferulic acid (0.05%-0.01%).

INTERACTIONS REVIEW

Strategic Considerations

One of the better known herbs from the materia medica of classical Chinese medicine, dang gui (in traditional terms) *supplements* (nourishes) *xue* (blood), moves and dispels blood stasis, and regulates menses. It is also used for moistening dry conditions, dispersing swelling, and promoting the discharge of pus.[1] The herb has been incorporated into Western herbal medicine, primarily as a women's tonic herb for menstrual disorders and infertility. Dang gui use for menopausal issues is not currently supported by clinical trial data.[2] The herb is also used for its cardioprotective, hepatoprotective, and mild immunomodulatory effects. In the contemporary practice of Chinese medicine, it is widely used in many herbal formulae, as well as in combination with conventional treatments, such as myelosuppressive chemotherapy.[3]

Much of the literature on dang gui is in Chinese-language journals, and many reports relate to formulae involving several ingredients, including dang gui. Few controlled trials are available, but there is a large body of traditional-use data, as well as a considerable number of uncontrolled trials in the East Asian medical literature. Many of the available studies, animal and human, involve parenteral administration, which cannot be readily extrapolated to oral administration used in the West. The herb is not referenced in official Western pharmacopoeias (although it was briefly in the *USD* in 1937) but has been official in the *PPRC* since 1977. The *American Herbal Pharmacopoeia* has produced a Western-oriented monograph, including a supplement on traditional Chinese usage,[4] and McKenna et al.[5] have reviewed much of the literature. Chen and Chen[6] have reviewed both the pharmacology and the traditional uses of the herb.

Interactions concerns about dang gui are largely the result of extrapolations from experimental pharmacological data of isolated ingredients, such as ferulic acid, ligustilide, or polysaccharide fractions of the herb, and usually stress the risks of concomitant use with anticoagulants. The traditional precautions and contraindications for dang gui, which include bleeding disorders, hemorrhagic disease, excessive menses, and first-trimester pregnancy, may be seen as equally appropriate in Western contexts.

Effects on Drug Metabolism and Bioavailability

Minimal data are available on the effects of dang gui on the different aspects of drug detoxification. Two Japanese studies are available. One screened a number of umbelliferous crude drugs in vitro for general cytochrome P450 (CYP450) inhibitory effects and found weak but measurable inhibition by dang gui, as well as other *Angelica* spp. After high-performance liquid chromatography analysis, the authors attributed this to the activity of a coumarin-derivative constituent, imperatorin.[7] A more specific in vitro study using rodent hepatic microsomes with various drug substrates found partial inhibition by dang gui extracts of CYP450 3A4, 2C9, and 2D6.[8] A Chinese study examined the effects of dang gui polysaccharide administration in normal and liver-damaged (by prednisolone) rodents and found that the herb fraction increased hepatic microsomal CYP450, glutathione-*S*-transferase, and reduced-glutathione content.[9] Pharmacokinetic interactions have not been reported, and in the case of warfarin have been ruled out as a mechanism of interaction[10] (see following discussion). Nonetheless, such effects seem theoretically possible, and further research is required to clarify the extent and significance of any potential pharmacokinetic interactions.

HERB-DRUG INTERACTIONS

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Evidence: Warfarin (Coumadin, Marevan, Warfilone).
Extrapolated, based on similar properties: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar); other drugs affecting hemostasis.

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

Probability:
4. Plausible

Evidence Base:
▽ Mixed

Effect and Mechanism of Action

Addition of dang gui to previously stabilized warfarin anticoagulation regimens may require the dose of oral anticoagulant to be adjusted to prevent excessive anticoagulation. Only one report is available, suggesting the interaction is unlikely to be clinically significant. Dang gui has multiple effects on hemorheological parameters, the mechanisms of which are not fully elucidated, and whether this is a strict interaction or merely an additive common pharmacodynamic effect has not been established.

Research

The literature on hemorheological activities of dang gui is dominated by an emphasis on isolated constituents (e.g., ferulate, butylidenephthalide) with parenteral administration at high dose levels in animal and human studies. The trend of the data supports a possible antiplatelet effect, probably operating through arachidonic acid metabolism.[11-17] Other hemorheological effects were observed in a study using parenteral dang gui (200 mL aqueous solution, intravenous administration daily for 20 days), in a group of 50 patients after acute ischemic stroke, where administration resulted in significant reductions ($p < 0.001$) in platelet adhesion, red blood cell (RBC) and platelet electrophoresis times, erythrocyte sedimentation rate (ESR) and serum fibrinogen, and blood and plasma adhesion ratios.[18] Oral administration of an aqueous decoction of dang gui and the related *Angelica acutiloba* were given to six healthy patients, and whole-blood viscosity was reduced ($p < 0.05$) after 180 minutes compared with controls.[19]

A study of warfarin and dang gui coadministration in rabbits investigated the effect of adding single-dose warfarin to animals pretreated with dang gui, as well as addition of dang gui to warfarin-stabilized animals, as measured by coagulation parameters. In the first case, adding warfarin to a dang gui pretreated group led to a ($p < 0.05$) lowering of prothrombin time (PT) compared with warfarin alone. Pharmacokinetic parameters of warfarin were not changed in the presence of dang gui pretreatment. Addition of dang gui to stable, warfarinized animals led to no significant change in PT or warfarin levels. In this study, warfarin was given at high dose levels subcutaneously, and a 2:1 extract of dang gui was given at 2 g/kg orally. The implication of this study appears to be that adding dang gui to stabilized warfarin is less problematic than adding drug to stabilized dang gui (in rabbits), although pharmacokinetic interactions were not observed.[10]

Reports

In a single but much-cited report, a 46-year-old female warfarinized patient experienced an unexplained rise in international normalized ratio (INR) to 4.05. Investigations revealed no identifiable cause, and she was advised to discontinue her 5-mg warfarin dose for 24 hours. The INR remained elevated on retesting 1 week later. The patient admitted taking a herbal preparation (Nature's Way brand of dang gui), 565 mg twice daily. She was advised to stop the herb, and the INR declined to 3.41, then to 2.48 after 1 week. Concomitant medications included digoxin and furosemide.[20] Fugh-Berman and Ernst[21] evaluated the interaction as "likely," scoring 8 of 10 on their report reliability scale.

Clinical Implications and Adaptations

The lack of reports of spontaneous bleeding associated with dang gui consumption alone, with only one report of the warfarin–dang gui interaction to date, suggests that concerns about the incidence and severity of the interaction are exaggerated. As always, self-prescription is a separate issue, and many warfarinized patients are poorly compliant with their monitoring test schedules. As a guideline, prescribing dang gui to warfarinized patients should generally be avoided unless there are compelling reasons for coadministration. In such cases, close monitoring of INR is required.

However, as is often the case from an integrative perspective, the potential interaction may be beneficial under specific circumstances. Dang gui has cardioprotective and thrombolytic effects that may be beneficial depending on the situation.[6,22] For example, patients receiving a typical 1 mg/day oral dose of Coumadin after temporary installation of vascular access ports/catheters for prevention of thrombosis at the catheter tip may benefit from the addition of dang gui, combined with natural antiplatelet and fibrinolytic agents, particularly if there are other indications for prescribing the herb. However, checking PT/INR weekly would be appropriate if coadministration is considered, because 1 mg Coumadin could affect PTs if circumstances altered (e.g., vitamin K deficiency).

Erythropoiesis-Stimulating Agents

Epoetin alpha (EPO, epocitin alfa, recombinant erythropoietin; Epogen, Eprex, Procrit), epoetin beta (NeoRecormon), darbepoetin alpha (darbepoetin alfa; Aranesp).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:
4. Plausible

Evidence Base:
☐ Inadequate

Effect and Mechanism of Action

Recombinant analogs of endogenous erythropoietin are used parenterally to correct anemia in seriously ill patients (cancer and chronic renal failure). The interaction is a pharmacodynamic additive effect on hematopoiesis. Dang gui may also help facilitate responsiveness to the drug.

Research

Several Chinese experimental studies have examined the effects of dang gui, particularly the polysaccharide fraction, in stimulating hematopoiesis and erythropoiesis. Hemoglobin, RBC count, and progenitor cells were all increased by the administration of the herb in normal and anemic mice as well as in cell culture systems.[23-25] Murine studies have demonstrated myeloprotective effects of dang gui and its polysaccharide fractions against cyclophosphamide-induced and radiation-induced leukopenia.[26,27]

Reports

Bradley et al.[28] reported a single case of an anemic hemodialysis patient who was apparently resistant to the recombinant drug. The patient started self-prescription of a decoction of dang gui and *Paeonia lactiflora*, and after 1 month the hematocrit increased from 29.7% to 34.4%, and the amount of the drug was reduced by more than 90%. The effect of the other component of the formula cannot be ascertained.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Published data substantiating this interaction are currently inadequate. However, the Chinese materia medica for *Supplementing the Xue/Blood* is an established part of protocols for supporting patients undergoing myelosuppressive chemotherapies in Chinese medicine. Dang gui is incorporated into many of these formulae, which are based on different patterns of bone marrow suppression according to traditional diagnostic criteria. Specialist review of these formulae is available from clinical texts, including Peiwen.[3] The risk/benefit ratios of this approach are favorable, and the combination requires further investigation by preclinical and controlled clinical studies.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Acetaminophen

APAP, paracetamol (Tylenol); combination drugs: acetaminophen and codeine (Capital with Codeine, Phenaphen with Codeine, Tylenol with Codeine); acetaminophen and hydrocodone (Anexsia, Anodynos-DHC, Co-Gesic, Dolacet, DuoCet, Hydrocet, Hydrogesic, Hy-Phen, Lorcet 10/650, Lorcet-HD, Lorcet Plus, Lortab, Margesic H, Medipain 5, Norco, Stagesic, T-Gesic, Vicodin, Vicodin ES, Vicodin HP, Zydone); acetaminophen and oxycodone (Endocet, Percocet 2.5/325, Percocet 5/325, Percocet 7.5/500, Percocet 10/650, Roxicet 5/500, Roxilox, Tylox); acetaminophen and pentazocine (Talacen); acetaminophen and propoxyphene (Darvocet-N, Darvocet-N 100, Pronap-100, Propacet 100, Propoxacet-N, Wygesic).

Dang gui extracts and polysaccharide fractions have been shown to have some moderate hepatoprotective activity. One study examined CCl4 and acetaminophen-induced hepatotoxicity and found that hepatoprotective effects for dang gui extracts were more pronounced in the case of acetaminophen, suggesting a glutathione-dependent mechanism for the protective effects.[29,30] The "interaction" of acetaminophen with dang gui described by Chen and Chen[6] is thus more likely an effect of general antioxidant hepatoprotective activity mediated by glutathione.

Cycloheximide, Scopolamine

Cycloheximide (Acti-aid, ActiDione, Actispray, actidone, hizaricin, kaken, naramycin, naramycin A, neocycloheximide), scopolamine (Scopace Tablet, Transderm Scop Patch).

A study with a rodent behavioral model examined the effects both hexane and methanol extracts of dang gui on amnesia induced by scopolamine and cycloheximide and *p*-chloroamphetamine. High doses of the hexane extract (1 g/kg) appeared to attenuate the amnesia induced by scopolamine and cycloheximide but not by chloramphetamine in this model. The authors suggest this implies an effect on memory function, but the significance of this for therapeutic doses of conventional extracts of dang gui in humans remains unclear.[31]

Nifedipine

Nifedipine (Adalat, Adalat CC, Nifedical XL, Procardia, Procardia XL); combination drug: nifedipine and atenolol (Beta-Adalat, Tenif).

Coadministration of nifedipine and dang gui in 40 patients with chronic obstructive pulmonary disease (COPD) led to a greater degree of reduction of pulmonary arterial pressure than in untreated controls or those treated with nifedipine alone.[32] Dose of dang gui was high (250 mL 25% solution/day) and was administered parenterally, which makes extrapolation from this study problematic, although some clinical evidence suggests that dang gui alone may have a vasodilator effect on the pulmonary circulation. More investigation is needed before this is confirmed as a clinically consequential interaction, particularly in light of the in vitro evidence suggesting a pharmacokinetic reduction of nifedipine level by inhibition of CYP450 3A4 and 2D6 by dang gui.[8]

Oral Contraceptives and Related Estrogen-Containing and Synthetic Estrogen and Progesterone Analog Medications

Oral contraceptives: monophasic, biphasic, and triphasic estrogen preparations:
Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCep. 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).
Hormone replacement therapy, estrogens: Chlorotrianisene (Tace); conjugated equine estrogens (Premarin); conjugated synthetic estrogens (Cenestin); dienestrol (Ortho Dienestrol); esterified estrogens (Estratab, Menest, Neo-Estrone); estradiol, topical/transdermal/ring (Alora Transdermal, Climara Transdermal, Estrace, Estradot, Estring FemPatch, Vivelle-Dot, Vivelle Transdermal); estradiol cypionate (Dep-Gynogen, Depo-Estradiol, Depogen, Dura-Estrin, Estra-D, Estro-Cyp, Estroject-LA, Estronol-LA); estradiol hemihydrate (Estreva, Vagifem); estradiol valerate (Delestrogen, Estra-L 40, Gynogen L.A. 20, Progynova, Valergen 20); estrone (Aquest, Estragyn 5, Estro-A, Estrone '5', Kestrone-5); estropipate (Ogen, Ortho-Est); ethinyl estradiol (Estinyl, Gynodiol, Lynoral).
Hormone replacement therapy, estrogen/progestin combinations: Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); conjugated equine estrogens and norgestrel (Prempak-C); estradiol and dydrogesterone (Femoston); estradiol and norethindrone, patch (CombiPatch); estradiol and norethindrone/norethisterone, oral (Activella, Climagest, Climesse, FemHRT, Trisequens); estradiol valerate and cyproterone acetate (Climens); estradiol valerate and norgestrel (Progyluton); estradiol and norgestimate (Ortho-Prefest).
Hormone replacement therapy, estrogen/testosterone combinations: Esterified estrogens and methyltestosterone (Estratest, Estratest HS).
Selective estrogen response modulators (SERMs): Raloxifene (Evista), tamoxifen (Nolvadex), toremifene (Fureston).

Partly because of its reputation as a "female tonic" herb, some sources suggest interaction of dang gui with female sex hormones (ERT, HRT) or hormone-modulating drugs (e.g., SERMs, aromatase inhibitors). Known phytoestrogenic

compounds have not been recorded in the root, and a controlled clinical trial of postmenopausal women found no changes in endometrial thickness or vaginal cell proliferation after 24 weeks' administration of a standardized extract of dang gui.[33] However, a cell line model found some evidence for both estrogen-dependent and estrogen-independent proliferative activity by a water extract of dang gui.[34] Recent reviews of botanicals for menopause have found no positive evidence of effects of dang gui alone on menopausal symptoms.[2,34,35] In the absence of estrogenic clinical effects or pharmacological estrogen receptor binding, suggestions of female hormone interactions with dang gui by some authors are unsupported at this time.[36]

Ouabain and Related Cardiac Glycosides and Antiarrhythmic Drugs

Evidence: Ouabain (g-strophanthin).

Extrapolated, based on similar properties: Amiodarone (Cordarone, Pacerone), deslanoside (cedilanin-D), digitoxin (Cystodigin), digoxin (Digitek, Lanoxin, Lanoxicaps, purgoxin), disopyramide (Norpace), dofetilide (Tikosyn), flecainide (Tambocor), ibutilide (Corvert), procainamide (Pronestyl, Procan-SR), quinidine (Quinaglute, Quinidex, Quinora), sotalol (Betapace, Betapace AF, Sorine).

Some experimental evidence exists for an antiarrhythmic effect of parenteral dang gui extracts, in animal models, including ouabain-induced ventricular fibrillation, as well as in digitalis- and epinephrine-induced arrhythmias.[37] Some secondary sources suggest that the herb must interact adversely with antiarrhythmic drugs, but logically a beneficial interaction would be suggested, and clinical reports of the adverse interaction are lacking.

The 37 citations for this monograph are located under Dang Gui on the CD at the back of the book.

Devil's Claw

Botanical Name: *Harpagophytum procumbens*, DC ex Meissner.
Pharmacopoeial Name: Harpagophyti radix.
Common Names: Devil's claw, grapple plant, Cape grapple plant.

HERB DESCRIPTION

Family

Pedaliaceae.

Parts Used

Secondary roots (tuber).

Common Forms

Dried: Cut/powdered secondary root, containing not less than 1.2% harpagoside.
Tincture, Fluid Extract, Hydroethanolic extracts 1:2, 1:3, 1:5 in 25% ethanol.
Standardized Extract: Tablets or capsules, standardized 6:1 to 9:1 on 8.5% harpagoside. (WS 1531, Schwabe GmbH) or 1.5:1 to 2.5:1 standardized at 2.5% harpagoside (Doloteffin, Ardeypharm GmbH).

INTERACTIONS REVIEW

Strategic Considerations

Devil's claw, a South African native, has been used in Western Europe for chronic arthritic conditions for several decades. The root tubers are bitter, containing iridoid glycosides, principally harpagoside.[1] The bitter nature of the remedy, suggested by Weiss[2] as comparable to gentian, led the German Commission E to approve its use for dyspepsia and loss of appetite.[3] In practice, however, it is only used for atonic digestion secondary to or associated with a primary arthritic condition. The European Scientific Cooperative on Phytotherapy (ESCOP) indications are for low back pain and osteoarthritis.[4,5] There is positive clinical trial evidence as well as pharmacological support for the use of the herb in painful, chronic arthritic conditions. Most of the trials to date have been German or French and recently reviewed.[6-8] Neither of the European therapeutic monographs notes any interactions between devil's claw and pharmaceutical drugs.

Pharmacologically, devil's claw has three principal areas of action: anti-inflammatory and analgesic, antiarrhythmic and hypotensive, and bitter tonic. Data regarding mechanism of the anti-inflammatory action has been conflicting, with initial studies suggesting a nonecosanoid mechanism because animal models of inflammation did not respond to the extract, although some direct effect on lipoxygenase and cyclooxygenase (COX) pathways was noted.[9-11] More recent studies suggest that there may be a downregulation of inducible COX-2 and inducible nitric oxide synthase (iNOS), as well as a similar effect on tumor necrosis factor alpha (TNF-α) transcription, probably resulting from upstream effects on activating protein-1 (AP-1).[12-15] This is consistent with the efficacy of the herb as a chronic, rather than acute, anti-inflammatory and analgesic agent operating through different pathways than the nonsteroidal anti-inflammatory drug (NSAID)–type direct effects on arachidonic acid metabolism.[16] Parallels with other botanical derivatives exist, and evidence is emerging for modulation of nuclear factor kappa B (NF-κB),[17] as well as the metalloproteinase TIMP-2.[18] Mechanism aside, clinical trials on the anti-inflammatory effects of devil's claw have revealed useful data relating to coadministration with several different NSAIDs and in clinical populations with chronic arthritic complaints using long-term NSAID therapy for management. This is a primary area for integrative use of the herb.

The cardiovascular effects of devil's claw have not been studied in humans, although studies of ex vivo Langendorff preparations (rabbit heart) and live rats strongly suggest the potential for protection against arrhythmias, including those induced by digoxin, together with a biphasic dose-response on heart rate.[19-21] Interestingly, harpagoside did not reproduce the electrophysiological effects of whole-plant extract. The same researchers noted a hypotensive reaction to the extract in normotensive rats, but only with intraperitoneal administration of high doses. Further studies on this aspect of the herb's pharmacology have not been published, and devil's claw clearly is a complex remedy that is not fully understood. Traditional South African indications include seizures, and some scientific corroboration of this has been found in a murine model.[22] Meanwhile, monitoring heart rate and blood pressure in patients with either preexisting hypotension or disturbances of rate or rhythm during early stages of administration of the herb may be prudent.

Effects on Drug Metabolism and Bioavailability

The bitter tonic aspects of the herb suggest that a potential for stimulation of hepatobiliary activity, but studies of the generic effect of bitters on drug metabolism and detoxification systems are unavailable, and pharmacokinetic interactions with devil's claw have not been reported to date. A single in vitro screening study of the effect of the herb on a mixture of human recombinant drug–metabolizing enzymes derived from baculovirus-infected insect cells suggested a potential inhibition of cytochrome P450 (CYP450) by devil's claw extracts.[23]

HERB-DRUG INTERACTIONS

Nonsteroidal Anti-Inflammatory Drugs and Related Antiarthritic Medications

Nonsteroidal anti-inflammatory drugs (NSAIDs):

COX-1 inhibitors: Diclofenac (Cataflam, Voltaren), combination drug: diclofenac and misoprostol (Arthrotec), diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), furbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen); combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen), indomethacin (indometacin; Indocin, Indocin-SR), ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Aleve, Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).

COX-2 inhibitors: Celecoxib (Celebrex).

Acetylsalicylic acid: acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin; combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Effect and Mechanism of Action

Additive pharmacodynamic anti-inflammatory effect enables reduced drug dose and reduction in drug adverse effects for a range of NSAIDs.

Research

Chrubasik et al.[24-29] have conducted several trials with a proprietary extract of devil's claw (Doleteffin) in various arthritic conditions, comparing both drug versus herb and drug in combination with various NSAIDs, including the COX-2 inhibitor rofecoxib (Vioxx). The general conclusions of this (ongoing) series of controlled trials and qualitative investigations are (1) for acute exacerbations of chronic arthritic conditions, including low back pain, knee pain, and hip pain, devil's claw extract is associated with fewer adverse effects than NSAIDs; (2) coadministation allows a lower dose of NSAIDs (or of opioid rescue medications in trials where these were allowed); and (3) for longer periods of administration, devil's claw was associated with almost twice the incidence of pain-free outcomes than rofecoxib. This latter result was from a subsequent pilot study, which, although it lacked the statistical power to establish the result as significant due to sample size, was interesting because the trial dropouts were almost all in the NSAID group, resulting from adverse effects of the drug.[26] In a qualitative study after coadministration of devil's claw with NSAIDs, the respondents were using a range of drugs that included aspirin, celecoxib, diclofenac, ibuprofen, indomethacin, ketoprofen, metazoal, naproxen, piroxicam, propyphenazon, and rofecoxib. This suggests that the effects observed in the controlled trials may be reasonably extrapolated to a number of anti-inflammatory drugs. In this connection, a 4-month trial compared diacerhein (an unrelated drug of the slow-acting drug for osteoarthritis–[SADOA] class) to devil's claw in 122 osteoarthritis patients. Diacerhein (a prodrug of the anthraquinone rhein, which is an interleukin-1 [IL-1] inhibitor), found fewer adverse effects and less rescue medication needed by the devil's claw group, although the degree of pain reduction was not significantly different.[30] Lipopolysaccharide (LPS)–stimulated COX-2 (and iNOS) messenger ribonucleic acid (mRNA) increases were inhibited by harpagoside through blocking of NF-κB activation of LPS in a human hepatoma cell line model, although the detailed mechanism of inhibition has not been established.[17]

Integrative Therapeutics, Clinical Concerns, and Adaptations

The NSAIDs, including selective COX-2 inhibitors, remain widely used for management of arthritic pain. The adverse effect profile of nonselective NSAIDs is a well-known problem, with gastropathies resulting in considerable expense for hospital care and responsible for about 17,000 deaths per year in the United States from major gastrointestinal bleeding. Emerging data also suggest that the COX-2 inhibitors are not as free from adverse effects as initially believed.[31,32] Recently, it has become clear that if aspirin (including low dose, i.e., 80 mg/day) or any classic NSAIDs are combined with COX-2 inhibitors, the risk of bleeding is higher than for classic NSAIDs alone. On the economic cost side of the equation, standardized devil's claw and COX-2 inhibitors are probably equal in cost. At this stage, however, the use of devil's claw as adjunctive, or even where possible as an alternative, medication in acute exacerbations of long-standing arthritis should be actively considered. Given that the adverse effect profile of the herb is benign, coadministration may not require professional management because symptom relief is the determining factor for the patient.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar), warfarin (Coumadin, Marevan, Warfilone).

A secondary survey of plant toxicology in the United Kingdom over a 5-year period included reference to a single case in which there was an alleged adverse interaction between devil's claw and warfarin.[33] However, the details of this case were completely unavailable, rendering it impossible to evaluate, a conclusion confirmed by Fugh-Berman and Ernst.[34] Nonetheless, a persistent repetition of this unsubstantiated interaction occurs in the secondary literature despite the lack of verifiability of the original source and an absence of preclinical or clinical evidence for its existence.

The 34 citations in this monograph are located under Devil's Claw on the CD at the back of the book.

Echinacea

Botanical Names: The three principal species used commercially are *Echinacea angustifolia* DC, *Echinacea purpurea* (L.) Moench, and *Echinacea pallida* (Nutt.) Nutt.
Pharmacopoeial Names: Echinaceae radix, Echinaceae herba.
Common Names: Echinacea; *E. angustifolia*: narrow-leaved coneflower, Western echinacea; *E. purpurea*: purple coneflower, purple echinacea; *E. pallida*: pale coneflower echinacea, pale echinacea.

SUMMARY

Drug/Class Interaction Type	Mechanism and Significance	Management
Cyclosporine Allograft immunosuppressive agents ✗	Theoretically, long-term concomitant use might require increased levels of immunosuppression in allograft patients. Inadvertent use without professional care may cause drug failure.	Avoid, except for short-term acute coadministration, with professional monitoring.
Cyclophosphamide ?/⊕/✗	Immunotherapeutic outcomes of low-dose drug protocols (*not* cytotoxic schedules) may be enhanced by concomitant administration. High-dose drug effects on myelosuppression may be reduced.	Adopt; coadminister only with integrative oncologist supervision.
Myelosuppressive Antineoplastic Chemotherapies ⊕/☼	Echinacea may help protect white blood cell (WBC) counts in chemotherapy induced myelosuppression. Natural killer (NK) cell number and activity increased by long-term administration.	Adopt; coadminister with related myeloprotective agents. Continue herb after chemotherapy.
Interferon, interleukin-2 (IL-2) Immunotherapeutic BRMs ?/⊕	Possible additive effects of herb and drug allow sparing of drug, reduction of drug side effects, and enhanced therapeutic responses.	Consider adopting; professional management required.
Tumor necrosis factor-alpha antagonists Immunosuppressive BRMs ?/⊕/✗	Echinacea may theoretically be used to enhance cellular immunity during temporary drug withdrawal mandated by opportunistic infection.	Stop drug; administer herb short-term only, before recommencing drug therapy.

BRMs, Biological response modifiers.

HERB DESCRIPTION

Family

Asteraceae.

Related Species

The *Echinacea* genus contains about 12 species, depending on the taxonomic authority consulted, although three major species (*E. angustifolia, E. purpurea, E. pallida*) are used in commerce. The minor taxa are sometimes classed as variants of the principal species. The minor species are confined to relatively small wild populations and include *Echinacea paradoxa, E. simulata,* and *E. atrorubens;* the Eastern species *E. tenneseensis* and *E. laevigata* are endangered.

Habitat and Cultivation

Echinacea angustifolia is native to the Great Plains and Atlantic drainage areas of the United States (U.S.) and Canada. *Echinacea purpurea* was introduced from the U.S. to Germany by Dr. Madaus before World War II and became cultivated on a large scale in Western Europe, where it is the dominant species of commerce.

Parts Used

Root and aerial flowering herb; commercially, the roots of Western echinacea *(E. angustifolia)* are preferred in the U.S.; aerial parts of purple echinacea *(E. purpurea)* are the principal part used in Europe.

Common Forms

Dried: Root powder and aerial parts.
Fluid Extract or Tinctures: Any of the above, 45% ethanol.
Fresh Stabilized Juice: Echinacin is a German preparation (Madaus AG) that consists of *E. purpurea* flowering tops' succus stabilized in 22% ethanol.
Solid Extracts, Tableted, or Encapsulated: Combinations of the above in different concentrations are available.
Standardized Extracts: In the U.S., echinacosides have been used as a marker; however, agreement on standardization is lacking, and manufacturers' preparations may vary.

HERB IN CLINICAL PRACTICE

Overview

The medicinal use of echinacea derived from indigenous Native American medicine. Widely used in the U.S. in the preantibiotic era for infectious diseases of all types, the modern view of the herb is narrower in focus, corresponding to the influence of European phytotherapy. An influential German clinical literature primarily employed aerial parts of *E. purpurea*, usually the stabilized fresh-juice preparation, administered both orally and parenterally. Historically, this resulted from the widespread cultivation of *E. purpurea* in Germany, which lacks native populations of echinacea. The roots of *E. angustifolia* are the preferred medicinal species in North American use. Modern clinical trials of echinacea focus largely on its use in prophylaxis and treatment of common colds and flu, whereas other therapeutic aspects of the herb remain underinvestigated by clinical researchers.

In popular use, echinacea is usually associated with prophylaxis and self-treatment of mild respiratory infections such as the common cold. However, the trial evidence for echinacea's efficacy for this indication remains conflicting and is perennially controversial in part because of the different *Echinacea* spp., different plant parts used in preparations, and different dosing regimens, as well as varying study design, methodology, and power.[1,2] The debate regarding the efficacy of echinacea in relation to the common cold has unfortunately become emblematic of divisions between advocates of natural medicine and those of conventional medicine. Arguably, this detracts from issues of more practical concern to clinicians, who likely are more focused on the general immunomodulating properties of the herb rather than on whether a trial shows "it works" for the common cold.

The detailed pharmacological mechanisms of action of echinacea remain to be fully characterized. It is well established, however, that the herb enhances cell-mediated immunity, particularly phagocytosis, and has moderate anti-inflammatory as well as beneficial wound-healing and connective tissue effects. Different constituent groups are thought to act in concert to affect immune parameters. Although there have been many studies of the herb, variations in the form of preparation, including differing plant parts and plant species used, as well as dose ranges and routes of administration, have contributed to a surprising lack of cohesive understanding of the pharmacology of echinacea. Novel discoveries about the immunological properties of echinacea emerge as research into this complex herb continues; recent examples include the discovery of a "melanin"-like constituent that activates nuclear factor kappa B (NF-κB) via a toll-like receptor (TLR2) mechanism, as well as a cannabinoid receptor–dependent pathway of immunoactivation unique to the alkylamide fraction.[3,4]

Historical/Ethnomedicine Precedent

Echinacea was used by Native American peoples as a medicinal agent for a wide variety of ailments, both topically and internally, including for snakebites, enlarged glands, and septic conditions. It was introduced into mainstream herbal medicine as a component of "Meyer's Blood Purifier" in the 1870s, where it came of the attention of the Eclectics, particularly John Uri Lloyd and John King. In the 1880s, Eclectic physicians started using echinacea, and the herb rapidly became a mainstay of their practice. Eclectic indications included carbuncles, furunculosis, abscesses, nasopharyngeal and respiratory catarrh, dysentery, syphilis, snakebites, sepsis, and cancer; their empirical reports constitute detailed, comprehensive, and authoritative contributions to the literature on echinacea.[5,6] Echinacea was official in the *National Formulary* from 1916 to 1946. Brinker[7] has systematically detailed the divergent historical, cultural, and pharmacological aspects of the two major medicinal *Echinacea* species, *E. angustifolia* and *E. purpurea*, in the U.S. and Europe.

Known or Potential Therapeutic Uses

Internal: Immunomodulation and promotion of cell-mediated immunity, particularly increasing phagocytosis by macrophages and monocytes, in a wide range of bacterial and viral conditions; chemotherapy-induced immunosuppression; recurrent candidiasis, sinusitis, etc.; upper respiratory tract infections (URIs); prophylaxis of URIs and infection in general.

Topical: Wound healing and connective tissue repair, venomous bites, including snakebites and spider bites.

Key Constituents

Caffeic acid derivatives, alkylamides, flavonoids, polyacetylenes, essential oil, polysaccharides, alkaloids. *Echinacea angustifolia* root contains isobutylamides; *E. pallida* lacks these compounds but contains polyacetylenes, which appear to have similar pharmacological effects on immune parameters. Constituent profiles also vary according to part used (root vs. herb) and the method of extraction; for example, immunoactive polysaccharides are not present in most hydroethanolic preparations because of their insolubility in ethanol. "Melanin" has recently been identified in phenolic extractions.[4]

Therapeutic Dosing Range

Suggested therapeutic dose ranges of the herb vary widely. Western echinacea root preparations are often administered at lower doses than *E. purpurea* aerial parts. Acute and chronic dose ranges also widely vary, as do posological approaches, which include the homeopathic through supraphysiological. The following are composite figures based on several sources.[8-13]

Chronic Dose Range

Dried Root: 1 to 5 g/day
Dried Aerial Parts: 2.5 to 6 g/day
Fluid Extract (1:1) 3 to 5.5 mL/day
Fresh Juice: 8 to 9 mL/day

Acute Dose

The chronic doses may be significantly increased for short-term administration in acute conditions; 10 to 15 g/day or equivalent in liquid preparations is common.

INTERACTIONS REVIEW

Strategic Considerations

Authoritative monographs for *Echinacea* spp. generally list no known interactions.[10,11,13,14] The German Commission E listed certain contraindications "in principle" that have been challenged as speculative (see Theoretical, Speculative, and Preliminary Interactions Research). Because the mechanisms of action of different constituents of echinacea are not fully characterized, extrapolations from the available data to in vivo interactions involve a degree of speculation, although consideration of specific clinical contexts of herb/drug administration can clarify potential interaction issues.

Self-prescribing consumers may administer echinacea for more serious conditions than colds and flu, as shown by a recent survey of nonconventional therapy use by cancer patients.[15] Echinacea is anecdotally used by herbalists as an immune stimulant for various indications, including immunosuppressive or immunosupportive pharmacotherapies, and for patients with immunodeficiency or autoimmune conditions and cancer. Possible interactions in these contexts are addressed later, despite lack of published data and inherent problems of extrapolating from limited experimental data to in vivo clinical practice. Echinacea in these settings is established in herbal practice, however, and this implies a wider concept of the therapeutic value of echinacea than the cold and flu treatment that dominates mainstream perceptions and

publications among conventional health care professionals and the lay public.[16,17]

As a nonspecific cell-mediated immunomodulator, echinacea has been combined with anti-infective pharmacotherapies, either to increase net antimicrobial effect or to provide a similar degree of antimicrobial action at a lower drug dose. Few studies support this type of strategic interaction, although a study showing that a combination of *E. purpurea* intravenously with econazole was more efficacious than econazole alone in preventing recurrent candidal infection over a 6-month period is an often-cited example.[18] Some secondary sources evaluate this single study as evidence for a specific econazole-echinacea interaction. However, it is probably more appropriate to consider it as a specific instance of a general additive combination with converging antimicrobial effects leading to an enhancement of T helper cell type 1 (Th1) immunity; this interaction could arguably be extrapolated to several classes of anti-infective drugs for which evidence is not currently available.

The emerging use of pharmaceutical *biological response modifiers* (BRMs) that target different molecular aspects of the inflammatory process constitutes a challenging and complex scenario for clinicians considering the use of immunomodulating herbs. Several such agents are approved in a variety of chronic inflammatory conditions, including psoriasis, inflammatory bowel disease, and rheumatoid arthritis, as well as spondylosing arthropathies. Currently, the most frequently used class of these drugs targets tumor necrosis factor alpha (TNF-α) through a variety of mechanisms. Although necessarily speculative at this stage, the interactions between echinacea and these important emerging agents are considered later. A related consideration that should not be overlooked is that herbs influence human physiology differently than drugs, even when the apparent effects are convergent, as with echinacea and recombinant interleukin-2 (rIL-2).[19]

Incorporation of echinacea as an ingredient in Western botanical formulae for bone marrow recovery after myelosuppressive chemotherapies is consistent with known pharmacology of the herb. At this time, coadministration with pharmaceutical colony-stimulating factors such as Neupogen lacks published support, although adverse event reports from concomitant administration are lacking. Related botanical strategies for protection of white blood cell (WBC) counts during chemotherapy are found in both Chinese and Western botanical integrative oncological settings.[19,20]

Effects on Drug Metabolism and Bioavailability

Until recently, data on the effects of echinacea on drug-metabolizing systems were unavailable. An in vitro fluorometric screening study by Budzinski et al.[21] suggested moderate in vitro inhibition of cytochrome P450 (CYP450) 3A4 by echinacea extracts, implying a potential for pharmacokinetic interactions with substrates of this drug-metabolizing enzyme, but such interactions have not been reported to date in the clinical literature. No other potentially significant pharmacokinetic interactions with drug absorption, distribution, metabolism, and excretion (ADME) parameters have been reported. An in vitro study using a Ca-co cell membrane model examined differential transport of the caffeic acid derivatives and alkylamides, the principal components of hydroethanolic extracts of echinacea, and found that the apparent intestinal permeability for the alkyl amides was significantly greater than that for the caffeic acid compounds.[22] Another in vitro study found no inhibition of CYP2D6 and mild to moderate inhibition of CYP3A4 that was, unusually, dependent on the substrate, but marked inhibition of CYP2C9.[23] Currently, minimal data exist on echinacea and drug-transporter proteins. An experimental model of the human organic anion-transporting polypeptide-B (OATP-B) revealed a moderate inhibitory effect on estrone-3-sulfate uptake after echinacea addition. However, the number of known OATP-B substrates in humans is limited at present, although it does include DHEA-S and estrone.[24] The in vivo relevance of these data remains to be established.

A clinical study by Gorski et al.[25] used in vivo CYP450 substrate specific probe techniques to examine the effect of echinacea on several drug-metabolizing enzymes in healthy volunteers. After a washout period following baseline probe administration, using as probe drugs caffeine (1A2), tolbutamide (2C9), dextromethorphan (2D6), and midazolam (hepatic and intestinal 3A4), echinacea was administered at 400 mg of dried root four times daily for 8 days; the probes then were readministered and blood samples taken. The echinacea appeared to have no effect on 2D6 but exerted moderate inhibition on 2C9 and 1A2 and a complex effect on 3A4 involving a near–self-canceling inhibition of intestinal 3A4 with induction of hepatic 3A4 (see Theoretical, Speculative, and Preliminary Interactions Research). Notably, the Gorski study used powdered *E. purpurea* root for 8 days, although aerial herb is the more typical form of purple coneflower preparation, and the healthy volunteers were not phenotyped for polymorphisms of the P450 enzymes studies, which is particularly relevant for 2C9. A wide range of intersubject variability in pharmacokinetic responses was noted, in line with predictable levels of individual variation known to be partly associated with genetic, genomic, and metabolomic differences.

More research with larger populations is required to examine the in vivo effects of echinacea on drug-metabolizing systems. Inhibition of drugs metabolized by CYP2C9 may be a potential risk. Principal among these would be the *S*-warfarin isomer, phenytoin, and the sulfonylureas. These interactions have not been observed or reported to date.

HERB-DRUG INTERACTIONS

Cyclosporine and Related Immunosuppressants

Evidence: Cyclosporine (Ciclosporin, cyclosporin A, CsA; Neoral, Sandimmune, SangCya).
Extrapolated, based on similar properties: Azothioprine (asathioprine; Azamun, Imuran, Thioprine), cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox), prednisolone oral (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone oral (Deltasone, Liquid Pred, Meticorten, Orasone), tacrolimus (FK-506, fujimycin; Prograf).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability:
4. Plausible

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

Enhancement of cell-mediated immunity by echinacea administration holds the potential to cause a shift in the level of immunosuppression required to maintain host-graft adaptation in transplant recipients. Arguably, this proposed phenomenon represents a "contraindication" rather than interaction.

Research

Studies have shown phagocytic activity of human peripheral blood monocytes can be stimulated by echinacea polysaccharide fractions.[26-31] Resistance to systemic infection in immunosuppressed animals was enhanced by echinacea.[32] Natural killer (NK) cell activity from human peripheral blood monocytes drawn from immunodeficient patients (AIDS, CFIDS) compared with normal subjects showed that cell-mediated immune activity was significantly enhanced after echinacea administration to the immunodeficient groups.[33] More controversially, a "melanin"-like compound from echinacea has been shown to activate NF-κB through a toll-like receptor (TLR) mechanism (involving TLR2), resulting in increased Th1 cytokine levels.[4] At this time the clinical role, if any, of plant melanins as immunomodulating agents remains to be established.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Immunosuppressed allograft recipients are more vulnerable to minor infection than normal individuals. Acute use of echinacea at the onset of symptoms (e.g., common cold, acute URIs) is preferred by some allograft patients and practitioners to antibiotic therapies, because preexisting susceptibility to opportunistic infection (e.g., *Candida*) is likely to be exacerbated by antibiotics. Assuming prior stable immunosuppression within accepted safety margins, as reflected in serum immunosuppressive drug levels, there seems no reason to oppose the use of echinacea acutely for prophylaxis or treatment of mild infection. However, compelling reasons would be needed to extend echinacea treatment to chronic use in this patient population. Clinical features of graft rejection must be treated by aggressive intensification of immunosuppressive therapy.

Cyclophosphamide

Cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox).

Effect and Mechanism of Action

This complex interaction may depend on the dose of drug and the clinical context. In cancer, low doses of cytotoxic agents such as cyclophosphamide have been found to have "paradoxical" immunostimulatory effects despite their myeloablative effects at high dose levels. Echinacea appears to increase the immunity-dependent anticancer effects of low-dose cyclophosphamide when given concurrently. In autoimmune disease, cyclophosphamide may be used at noncytotoxic doses to achieve immunosuppression, in which context echinacea would be theoretically contraindicated.

Research

Emerging interest in the anticancer effects of nontoxic doses of cyclophosphamide and other agents (e.g., vinca alkaloids) has established an immunity-dependent mechanism of action. Although not fully understood, it is considered that T-regulatory cells are effectively disabled by low doses of the drug. Interleukin-10 (IL-10) and TNF-α have also been implicated as possibly mediating the effect in animal studies.[34-37] Echinacea administration is associated with increases in interleukin-1 (IL-1), IL-10, and TNF-α by macrophages, although other mechanisms may be, and likely are, involved in echinacea effects.[28,38] Cytokine and chemokine cascades are interrelated, complex, and difficult to study, in that they occur rapidly and are often confined to a small cellular compartment and not reflected in serum levels of these compounds. At the current level of scientific knowledge, such interactions are best gauged clinically, although continued research is essential to improving our ability to understand, predict, and utilize the potential value of this botanical-pharmaceutical interaction.

Lersch et al.[39,40] investigated the effects of combining echinacea in the form of intramuscularly administered Echinacin and concurrent thymostimulin (a thymic peptide preparation) with low-dose cyclophosphamide (300 mg/m^2 intravenously, every 28 days) in two small groups of patients, one with advanced hepatocellular carcinoma and the other with advanced colorectal carcinoma. Numbers of CD4+ and NK cells as well as lymphokine-activated killer (LAK) cell activity increased significantly in the hepatoma patients. In the colorectal patients, all of whom had previous surgery and progressive disease, partial regression was noted in one patient and stabilization in six others, with a decrease in tumor markers and tumor volume (by ultrasonography).

Steinmuller et al.[32] used a rodent model of cyclophosphamide-induced immunosuppression and found that resistance to opportunistic infection by *Candida albicans* or *Listeria monocytogenes* was restored in echinacea polysaccharide–treated animals compared with controls. They also found an increase in TNF-α and enhanced cytotoxic activity in macrophages from the echinacea polysaccharide–treated animals.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Although published data are tentative, the possibility of strategic enhancement of responsiveness to immunotherapeutic agents (e.g., low-dose Cytoxan) and recombinant agents (e.g., IL-2, interferons) by concurrent echinacea administration will be of interest to integrative practitioners attempting to address modulation of immunoreactivity.[19] Although parenteral preparations were used in the studies, as typical in Germany, most intravenous echinacea effects apply also to oral administration. (See also Astragalus monograph, as well as following section on myelosuppressive chemotherapy.) Because the therapeutic objectives of cyclophosphamide treatment vary in different situations and the effects may vary with different doses (biphasic responses), experienced professional management is required for coadministration of cyclophosphamide with echinacea.

Interferon Alpha (IFN-α), Interleukin-2, and Other Immunotherapeutic Biological Response Modifiers

Aldesleukin (IL-2, recombinant interleukin-2 (rIL-2); Proleukin), GCSF/filgrastim (Neupogen), GMCSF/sargramostim (Granulocyte-Macrophage Colony-Stimulating Factor), interferon alpha (IFN-α; Alferon N, Intron A, Roferon-A), interferon gamma-1b levamisole (Ergamisol), oprelevkin (Neumega), pegfilgrastim (PEG-filgrastim; Neulasta), pegylated interferon alfa-2b (PEG-Intron).

□ Inadequate

Effect and Mechanism of Action

Echinacea may increase endogenous interferon production by leukocytes and potentiate the effects of therapeutic recombinant interferon administration. It also increases NK cell number and activity, a target of IL-2 treatment.

Research

Research on the coadministration of echinacea and interferon is lacking, although preliminary positive data exist for astragalus, another interferon-enhancing herb (see also Astragalus monograph, aldesleukin/IL-2 discussion). However, in vitro, ex vivo, and in vivo evidence indicates that echinacea extracts increase IFN-α, which is consistent with its antiviral effect.[41,42] Miller[19] has used murine models to compare echinacea effects on NK cells to IL-2.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Combining immunomodulating BRMs with echinacea has not been studied. At this time, extrapolations from echinacea pharmacology merely suggest the possibility of an additive enhancement (or sparing); data are insufficient to make clear recommendations.

Myelosuppressive Antineoplastic Chemotherapy

Alkylating agents: Busulfan (Myleran), carboplatin (Paraplatin), chlorambucil (Leukeran), cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox), dacarbazine (DIC, DTIC, DTIC-Dome, imidazole carboxamide), ifosfamide (Ifex, Mitoxana), mechlorethamine (Mustargen, nitrogen mustard), melphalan (Alkeran), oxaliplatin (Eloxatin), phenylalanine mustard (Melphalan), pipobroman (Vercyte), streptozocin (Zanosar), temozolomide (Temodar), thiotepa (Thioplex), uracil mustard (uramustine).
Cytotoxic antibiotics: Bleomycin (Blenoxane), dactinomycin (Actinomycin D, Cosmegen, Cosmegen Lyovac), mitomycin (Mutamycin), plicamycin (Mithracin).
Antimetabolites: Agalsidase beta (Fabrazyme), capecitabine (Xeloda), cladribine (Leustatin), cytarabine (ara-C; Cytosar-U, DepoCyt, Tarabine PFS), floxuridine (FUDR), fludarabine (Fludara), fluorouracil (5-FU, Adrucil, Efudex, Efudix, Fluoroplex), gemcitabine (Gemzar), lometrexol (T64), mercaptopurine (6-mercaptopurine, 6-MP, NSC 755; Purinethol), methotrexate (Folex, Maxtrex, Rheumatrex), pentostatin (Nipent), pemetrexed (Alimta), raltitrexed (ZD-1694; Tomudex), thioguanine (6-thioguanine, 6-TG, 2-amino-6-mercaptopurine; Lanvis, Tabloid), ZD9331.
Mitotic inhibitors: Docetaxel (Taxotere), paclitaxel (Paxene, Taxol), paclitaxel, protein-bound (Abraxane), vinblastine (Alkaban-AQ, Velban, Velsar), vincristine (Leurocristine, Oncovin, Vincasar PFS), vinorelbine (Navelbine).
Similar natural compounds.

Effect and Mechanism of Action

Echinacea may help support and protect bone marrow myelopoiesis during chemotherapy, thereby ameliorating toxic effects of these agents on white blood cell counts.

Research

In animal studies, echinacea has proliferative effects at both spleen and bone marrow levels in rodents, although this study was confined to examining elevations in NK cells.[43] The same group examined the effects of echinacea on myeloid progenitor cells in spleen and marrow and found that echinacea did not significantly increase granulocyte precursors.[44] Weight loss was reduced and recovery from cisplatin administration was increased in rodents pretreated with *E. pallida* extracts intraperitoneally.[45] A German study on 70 breast cancer patients post-chemoradiotherapy found that a formula containing extracts of *E. angustifolia* and *E. purpurea* root with *Thuja occidentalis* and *Baptisia tinctoria* exhibited a limited ability to protect peripheral blood counts, although the doses of preparation were low at 1.25 mL of the formula per day.[46] A subsequent study involving 15 patients with advanced gastric cancer undergoing palliative chemotherapy with 5-FU, leucovorin, and etoposide received 2 mg daily of intravenous *E. purpurea* polysaccharide extract for 10 days total (3 days before chemotherapy) showed significant increases in leukocyte numbers compared with controls.[47]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Many classes of antineoplastic agents exhibit dose-limiting toxicities on myelopoiesis, involving some or all cell lines, to the extent that leukopenia, thrombocytopenia, and anemia may prevent continued administration of chemotherapy. Nutritional status and general health of patients undergoing myelosuppressive chemotherapy are recognized as important factors in successful treatment toleration. A number of herbal and nutritional agents have been used as myeloprotective influences during chemotherapy, including echinacea extracts. These agents are often combined with other herbs directed at minimizing related chemotherapy-induced toxicities. Chinese medicine has explored these strategies more fully than Western herbal medicine to date, although echinacea can be incorporated into Western formulae for this purpose. Additionally, anecdotal clinical experience suggests that use of recombinant agents such as granulocyte colony-stimulating factor (G-CSF) would not be compromised by such approaches, and concomitant administration may potentially be beneficial. The additional effects of Th1 cytokine promotion (cell-mediated immunity) further support the rationale of using echinacea, particularly in combination formulae, in this context.[48]

Tumor Necrosis Factor-Alpha (TNF-α) Antagonists

Adalimumab (Humira), infliximab (Remicade), etanercept (Enbrel).

Interaction Type and Significance

? **Interaction Likely but Uncertain Occurrence and Unclear**
⊕/✗ **Bimodal or Variable Interaction, with Professional Management**

Probability:
6. Unknown

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

At this time, the interaction is a theoretical concern but with important implications. Approved BRMs targeting the cytokine TNF-α reduce chronic inflammatory processes but increase susceptibility to infection. Echinacea extracts,

administered short-term in acute doses, upregulate cell-mediated immunity to enhance drug-induced depression in mounting endogenous immune responses to pathogenic agents.

Research

Some experimental pharmacological in vitro and in vivo evidence suggests that fresh-pressed juice extracts of echinacea may increase TNF-α.[28-30,38,41] These results have not been replicated with hydroethanolic echinacea root extracts (which lack in polysaccharides) or with oral administration to healthy human subjects.[42,49,50] Immunosuppressed animals (with cyclophosphamide or cyclosporine) given echinacea respond to opportunistic infection more effectively than untreated animals.[32]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Despite their common ability to inhibit cytokine bioactivity, the molecular structures and mechanisms of action of the various anti–TNF-α drugs currently approved for different conditions are in turn significantly different. For example, the TNF-binding moiety of etanercept is derived from soluble TNF receptor subunits; infliximab is a chimeric (mouse-human) monoclonal antibody to TNF, and adalimumab is a fully human anti-TNF monoclonal antibody.[51] A significant side effect of these agents is an increase in susceptibility to opportunistic infections, including by potentially ominous pathogenic agents such as tuberculosis.[52]

Current manufacturer recommendations suggest the cessation of TNF-α antagonists at the onset of self-limiting infections such as influenza, to allow for resolution of the infection, before recommencing drug therapy. The shortest half-life among this class of drug is etanercept (5 days). This window would be a time to use echinacea as a short-term immunostimulant, in acute doses, to enhance cell-mediated immune responses to accelerate resolution of infection before resumption of the anti-inflammatory therapy. The kinetics of echinacea effects on immune cells is known to be rapid. At this time, use of echinacea and other herbal immunomodulators in patients using BRMs as chronic anti-inflammatories remains problematic due to lack of data, partly because of the novelty of the TNF-α antagonist drugs, but is likely to become an increasingly important therapeutic concern for integrative practitioners with the increasing adoption of such agents.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Antimicrobials Such as Antibiotic, Antifungal, Antimycobacterial, and Antiretroviral Agents

Evidence: Econazole (Ecostatin, Spectazole).

Because of its ability to stimulate nonspecific immunity, echinacea, when taken alone, can be beneficial in a wide range of infectious conditions. Echinacea may also be helpful when coadministered with many antimicrobial drugs. Studies specifically examining the possible benefits of coadministration are rare. Cocugniet and Kuhnast[18] compared topical econazole nitrate in 60 patients with recurrent candidiasis with econazole and *E. purpurea* given orally, subcutaneously, or intravenously. Rate of recurrence dropped from 60.5% with econazole alone to 15% to 16% for the echinacea plus econazole groups (oral and parenteral), and *Candida* recall antigen sensitivity was increased two to three times for all echinacea groups. Although some authors describe this as an echinacea-econazole interaction, there would appear to be reasonable grounds, derived from the known immunostimulating pharmacology of echinacea, for regarding it as one example of how echinacea may be beneficially combined with antimicrobial agents. Trials combining nonspecific immunomodulating herbs such as echinacea with different antimicrobials are required for evidential support of such a generic interaction claim. Well-designed and adequately powered clinical trials using combination botanicals and drugs methodology are, unfortunately, likely to remain the exception rather than the rule in the short term because of the limited interest in such integrative strategies. However, this may change with the increasing concerns over issues such as the rise of drug-resistant strains, hospital-acquired infections, and high drug development costs.

A recent trial on echinacea in the treatment of the common cold in children failed to account for a substantial proportion of the children in both the placebo and the echinacea group taking a variety of over-the-counter (OTC) medications, as well as various dietary supplements, presumably assuming that these would not have any effect when combined with the echinacea.[53] The trial has also been criticized on other methodological grounds.[54,55] Meanwhile, although integrative practitioners might find that coadministration has multiple benefits, this sweeping generic interaction is classified here as "speculative."

Cytochrome P450 1A2 Substrates, Including Clozapine and Related Atypical Antipsychotics, Cyclobenzaprine, Tacrine, and Tertiary Tricyclic Antidepressants

Atypical antipsychotics: Aripiprazole (Abilify, Abilitat), clozapine (Clozaril), olanzapine (Symbyax, Zyprexa), quetiapine (Seroquel), risperidone (Risperdal), ziprasidone (Geodon).
Cyclobenzaprine (Flexeril), tacrine (tetrahydroaminoacridine, THA; Cognex).
Tertiary tricyclic antidepressants: Amitriptyline (Elavil), combination drug: amitriptyline and perphenazine (Etrafon, Triavil, Triptazine), clomipramine (Anafranil), doxepin (Adapin, Sinequan), imipramine (Janimine, Tofranil), trimipramine (Surmontil).

Recent in vivo human pharmacokinetic data suggest that echinacea may inhibit CYP1A2.[25] (See Strategic Considerations earlier.) Interactions between echinacea and 1A2 substrates have not been reported to date. A low-affinity, high-throughput CYP450 isoform, 1A2 is subject to induction by a range of environmental and dietary factors, including caffeine, brassicaceous vegetables, charbroiled foods, and tobacco smoking. Theoretically, the predominant patterns of echinacea prescription (i.e., short-term acute dosing for URIs) may mitigate any tendency to generate significant interactions caused by CYP450 effects. Until further data are available, however, a few critical substrates of 1A2 should be noted for potential interactions with prolonged echinacea use. These include the cholinesterase inhibitor tacrine (also a 1A2 inhibitor), the methylxanthines theophylline and caffeine, cyclobenzaprine, clozapine, and related antipsychotics. Tertiary tricyclics are cosubstrates of 1A2 and 3A4, which may be relevant if 3A4 is also inhibited by echinacea.

Cytochrome P450 3A4 Substrates

At present, interactions between narrow-therapeutic-index CYP3A4 drugs and echinacea have not been reported. Budzinski et al.[21] originally reported in vitro evidence for inhibition of 3A4. Gorski et al.[25] found that echinacea inhibited intestinal 3A4 and induced hepatic 3A4 in a manner that tended to offset the net effects on availability of 3A4 substrates. Yale and Glurich[23] found that in vitro, *E. purpurea* extracts moderately inhibited

one 3A4 model substrate but did not affect another. This suggests that predicting the effect of echinacea on 3A4 substrates is likely to be complex, and that the actual effects will be variable. Further research is required to clarify whether echinacea administration will in lead to any significant 3A4 substrate drug interactions.

Warfarin

Coumadin, Marevan, Warfilone.

Warfarin is metabolized by both CYP1A2 (the *R*-enantiomer) and 2C9 (the *S*-enantiomer). The Gorski study on echinacea inhibition of P450 enzymes found a significant inhibition of 1A2 and a moderate inhibition of 2C9.[25] Yale and Glurich[23] confirmed 2C9 inhibition in vitro. This suggests that warfarin levels may theoretically be increased in susceptible individuals (2C9-poor metabolizers) because of lowered clearance after coadministration with echinacea; however, this interaction has not been reported clinically. Theoretically, normal monitoring and adjustment of warfarin levels would preclude the potential for increased risk of bleeding resulting from elevated drug levels.

Related Issues

Duration of Use, Hepatotoxicity, Autoimmunity, and Interactions with Hepatotoxic Drugs, Including Anabolic Steroids, Amiodarone, Methotrexate, and Ketoconazole

It has been asserted that echinacea administration exceeding 8 weeks induces hepatotoxicity, which leads to adverse interactions with a variety of hepatotoxic drugs, including anabolic steroids, amiodarone, methotrexate, and ketoconazole.[56] This assertion may be based on the presence of trace amounts of pyrrolizidine alkaloids (PAs) (~0.0006% of tussilagine and isotussilagine) in the roots of *E. pallida* and *E. angustifolia*.[57] These PAs in fact lack the necessary necine macrocyclic ring structure of the hepatotoxic PAs that are metabolized into intermediate compounds, which form covalent adducts in hepatocytes, leading to the characteristic veno-occlusive disease toxicity.

The issue of limits to duration of use originated from Commission E, who stated that oral preparations of *E. purpurea* herb and *E. pallida* root should be consumed for no longer than 8 weeks.[13] No evidence exists for imposing restrictions on duration of use, either from adverse effects, suppression of immune function, or tachyphylaxis, and this assertion has been refuted in recent literature.[16,58] Miller[19] used a murine model to demonstrate that long-term administration actually *increases* health and longevity, with sustained improvements in immunological parameters.

Echinacea was also stated by Commission E "in principle" to be contraindicated in "progressive systemic diseases" such as tuberculosis, "leucosis" (sic), collagenosis, multiple sclerosis, acquired immunodeficiency syndrome (AIDS), human immunodeficiency virus (HIV) infection, and other autoimmune diseases. In fact, phytotherapists regularly use echinacea in several autoimmune conditions, with studies on its use in HIV infection and AIDS, as well as a report of extended administration in chronic lymphocytic leukemia.[59,60]

Historically, Eclectic physicians used echinacea to treat thousands of patients with tuberculosis. Among professional herbalists and naturopathic physicians, possible aggravations of autoimmune disease have been extensively discussed, and although the consensus is that a blanket contraindication is generally unsupported, isolated incidents of symptom flare-up in patients with systemic lupus erythematosus (SLE) associated with echinacea use have been informally reported.

Given the heterogenous and multifactorial mechanisms of autoimmunity and the currently available data, a prudent conclusion at this time would be to approach echinacea use with caution in patients with serious or progressed autoimmune disease, especially those who are susceptible to symptom flare, as in lupus (SLE) and some forms of multiple sclerosis.

Allergenicity

A review by Parnham[61] of echinacea adverse event data in Germany from 1989 to 1995 found 13 adverse drug reactions (ADRs) possibly related to oral Echanacin use, of which four were attributed to echinacea exposure. All were allergic reactions with skin manifestations. In the study period, an unknown number of doses of echinacea were consumed in Germany, but Dr. Bauer, an acknowledged echinacea expert, estimates that 10 million doses are sold annually in Germany; allowing for a degree of underreporting of herbal ADRs, frequency of allergic response would appear to be low.

An Australian report of an atopic female patient who experienced allergic symptoms requiring emergency room attention was followed by a review of Australian safety data by the investigator.[62] The author concluded that 26 patients, of whom more than half were known to be atopic, had experienced echinacea-related allergic symptoms, and that IgE-mediated ADRs are possible from echinacea exposure among susceptible individuals.[63] The national usage data for echinacea in Australia were not given, but if the figures are of the same order of magnitude as in Europe and the U.S., the risk/benefit ratio would appear to be lower rather than higher. This is corroborated by a skin test study of sensitivity to various herbal preparations involving more than 1000 subjects, in which echinacea caused dermatological reactions in only two subjects.[64]

Probiotics

In a 10-day randomized trial involving 15 healthy adults, Hill et al.[65] observed potentially problematic changes in intestinal microbiota after *Echinacea* administration. Standardized *E. purpurea* (1000 mg daily) stimulated the growth of certain *Bacteroides* spp. of intestinal bacteria, which may act as pathogens, particularly when the gut ecology has been disrupted. In stool samples, *Echinacea* use was associated with increased counts for three groups of organisms: the total group of aerobic bacteria, the anaerobic *Bacteroides* in general, and *Bacteroides fragilis* in particular. The authors concluded that the "health consequences associated with this change are unknown."[65] Notably, reports of potentially related adverse events associated with *Echinacea* use are lacking, such as irritable bowel syndrome or other pathological responses that might be predicted to result from such unfavorable alterations.

Although similar findings for echinacea or other herbs (e.g., goldenseal, isatis) often used as antimicrobial or immunostimulant agents are generally absent in the scientific literature, such effects from chronic use at high doses would not necessarily be unexpected. Further research and judicious pharmacovigilance are appropriate and necessary as the use of botanical medicine grows within the consumer self-care market and professional therapeutic application.

The 65 citations for this monograph are located under Echinacea on the CD at the back of the book.

Eleuthero

Botanical Name: *Eleutherococcus senticosus* (Rupr. and Maxim.) Maxim.
Pharmacopoeial Name: Radix Eleutherococci.
Synonym: *Acanthopanax senticosus* (Rupr. and Maxim.) Maxim.
Common Names: Eleuthero, Siberian ginseng.

SUMMARY

Drug/Class Interaction	Mechanism and Significance	Management
Antineoplastic treatments Myelosuppressive chemotherapies Radiation ⊕/☼	Eleuthero promotes myelopoiesis, helps protect white blood cell (WBC) counts during cyclophosphamide or other myelosuppressive chemotherapies. May synergize with radioprotective agents. Laboratory support and limited clinical evidence; controlled studies lacking, but interaction likely.	Pretreat, coadminister, and continue after chemo/radiotherapy until WBC count normalized (use with related adaptogenic herbs).

HERB DESCRIPTION

Family

Araliaceae.

Habitat and Cultivation

Native to northern and eastern Russia, northern China, Korea, and Japan; commercially grown in Siberia, as well as parts of China.

Parts Used

Root; the leaf is also used in Russia.

Common Forms

Dried: Powdered root.
Tincture: 1:5.
Fluid Extract: 1:1, 33% to 40% ethanol.
Standardized Preparations: Usually based on eleutheroside E > 1.0% and/or eleutheroside B.

HERB IN CLINICAL PRACTICE

Overview

Eleuthero is considered one of the defining adaptogen medicinal plants. *Adaptogens* have no equivalent among conventional pharmaceutical agents. The term was coined by Soviet researcher Lazarev in 1947 and subsequently defined by Brekhman in terms of three salient qualities: *nonspecific* (in relation to a wide range of stressor stimuli), *nontoxic* (cause minimal disturbance to normal physiological function), and *normalizing* (direction of action varies depending on the prior state of response to stressor and always normalizes).[1,2] The properties of adaptogens have been reviewed recently by Panossian[3] and Wagner.[4] Panossian and Wagner[5] also recently published an important paper distinguishing between the adaptogenic effects of the herb resulting from chronic dosing protocols compared with the stimulating effect of single acute doses.

With more than 1000 studies, eleuthero was initially the most widely studied adaptogenic herb, although *Panax ginseng* has a more voluminous literature. Eleuthero has established immunomodulating, anabolic, radioprotective, chemoprotective, antiviral, gonadotrophic, antiviral, and insulinotropic/antidiabetic effects; enhances learning, memory, visual and auditory acuity, and exercise endurance and recovery; and has antitoxic and antialcohol effects, as well as a range of antineoplastic actions.

Western reviews of some of the literature are available by Wagner and Norr,[4] Farnsworth et al.,[6] McKenna et al.,[7] Davidov and Krikorian,[8] and Baranov.[9] Therapeutic monographs are available from the European Scientific Cooperative on Phytotherapy,[10] World Health Organization (WHO),[11] German Commission E,[12] and British Herbal Medical Association.[13]

Confusion over nomenclature for the herb exists both with the binomial name (it is known as *Acanthopanax senticosus* in Chinese medicine) and the common name; the previous name "Siberian ginseng" implies similarity with "true" *Panax ginseng*. The current common name "eleuthero" was recently adopted in commerce to emphasize that although both plants are adaptogenic, eleuthero is pharmacologically distinct from *Panax ginseng* in terms of both constituents and activity profile. Medical reports often fail to use the correct binomial designation to identify herbal ingredients, and eleuthero has notoriously been confused with the entirely different species *Panax ginseng* (see Ginseng monograph).

Historical/Ethnomedicine Precedent

Eleuthero root *(Ci Wu Jia)* has been used in traditional Chinese medicine as a spleen *(Pi)* and kidney *(Shen) qi* tonic and is claimed to calm the Spirit/Mind *(Shen)*. The root bark is considered a separate remedy. Eleuthero was incorporated into Western medicine in Russia in the early 1960s after two decades of Soviet research to locate more economic adaptogenic species than the slow-growing *Panax ginseng*, and it was introduced to the U.S. market in the 1970s.[9] As with many herbs used in Chinese medicine, *Ci Wu Jia* is used in complex formulae corresponding to specific classical diagnostic patterns and is prescribed in higher typical dose levels than in Western usage.[14]

Known or Potential Therapeutic Uses

Stress reduction and neuroendocrine balancing (e.g., dysglycemia, adrenal deficiency); fatigue, convalescence; enhancement of stamina, exercise, athletic, and work capacity and performance; increasing mental alertness and cognitive performance (e.g., memory, visual acuity); adjunctive to radiation and chemotherapy treatment; various psychological

complaints (e.g., insomnia, depression); immunoprotection and immunomodulation; prophylaxis of infection, especially viral infection; antineoplastic.

Key Constituents

Lignans and other phenylpropanoids.
A series of "eleutheroside" compounds have been identified (eleutherosides A-M), but none of these is unique to eleuthero, and not all are the eleutheroside homologous compounds.
Oleanic acid derivatives (eleutherosides I-M), senticosides A-F, and polysaccharides, including glycans (eleutherans A-G); miscellaneous sterols, saponins, vitamins, and carbohydrates.

Therapeutic Dosing Range

Dried Root: 2 to 3 g daily (Western); 9 to 30 g daily (Chinese).
Tincture: 3.0 to 12.0 mL daily (equivalent 1:1).
Standardized Dry Extract: 150 to 300 mg three times daily; 10:1 extracts standardized to eleutherosides B and E.

INTERACTIONS REVIEW

Strategic Considerations

Authoritative monographs on eleuthero do not list any known interactions between eleuthero and pharmaceuticals.[10-13] The WHO monograph does refer to a case report that suggested eleuthero extracts interacted with digoxin. This case is considered likely an issue of adulteration or of interference between certain constituents of the herb and the digoxin assay and is discussed later (see Theoretical, Speculative, and Preliminary Interactions Research).

The general adaptogenic properties of eleuthero (according to the criteria of Lazarev and Breckhman) have been substantiated by a number of indexed Western studies, particularly regarding performance enhancement, although the bulk of the supporting literature, both experimental and clinical, is in Russian-language journals, much of it dating from the 1950s through the 1970s. Authoritative evaluations of the original literature in terms of study design, statistics, methods, and materials are not generally available. In the 1980s, Farnsworth et al.[6] and Baranov[9] attempted to summarize a number of eleuthero studies from the earlier Russian literature.

From an integrative perspective, the use of eleuthero in oncological settings is of particular interest because of the putative protective effects against chemotherapy- and radiation-induced toxicity suggested by the Russian research. Unfortunately, little corroborative work has been undertaken in the West to support the Soviet-era data. This is discussed later as a generic interaction.

As with other adaptogenic herbs, the nonspecific immunomodulating properties may bring about beneficial interactions with antimicrobial agents, although for eleuthero there are minimal data on this application.[15] (See also Ginseng *[Panax ginseng]* monograph.)

Effects on Drug Metabolism and Bioavailability

An in vitro fluorometric probe study failed to detect any effect of eleutherosides E and B on a battery of recombinant human cytochrome P450 (CYP450) isoforms (1A2, 2C9, 2C19, 2D6, and 3A4).[16] A "before and after" study on 12 healthy human volunteers failed to establish any effect of standardized *Eleutherococcus* extract (485 mg twice daily) with dextromethorphan and alprazolam probes. The authors concluded that the extract is likely to alter disposition of drugs metabolized by 3A4 and 2D6.[17] From the limited data currently available, pharmacokinetic interactions caused by eleuthero effects on phase-one drug-metabolizing enzymes seems unlikely, and clinical reports of such interactions have not to date been made.

HERB-DRUG INTERACTIONS

Antineoplastic Chemotherapy, Including 6-Mercaptopurine, Cyclophosphamide

Cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox), mercaptopurine (6-mercaptopurine, 6-MP, NSC 755; Purinethol).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
2. Probable

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Eleuthero extracts are used to reduce adverse effects of antineoplastic therapies through a variety of mechanisms, including protection against and reversal of leukopenia, reduction of chemical toxicities, and enhancement of general stress resistance.

Research

In vitro and animal studies confirm that eleuthero extracts can modulate the immune system through a variety of mechanisms. These include increases in phagocytosis, natural killer (NK), and cytotoxic T-cell activity; modulation of T helper cell types 1 and 2 (Th1 and Th2) cytokines; and increased endogenous granulocyte colony-stimulating factor (G-CSF) production.[18-28] Two human studies are available. A flow-cytometry study was performed by Bohn et al.[21] on healthy human volunteers, who consumed 10 mL of eleuthero extract three times daily for 4 weeks. Significant increases in Th1 and NK cell numbers were observed, with increased activity of T cells. Russian researchers Kupin et al.[29,30] reported stimulation of immunological reactivity in breast cancer patients treated with eleuthero extracts. Although limited, these studies suggest that eleuthero has immunostimulating and immunomodulating activities in humans.

Coadministration of eleuthero with various antineoplastic agents (as well as radiation) has been reported in a number of Russian studies. Farnsworth et al.[6] report several animal studies in the Russian literature by Monakhov[31,32] and other researchers that involved a variety of antitumor agents, including 6-mercaptopurine, cyclophosphamide, and ethydimine. An in vitro study by Hacker and Mendon[33] found that eleuthero extracts at 75 µg/mL potentiated the effects of antileukemic agents cytarabine and N6-adenosine against murine L1210 leukemia cells. In a controlled study, Brekhman[34] reported a reduction of adverse effects in a controlled study of 80 breast cancer patients undergoing chemotherapy and/or radiation treatment when treated concurrently with eleuthero extracts, compared with controls not treated with eleuthero. Radioprotective effects of the herb have also been documented.[35,36] A rodent study by Minkova and Pantev[37] found that a radioprotective drug known as "adenturone" was potentiated by prophylactic pretreatment with eleuthero, although the dose of herb used was very high (5 g/kg orally).

Integrative Therapeutics, Clinical Concerns, and Adaptations

The documented evidence supporting benefits of coadministration of eleuthero with chemotherapy and/or radiation in oncology patients is limited, but sufficient data exist to justify the inclusion of eleuthero with other adaptogenic herbs in protective protocols designed to minimize myelosuppressive side effects of cancer treatment. (See also Ginseng monograph.)

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

The lack of equivalent pharmaceutical agents corresponding to herbal adaptogens may confound "theoretical" extrapolated interactions based on in vitro pharmacology, if adaptogens are "normalizing" as claimed.[38,39] Such extrapolations have been attempted, however, as in an adverse interaction with alcohol (from prolonged sleeping time with hexobarbital in a rodent model) and with oral hypoglycemics (from a rodent study suggesting alloxan-induced diabetic rats' blood glucose is lowered by eleuthero). In fact, eleuthero has been used anecdotally both for treatment of alcoholic toxicity and withdrawal and for "balancing" blood sugar, depending on whether the prior state was hypoglycemic or hyperglycemic.[40] The herb has more recently been shown to be more stimulating than sedative, at least in single doses.[5]

Digoxin and Related Cardiac Glycosides

Digoxin (Digitek, Lanoxin, Lanoxicaps; purgoxin).
Extrapolated, based on similar properties: Deslanoside (cedilanin-D), digitoxin (Cystodigin), ouabain (g-strophanthin).

An isolated case report describes a 74-year-old man with atrial fibrillation, stable on taking digoxin, who was tested for excessively high serum digoxin levels during routine monitoring, although he was asymptomatic. The digoxin was stopped, but the elevated level persisted. The patient disclosed self-administration of eleuthero. The product was not specified, and no analysis was performed to confirm the identity of the commercial preparation reported as consumed. After cessation of the supplement, digoxin levels normalized, and the patient resumed digoxin therapy.[41] Because eleuthero contains no cardiac glycosides, two hypotheses have been advanced to explain the apparent interaction. First, variation in eleuthero commercial products is well known.[42] Second, commercial samples of eleuthero, especially those sourced from China, have been documented on occasion as being contaminated with the species *Periploca sepium* Bge., a different Chinese herbal substance whose bark resembles that of eleuthero. *Periploca* is cardiotoxic in the doses that equate to nontherapeutic levels of eleuthero because of the presence of cardiac glycosides.[43] Given the failure to test the composition of the suspected eleuthero product involved in the case, Awang[44] postulated that adulteration with *Periploca* could explain the apparent test elevations.

An alternative explanation is that the botanical preparation may have interfered with the digoxin assay, causing falsely elevated readings. A recent investigation by Dasgupta et al.[45] supports this possibility, showing in vitro, as well as in vivo with human subjects, that eleuthero extracts can interfere with fluorescence polarization, creating false elevations in digoxin assay readings. The modest "false" elevated digoxin test readings caused by eleuthero may not explain the total apparent increase found in the case reported by McRae,[41] and combination factors still may have been involved. Finally, it has not been established that eleuthero is without effect on the P-glycoprotein transporter, of which digoxin is a substrate.

In summary, currently available data do not support the existence of any interaction between eleuthero and cardiac glycosides.

Antimicrobial Agents, Including Aminoglycoside Antibiotics

Evidence: Kanamycin (Kantrex), paromomycin (monomycin; Humatin).

An uncontrolled study by Vereshchagin et al.[15] suggests that coadministration of eleuthero with antibiotics (monomycin/paromomycin or kanamycin) in the treatment of children with *Shigella*- or *Proteus*-related gastrointestinal infections was more effective than treatment with antibiotic alone. As discussed by Brinker,[46] this possible interaction is circumstantially supported by some experimental data on the effects of eleuthero on increasing lymphocyte and NK cell activity.[21] Full evaluation of the original Russian-language study in unavailable in English, and the absence of corroborative data on antimicrobial-eleuthero combinations indicates that the potential interaction required may best be categorized as "overstated" at this time. It is theoretically arguable that such an interaction may be of widespread clinical applicability with a variety of antimicrobial drug classes, but this hypothesis remains to be tested. (See also interactions between *Panax ginseng* and beta-lactam antibiotics as discussed in the Ginseng monograph.)

Monoamine Oxidase-B (MAO-B) Inhibitors

Isocarboxazid (Marplan), moclobemide (Aurorix, Manerix), phenelzine (Nardil), procarbazine (Matulane), tranylcypromine (Parnate).

Reports of a ginseng-phenelzine interaction persist in the literature on *Panax ginseng*. These reports have been shown to be incorrect, arising from a confusion of *Panax ginseng* with eleuthero.[47] In any event, the reports contained insufficient or inadequate data for evaluation.

The 47 citations for this monograph are located under Eleuthero on the CD at the back of the book.

Ephedra

Botanical Names: *Ephedra sinica* Stapf., *Ephedra equisetina* Bunge., *Ephedra intermedia* Shenk and CA Meyer.
Pharmacopoeial Name: Ephedrae herba.
Common Names: Ephedra, *Ma-huang*, *Ma huang*, jointfir.

SUMMARY

Drug/Class Interaction Type	Mechanism and Significance	Management
Acetazolamide Urinary pH modifiers ◇/?	Probable pharmacokinetic interaction. Significance not established. Drug may increase herb levels by renal retention.	Avoid.
Caffeine, Theophylline Methylxanthines XX	Well-established additive increase in sympathetic adverse events by multiple mechanisms.	Coadministration requires professional assessment and monitoring.
Dexamethasone Corticosteroids, oral glucocorticosteroids ?	Possible pharmacokinetic increase in drug clearance during coadministration. Significance and applicability to other steroidal drugs unknown.	Avoid.
Guanethidine Peripheral adrenergic blockers XXX	Herb reduces drug action and may greatly increase hypertension when coadministered.	Avoid.
Phenelzine MAO inhibitors XXX	Potential for increased sympathetic adverse effects by multiple mechanisms.	Avoid.
Reserpine, clonidine Sympatholytics XXX	Herb and drug have directly conflicting pharmacodynamic mechanisms. Coadministration (unlikely) will impair therapeutic efficacy of drug or herb.	Avoid.

MAO, Monoamine oxidase.

HERB DESCRIPTION

Related Species

The three main *Ephedra* spp. (*E. sinica*, *E. equisetina*, *E. intermedia*) are official in the Chinese and Japanese pharmacopoeias. Commercial sources also include *E. distachya* L. and *E. geradiana* Wall. ex Stapf. The latter is common in medicinal use in India. The North American species known as Mormon or Brigham Tea (*E. nevadensis* S. Wats.) contains little or no alkaloid and is not used medicinally.

Habitat and Cultivation

Widespread perennial shrub native to China, Mongolia, Tibet, Siberia, Japan, India, Pakistan, and Afghanistan; it is also extensively cultivated.

Parts Used

Dried aerial parts (stems); the roots and rhizomes, known as *Ma Huang gen*, are a separate medicinal agent in Chinese medicine with distinct actions and uses.

Common Forms

Dried: Powdered stems.
Tincture: 1:4, 45% alcohol (BHP).
Standardized Extracts: Unavailable.

Alkaloid content of ephedra-containing dietary supplement combinations in the United States and elsewhere are often not accurately labeled, and significant product variability has been demonstrated.[1-3] Crude herb extracts are subject to seasonal and species variations in alkaloid content.[4] Ephedra is a component of several commercially available Chinese standard formulae.

HERB IN CLINICAL PRACTICE

Overview

Ephedra has a long history of use in Chinese medicine, dating from 3100 BCE. Some authorities consider ephedra to be the mythical *soma* plant of the Vedas.[5,6] Traditionally, ephedra, or *Ma Huang*, has been used as a bitter warming herb for feverish and catarrhal conditions of the respiratory tract. Currently, regulatory restrictions permitting, it continues to be used clinically for its traditional indications, including bronchial asthma, allergic rhinitis, and as a diaphoretic in colds and influenza in both Western and Chinese medical formulations.

The activity of the crude herb is dominated by sympathomimetic phenethylamine alkaloid constituents, principally ephedrine and pseudoephedrine. Synthetic (racemic) ephedrine itself was produced by Merck in 1926 and introduced into clinical medicine as a treatment for pediatric asthma in 1927; thereafter it rapidly replaced epinephrine because it could be orally administered. Then, as now, the undesirable central stimulating effects of ephedrine were considered limiting factors on its clinical use.

Ephedra monographs by both the World Health Organization (WHO)[7] and the German Commission E support its traditional use for catarrhal conditions of the respiratory tract.[8] The clinical literature on ephedra appears extensive but actually is dominated by a persistent confusion of the crude

herb with isolated ephedrine alkaloid. To a limited degree, pharmacokinetic and pharmacodynamic data suggest a similarity between crude ephedra and ephedrine, and the general sympathomimetic activity of ephedra is broadly correlated with ephedrine content. However, aspects of ephedra pharmacology, such as cytotoxicity or phosphodiesterase inhibition, cannot be attributed to ephedrine alone.[9,11] In answer to the question of whether there is full equivalence between synthetic ephedrine and ephedra, eminent German phytotherapist Weiss replied, "On the whole yes, but not quite."[5]

The problems of literature interpretation and data comparison are compounded by the variable ingredients and combinations of agents contained in dietary supplements marketed as "weight loss" products that have been used in clinical trials.[2,9] Caffeine or caffeine-containing herbs such as guaraná *(Paullinea cupana)* may be present, with aspirin or salicylate-containing herbs such as willow bark *(Salix alba)* sometimes combined with micronutrients such as trivalent chromium. Most recent trials have invariably examined these combination products and often incorrectly describe the results as referring to "ephedra." This in turn casts some methodological doubts on metastudies such as the Cantox and RAND reports, and although both reviews acknowledged the problem, their conclusions should be critically qualified in this regard.[12,13]

In the U.S., ephedra-containing supplements previously permitted under the Dietary Supplement Health and Education Act (DSHEA) have been banned since 2003, largely because of inappropriate consumption of ephedrine-containing weight loss and "natural stimulant" products resulting in a significant number of adverse events (see Note: Regulation, Safety, and Ephedra Weight Loss Products).

Historical/Ethnomedicine Precedent

Chinese traditional uses include acute wind-cold syndromes (characterized by chills, mild headaches, fevers without sweating, runny or stuffy nose, and body or joint aches) as well as bronchial asthma and allergic rhinitis. Several millennia-old classical Chinese formulae contain Ma Huang, including *Ma Huang Tang* (ephedra decoction), *She Gan Ma Huang Tang* (belamcanda and ephedra decoction), *Ge Gan Tang* (pueraria decoction), and *Xiao Qing Long Tang* (minor blue dragon decoction). In these combinations, ephedra comprises 15% to 25% of the total prescription, delivering 60 to 90 mg total alkaloid daily at normal adult dose levels.

In Chinese medicine, a further distinction is made between the stems of the plant, *Ma Huang*, and the root, *Ma Huang gen*. The roots contain dimeric flavonols and macrocyclic alkaloids not found in the aerial parts. In Chinese medicine the root is considered antisudorific, used for night sweats and excessive perspiration, whereas the stem is diaphoretic.

Known or Potential Therapeutic Uses

Asthma, coryza of common colds, fevers, allergic and vasomotor rhinitis, hives, and topical use for insect bites, stings, and allergic irritations of the skin and enuresis.

A recent comprehensive meta-analysis of these trials supports a moderate short-term weight loss effect from ephedra alkaloids when combined with stimulants such as caffeine.[14,15] Ephedrine and pseudoephedrine are approved for use in over-the-counter (OTC) bronchodilator and nasal decongestant products. Ephedrine has limited use in the hospital setting for the management of hypotension during epidural block and inhalational anesthesia in the operating room (intravenous and intramuscular). Ephedrine has been historically used as a mydriatic and also as a pharmacotherapeutic agent for Stokes-Adams heart block, for enuresis, and for myasthenia gravis, in which latter its mechanism of action is unclear.[16] Some herbal texts also mention the latter two indications, but these are not general practice today, although some urologists continue to investigate the use of ephedrine for enuresis.[17]

Key Constituents

Phenylethylamine alkaloids, from approximately 0.5% to more than 2.4% total. (See Note.)
Catechin tannins, including epicatechin and epigallocatechin as well as catechin and gallocatechin.
Volatile oil, including terpinol, cineole, and tetramethylpyrazine; biflavonols.
The roots contain dimeric flavonols and spermine alkaloids not found in the stems.

Note: Proportions of the different alkaloids vary. The majority is 1R,2S-ephedrine (up to 80%), which occurs alongside the optical isomer 1S,2S-pseudoephedrine and their corresponding nor- and methyl- derivatives. The ratio of ephedrine to pseudoephedrine is variable and even reversed in some minor species of *Ephedra*.[4] Alkaloid composition can be used to "fingerprint" product samples containing ephedra herb because of the four possible optical isomers of ephedrine, only 1R,2S-ephedrine and 1S,2S-pseudoephedrine occur naturally.[18]

Therapeutic Dosing Range

Adults

Dried prepared herb for traditional decoction: 3 to 9 g daily.
Typical recommended doses in Chinese and Western herbal practice deliver between 60 to 90 mg total alkaloid daily.
Commission E: 15 to 30 mg single dose and maximum of 300 mg daily total ephedra alkaloid.
OTC ephedrine: Up to 150 mg alkaloid daily.
OTC pseudoephedrine: Up to 240 mg alkaloid daily.

Children

Not to be administered to children under 6 years of age.
Pediatric dose up to 0.5 mg total alkaloid per kg body weight daily; according to Commission E and WHO figures.[7,8]

INTERACTIONS REVIEW

Strategic Considerations

Ephedra alkaloids act as combination direct and indirect sympathomimetic agents at all alpha and beta adrenoceptor subtypes and have multiple effects on catecholamine pathways.[19] As a result, ephedra may interact with a variety of drugs that directly target the sympathetic nervous system. They may also indirectly interact with other classes of drug, such as antihypertensives or antiarrhythmics that do not directly affect the adrenergic pathways.

Within an integrative medical setting, however, the use of ephedra-containing formulae for traditional indications is limited and largely unproblematic when used by professionals trained in botanical medicine. Using traditional formulation models, ephedra is combined with other herbs that mitigate its "warming" energetics and the central nervous system (CNS) stimulatory aspects of its actions. The proportion of ephedra in a given formula is rarely more than approximately 15% to 20% of

the total. Administered at therapeutic doses for traditional indications, ephedra is generally considered safe. This is supported by the complete absence of adverse event reports associated with administration of the crude herb or crude herb extracts either alone or in traditional formulations, as opposed to isolated alkaloid in multi-ingredient commercial preparations. Ephedra alkaloids are not degraded by monoamine oxidase, lacking the necessary hydroxyl configuration, and are excreted almost entirely unchanged renally, with a half-life of 3 to 5 hours.[20]

Adverse effects of the herb result from the CNS stimulatory actions and sympathomimetic actions and include insomnia, anxiety, tachycardia, tremors, and at higher doses, arrhythmias and increased blood pressure. Prolonged and repetitive use may induce tachyphylaxis, but suggestions of "dependency" are not corroborated by clinical reports. Nonclinical toxicological data is based on studies of the isolated alkaloids, principally ephedrine. Clinical data on safety are derived from adverse drug reactions (ADRs) noted in clinical trials on weight loss, and anecdotal reports following initial use or with abuse of ephedrine-containing combination weight loss products.

Assuming normal clinical practice and basic professional physiology and pharmacology knowledge, ephedra herb and its crude extracts do not present any hazardous interactions issues, despite the recent increases in adverse reports related to weight loss dietary supplements and isolated alkaloids (see Note: Regulation, Safety; and Ephedra Weight Loss Products). Professional management of ephedrine interactions for therapeutic purposes also occurs within the hospital setting, typically in relation to management of anesthesia-induced hypotension.

HERB-DRUG INTERACTIONS

Acetazolamide and Other Urinary PH Modifiers

Acetazolamide (Diamox, Diamox Sequels), aluminum hydroxide, ammonium chloride, kaolin clay, sodium bicarbonate.

Interaction Type and Significance

◇ **Adverse Drug Effect on Herbal Therapeutics—Strategic Concern**

? **Interaction Likely but Uncertain Occurrence and Unclear Implications**

Probability:
4. Plausible

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

This pharmacokinetic interaction causes retention of ephedrine and pseudoephedrine (and amphetamine) by means of reduced urinary elimination under alkaline conditions. As pH rises, the pKa of ephedrine favors the nonionic association form, which is more lipophilic and reabsorbable at the nephron. This effectively reduces clearance and increases half-life.

Research

The mechanism of this interaction has been experimentally established in animals and humans using ephedrine and ammonium chloride,[21] as well as with pseudoephedrine and ammonium hydrochloride.[22]

Reports

Reports of this ADR in patients are rare. After encountering the interaction in a patient with persistently alkaline urine, Brater et al.[23] studied ephedrine and pseudoephedrine excretion in normal patients and those with renal acidosis. They concluded that the rate of flow of urine as well as pH affected the elimination of ephedrines.

Clinical Implications and Adaptations

Although acetazolamide is usually listed as the interacting agent, this is an extrapolation from the studies with inorganic alkalizing compounds. The further extension from ephedra alkaloids to ephedra herb adds an additional layer of imponderability to the clinical significance and implications of this interaction, which is therefore of unknown or problematic status.

Caffeine, Theophylline, and Other Methylxanthines

Caffeine (Cafcit, Caffedrine, Enerjets, NoDoz, Quick Pep, Snap Back, Stay Alert, Vivarin); combination drugs: acetylsalicylic acid and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA, codeine, butalbital, and caffeine (Fiorinal); acetaminophen, butalbital, and caffeine (Fioricet).

Theophylline/aminophylline (Phyllocontin, Slo-Bid, Slo-Phyllin, Theo-24, Theo-Bid, Theocron, Theo-Dur, Theolair, Truphylline, Uni-Dur, Uniphyl); combination drug: ephedrine, guaifenesin, and theophylline (Primatene Dual Action).

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

Probability:
1. Certain

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

The effects of ephedrine on weight loss through thermogenesis, lipolysis, and appetite suppression are potentiated by caffeine. Frequency and severity of sympathomimetic adverse events, principally palpitations, tachycardia, agitation, and insomnia, are also increased when theophylline or caffeine are coadministered with ephedrine.

Research

Numerous studies have shown the combination of caffeine and ephedrine moderately increases weight loss, whereas the agents administered separately show little or no effect.[15,24-31] The mechanism of the interaction is multifactorial. Methylxanthines antagonize adenosine receptors and are phosphodiesterase (PDE) inhibitors. Their action on the cardiovascular system is complex, mediated by brainstem vasomotor and vagal centers as well as by direct effects on the vascular and cardiac tissues, mediated by both catecholamines and the renin system. At higher doses, caffeine and theophylline definitely induce tachycardia and are proarrhythmic, with sensitive individuals likely to experience premature ventricular contractions (PVCs). As with the ephedra alkaloids, caffeine is also centrally stimulating, and in methylxanthine-naive individuals, administration of caffeine or theophylline can cause elevation of circulating epinephrine and initial hypertension; however, tolerance rapidly develops.[32-35] Caffeine alone is not associated with increased frequency of arrhythmia in normal subjects or those with history of ventricular ectopy.[36]

In a recent study on a proprietary formulation (Metabolife 356) containing 12 mg ephedra extract and 48 mg caffeine, among several other ingredients, single dosing caused

significant prolongation of QTc interval, at levels associated with possible torsades de pointes arrhythmia in conventional drugs (~30 msec prolongation).[37] However, a long-term rodent study showed no effects on metabolic cardiac parameters after 1 year of ephedrine-caffeine administration at 10 times the normal human dose.[38] Interestingly, crude ephedra has been shown to have PDE inhibitory activity that is not exhibited by pure ephedrine.[11,39] Theophylline is generally more potent than caffeine in its effects; it was often combined with ephedrine in nasal decongestant products before more selective adrenergic blockers became available. An early study found the theophylline-ephedrine combination no more effective than theophylline alone in 23 asthmatic children, whereas the ADR rate was higher for the combination than for theophylline.[40] Another study of asthmatic children, however, showed no additional adverse effects from the combination.[41]

Reports

Shekelle et al.[13] reviewed hundreds of ADR reports from the ephedrine-caffeine combination in the RAND study and concluded the quality of data was too poor to draw conclusions about a causal association of the ADRs with the combination. At the same time, they noted that clinical data suggest that the combination is associated with a significant risk of nausea, vomiting, anxiety, mood changes, autonomic hyperactivity, and palpitations. Other researchers, however, have concluded that adverse effects during trials involving the combination are not significant.[21,42]

Clinical Implications and Adaptations

Any synergy of effect on weight loss from the ephedrine-caffeine combination is largely offset by associated increase in adverse effects. Professional management, screening of at-risk patient groups, and therapeutic monitoring might largely preclude the development of serious adverse effects from the combination. However, pharmacotherapy for obesity does not generally favor use of herbal combination products, and integrative approaches to obesity do not emphasize pharmacotherapy.[43] In traditional use, ephedra is not combined with other stimulants, and obesity is not considered an indication for ephedra herb. Therefore the notoriety attached to the interaction of these agents is incommensurate with the significance of the issue in informed clinical practice.

Dexamethasone and Other Oral Corticosteroids

Evidence: Dexamethasone (Decadron).
Related but evidence lacking for extrapolation: Betamethasone (Celestone), cortisone (Cortone), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol), prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).

Interaction Type and Significance

? Interaction Likely but Uncertain Occurrence and Unclear Implications

Probability: **3. Possible**
Evidence Base: **◉ Emerging**

Effect and Mechanism of Action

A pharmacokinetic interaction is possible whereby the clearance of dexamethasone is increased during concurrent ephedrine administration.

Research

The mechanism of this interaction was experimentally established in nine asthmatic patients, comparing the effects of ephedrine, theophylline, and placebo on airway symptoms. The interaction apparently does not occur between theophylline and dexamethasone. This finding helped tilt bronchodilator products for asthmatic patients away from ephedrine and toward theophylline.[44]

Reports

Despite some cautions in the drug interactions literature,[45] the importance and significance of this interaction remain problematic, and extension to other glucocorticoids has not been established.

Clinical Implications and Adaptations

The implications of this interaction are unclear, other than monitoring concurrent corticosteroid and ephedra use.

Guanethidine and Related Peripheral Adrenergic Blocking Agents

Evidence: Guanethidine (Apo-Guanethidine, Ismelin).
Similar properties but evidence lacking for extrapolation: Betanidine (Esbatal, Regulin), bretylium, debrisoquine, guanadrel (Hylorel).

Interaction Type and Significance

✗✗✗ Potentially Harmful or Serious Adverse Interaction—Avoid

Probability: **1. Certain**
Evidence Base: **● Consensus**

Effect and Mechanism of Action

Guanethidine and related drugs are prevented from entering, and are displaced from adrenergic neurons by, sympathomimetics. This abolishes the hypertensive effect of the blockading drug and also results in superadditional hypertensive effects because of the release of norepinephrine from the presynaptic terminal by ephedrine-induced indirect stimulation.

Research

The mechanism of this established interaction has been confirmed experimentally in humans and cats with amphetamine.[46] In a clinical study involving 16 hypertensive patients maintained on 25 to 35 mg guanethidine, Gulati et al.[47] observed abolition of the effects of guanethidine, as well as hypertension in excess of the treatment level, when subjects were treated concurrently with a range of oral sympathomimetics, including ephedrine.[47]

Reports

Despite clinical confirmation of the underlying mechanism of the interaction, recent reports of its occurrence are lacking.[48] Also, it is unclear to what extent this is an issue with the combination of sympathomimetic alkaloids in ephedra herb or crude extracts. The German Commission E suggests that the interaction may "enhance the sympathomimetic effect," which presumably refers to the experimentally confirmed fact that peripheral adrenergic blockade causes a hypersensitization of the postsynaptic receptors to *direct* sympathomimetic stimulation.[8] The significance of this in practice with mixed sympathomimetics is unknown, although guanethidine and epinephrine are known to result in exaggerated pressor and mydriatic responses.[49]

Clinical Implications and Adaptations

Although this must be viewed as a serious and an established interaction, the poorly tolerated guanethidine is no longer in widespread use for hypertension as it was in the 1970s. The newer derivatives are restricted to use in cases where other blocking agents (e.g., reserpine, methyldopa) have unacceptable CNS adverse effects. The clinical significance of the interaction is therefore limited in practice, although it is usually often cited without qualification as a principal ephedra-drug interaction in the herbal literature.

Phenelzine and Other Monoamine Oxidase Inhibitors (MAOIs)

MAO-A inhibitors: Isocarboxazid (Marplan), moclobemide (Aurorix, Manerix), phenelzine (Nardil), procarbazine (Matulane), tranylcypromine (Parnate).

MAO-B inhibitors: Selegiline (deprenyl, L-deprenil, L-deprenyl; Atapryl, Carbex, Eldepryl, Jumex, Movergan, Selpak); pargyline (Eutonyl), rasagiline (Azilect).

Interaction Type and Significance

✗✗✗ Potentially Harmful or Serious Adverse Interaction—Avoid

Probability: **1. Certain**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

As indirect and direct sympathomimetics, ephedra alkaloids have "double" potential to cause rapid elevations of epinephrine at adrenergic and noradrenergic terminals if cytosolic monoamine oxidase (MAO) is inhibited. Monoamine oxidase inhibitors (MAOIs) cause presynaptic epinephrine accumulation. Ephedra will both promote release of the accumulated presynaptic epinephrine and simultaneously have a direct stimulating effect on the postsynaptic receptors itself. Exaggerated pressor responses will result, with possible hypertensive crisis or hemorrhagic stroke.

Research

The sympathomimetic action of ephedra alkaloids is well established.[50,51] However, the literature seldom mentions that ephedrine, pseudoephedrine, and norephedrine are themselves all unlabeled MAOIs, although weak and reversible in character.[52,53] Thus, they may also affect levels of 5-hydroxytryptamine (5-HT, serotonin) and dopamine both centrally and peripherally, as well as interact with tyramine-containing foods such as aged cheese and red wine. The manufacturers of serotonin agonists such as sibutramine caution against combining with ephedra alkaloids. Although a theoretical basis for this may exist because of the MAOI-like action of ephedra, the risk of serotonin syndrome is apparently low, and reports are lacking. Theoretically the newer, selective MAO-A or MAO-B drugs should be less interactive, but reports show that moclobemide increases the pressor action of ephedrine twofold to fourfold in healthy volunteers.[54] On the other hand, a recent case report describes ephedrine and phenylephrine being used uneventfully to control hypotension during epidural anesthesia in a patient taking moclobemide.[55]

Reports

The standard drug interactions literature through the 1960s and 1970s contains isolated reports of fatal intracranial and subarachnoid hemorrhage, but these refer to amphetamines combined with older MAOI drugs.[49] More recently, concerns have been raised about a renewed increase in occurrence of this interaction caused by the increased use of ephedrine-containing weight loss products.[56]

Clinical Implications and Adaptations

The older, nonselective, irreversible MAOIs, whether prescribed for hypertension or depression, should never be combined with indirect sympathomimetics. Even the newer, selective, reversible MAOIs should not be combined with sympathomimetics. This established and serious drug interaction can be plausibly extended to ephedra. After use of irreversible MAOIs, renewed MAO synthesis takes time, and 2 weeks has been suggested as a safe period after which ephedrine can be administered.[56]

Sympatholytic Agents, Including Clonidine, Methyldopa, Opioids, Reserpine

Clonidine (Apo-Clonidine, Catapres Oral, Catapres-TTS Transdermal Dixarit, Duraclon, Novo-Clonidine, Nu-Clonidine); combination drug: clonidine and chlorthalidone (Combipres); methyldopa (Aldomet); combination drugs: methyldopa and chlorothiazide (Aldoclor), methyldopa and hydrochlorothiazide (Aldoril); reserpine (Harmonyl).

Interaction Type and Significance

✗✗✗ Potentially Harmful or Serious Adverse Interaction—Avoid

Probability: **3. Possible**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Although each of these agents has somewhat different mechanisms of action, they can be considered as a group because their interaction is theoretically likely to induce the adverse effect of hypertension. The rauwolfia alkaloids exert their sympatholytic effects through depletion of epinephrine and norepinephrine at the presynaptic vesicles. This has the dual effect of sensitizing the postsynaptic receptors to direct sympathomimetics and rendering indirect (presynaptic) sympathomimetics ineffective. Mixed direct and indirect sympathomimetics are likely to have mixed effects in combination with reserpine. Clonidine is a central alpha agonist that reduces peripheral sympathetic outflow; methyldopa may act in a similar manner.[50]

Research

Early experiments in dogs, in vivo and in vitro, suggest that the pressor effects of indirect sympathomimetics are reduced or abolished by reserpine.[57] Human data are sparse, but patients undergoing ocular surgery who were already taking reserpine were found to have blood pressure elevations of +30/+13 mm Hg after administration of phenylephrine eyedrops.[58] There are no data on the methyldopa-ephedrine combination; however, an 80-patient trial, in which subjects were pretreated with clonidine, showed a blood pressure augmentation when given intravenous ephedrine at 0.1 mg/kg in both anesthetic and waking control groups.[59]

Reports

Clinical reports of ADRs from interactions involving these combinations are unavailable.

Clinical Implications and Adaptations

There are obvious pharmacological implications of combining sympatholytics with sympathomimetics. Concurrent prescription

would be unusual, which may account for the lack of adverse effect reports. Reserpine is rarely used in hypertension treatment, although rauwolfia herbal extracts are frequently used in natural medicine as short-term hypotensives, usually with a holding strategy while implementing long-term lifestyle and dietary changes. The methyldopa interaction remains speculative, and the clonidine interaction is of questionable practical importance.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

The principal scientific and clinical literature base describing ephedra interactions is almost entirely synonymous with the literature on the interactions of ephedrine, pseudoephedrine, and related indirect sympathomimetics, including phenylpropanolamine. Extrapolations to the herb are plausible and may provide useful guidance to practice. Although the data could be regarded as theoretical, the advantage is that the pure-alkaloid safety data will provide a conservative assessment when applied to the crude herb.

A low frequency of reported ephedrine interactions in the mainstream drug interactions literature may reflect the historic decrease in the clinical use of ephedrine in favor of more receptor-selective adrenergic agents. This is in stark contrast to the increase in anecdotal reports of self-prescribed ephedrine-containing weight loss combinations, most of which are technically caffeine-ephedrine interactions, or multiple interactions involving the caffeine-ephedra combination with other agents.

Likewise, the herbal and phytotherapeutic literature on ephedra interactions is also controversial. The German Commission E posits certain interactions, without substantiation of mechanism or context, which have been widely repeated by derivative sources.[8]

Cardiac Glycosides

Deslanoside (cedilanin-D), digitoxin (Cystodigin), digoxin (Digitek, Lanoxin, Lanoxicaps; purgoxin), ouabain (g-strophanthin).

Commission E suggests the interaction between ephedra and cardiac glycosides, citing increased risk of arrhythmias.[8] Despite the large repertoire of known interactions associated with digoxin, there are no reported interactions between digoxin (or other cardiac glycosides) and ephedrine (or other sympathomimetics) in the drug interaction literature. In clinical practice the interaction is unlikely.

Halothane and Other Halogenated Inhalational Anesthetic Agents

Desflurane (Suprane), enflurane (Ethrane), halothane (Fluothane), isoflurane (Forane), sevoflurane (Sevorane, Ultane).

Commission E warns that ephedra interacts with halothane.[8] Halothane was a primary inhalational anesthetic for more than 25 years. It has largely been replaced by related halogenated derivatives (enflurane, isoflurane, desflurane, sevoflurane) because of concerns of postoperative hepatic necrosis associated with halothane. The ability of these agents to sensitize the myocardium to arrhythmia is well known in anesthesiology and probably underlies Commission E's position, although this is not stated.

The halothane "interaction" is arguably a misleading one, especially in the context of consumer-oriented literature. Administration of intramuscular or intravenous ephedrine remains the best choice in management of anesthetic-induced hypotension, both for epidural block and with propofol and sevoflurane.[60-62] In other words, the interaction is beneficial with appropriate management. Advice to disclose ephedra use, along with any other relevant herbs and supplements, before surgery is more appropriate to anesthesia management issues than repeating solemn warnings to the general public about the danger of interactions with an inhalational anesthetic that is no longer generally used.[63]

Oxytocin

Oxytocin (Pitocin, Syntocinon).

Commission E lists the interaction between ephedra and oxytocin.[8] Oxytocin causes vascular relaxation and hypotension with reflex tachycardia. There are no reports of oxytocin and ephedrine interactions, and the probability of concurrent administration clinically is remote because induction of labor is an unlikely context for ephedrine use. This interaction may be regarded as speculative.

Oral Hypoglycemic Agents and Insulin

Buformin (Andromaco Gliporal, Buformina), chlorpropamide (Diabinese), glimepiride (Amaryl), glipizide (Glucotrol; Glucotrol XL), glyburide (glibenclamide; Diabeta, Glynase, Glynase Prestab, Micronase, Pres Tab), insulin (animal-source insulin: Iletin; human analog insulin: Humanlog; human insulin: Humulin, Novolin, NovoRapid, Oralin), metformin (Dianben, Glucophage, Glucophage XR); combination drugs: glipizide and metformin (Metaglip), glyburide and metformin (Glucovance); phenformin (Debeone, Fenformin), tolazamide (Tolinase), tolbutamide (Orinase, Tol-Tab).

An antagonistic interaction between ephedra and hypoglycemics such as insulin has been implied by some secondary sources. There is no evidence for this interaction, and, in fact, ephedra extracts have hypoglycemic activity and pancreatic islet regenerative effects.[64,65]

Secale Alkaloids

Commission E suggests an interaction between ephedra and "secale alkaloids" (i.e., ergotamine derivatives from the rye grass fungus *Claviceps* spp.), presumably based on theoretical additive pressor effects.[8] Because ergotamine derivatives are primarily used in postpartum hemorrhage or as migraine prophylaxis, the interaction is clinically improbable. The drug interactions literature lacks any reports of this interaction, and its repetition by secondary sources is presumably derived from the original, unsubstantiated claim in Commission E.

Note: Regulation, Safety, and Ephedra Weight Loss Products

Ephedrine-containing dietary supplements sold as weight loss aids have been associated with numerous adverse event reports in the U.S., including hypertension, tremors, myocardial infarction and hemorrhagic stroke. After a long controversy, this led the Food and Drug Administration (FDA) to invoke a sweeping restriction on the public sale of ephedra-containing products in 2003, directed specifically at commercial weight loss supplements. Subsequent clarification has effectively granted limited access to licensed practitioners of Chinese medicine. As of 2007, this regulation remains in force. In the context of practitioner-level information, political and regulatory concerns over weight loss products containing ephedra alkaloids are of secondary importance; the primary interactions issue is the underlying ephedra alkaloids–methylxanthine interaction.

Two major comprehensive reviews of safety and toxicity data on ephedrine-containing weight loss products are available.[12,13] The RAND report of Shekelle et al.[13] also

reviewed efficacy trials for weight loss and athletic performance enhancement. None of these clinical trials or case reports involved ephedra crude herb alone, but only combinations of herbal extracts or isolated ephedrine with stimulants such as caffeine. The RAND report analyzed adverse event data from both clinical trial reports and postmarketing pharmacosurveillance sources, including reports to the FDA's MEDWATCH, and data from the customer files of a major weight loss product manufacturer (HerbaLife). The reviewers concluded that ephedrine-containing formulations are associated with a significant risk of nausea, vomiting, anxiety, mood changes, autonomic hyperactivity, and palpitations. Their meta-analysis of the clinical trials on weight loss confirmed that products combining ephedrine with caffeine were capable of producing short-term weight loss of about 1 kg (2.2 lb) per month compared with placebo.[13]

The possible role of adrenoceptor (AR) polymorphisms as an explanatory factor in the variability of weight loss data has not been considered by these reviewers, despite its known relevance to obesity. The precise contribution of direct receptor interaction, indirect release of endogenous catecholamines, or reuptake inhibition to the overall action of ephedrine remains unclear. Recently, ephedrine has been shown to act directly on the human beta-3 AR, which is involved in lipolysis in human brown adipose tissue as well as thermogenesis, which may explain the moderate effects on short-term weight loss, especially combined with the central anorectic properties of the phenylethylamines.[66,67] The emerging pharmacogenomic data on AR polymorphisms may partially explain the variable results with obesity and could theoretically support more effective drug targeting of ephedrine in obese patient populations.[68] However, the "therapeutic gap" between current AR polymorphism data and their implications for clinical practice remains sizable.[66,69]

Several sympathomimetic agents are licensed as prescription medications for short-term use (< 12 weeks) in weight loss, including benzphetamine and phendimetrazine, both of which are FDA Schedule III because of their abuse potential. Phenylpropanolamine (PPA), which is identical to norpseudoephedrine found in ephedra, was recently withdrawn from the market because of concerns about hemorrhagic stroke in women.[70] However, the norpseudoephedrine content in ephedra is generally very low, and although a small proportion of ephedrine may also be metabolized to norephedrine, the threshold dose of PPA considered to constitute a risk for hemorrhagic stroke is 75 mg/day.[70] A recent case-control study found no association between ephedrine use and hemorrhagic stroke.[71]

Meanwhile, research and trials continue on new pharmacological interventions for obesity, with recent emphasis on selective beta-3 AR agonist drugs. Despite the prevalence of overweight and obesity and the alarming rate of increase in obesity-related conditions, the overall understanding of this multifactorial condition and the efficacy of current pharmacological treatments remain limited.[43]

The adverse events reviewed by RAND and others can be extrapolated to ephedra herb with some minor qualifications. The crude herb contains tannin constituents that have angiotensin-converting enzyme (ACE)–inhibiting activity, as well as multiple constituents that include organic acids, flavonoids, and volatile oils that will modulate the alkaloid-fraction effects.[72] It is plausible that extrapolations from ephedrine effects will be overly conservative with respect to the crude herb.[72] Again, these studies used combinations with caffeine or caffeine-containing herbs.

Classic pressor responses have been established for the crude herb, but the dose-response kinetics are significantly slower than for pure ephedrine, and the pressor response is small, with considerable individual variation.[73] Nephrolithiasis has been reported recently after crude herb consumption; the urologists' search of the Louis C. Herring and Company kidney stone database show that this is an endemic complication of ephedrine, with hundreds of previous episodes.[74] At the same time, one experimental study has showed a significant reduction of uremic toxins after administration of aqueous crude herb extract in an animal model of renal failure.[75]

The recent banning of ephedra-containing weight loss products by the FDA has changed the degree to which undisclosed use of ephedra may be a potential danger in most cases. The market for weight loss products remains active, and "ephedra-free" formulations are available to the public that attempt to circumvent regulatory restrictions, based on extracts of *Citrus aurantium* (bitter orange), which contains the mildly sympathomimetic alkaloid synephrine. Lipolytic effects in human adipocytes have been demonstrated, but convincing evidence for efficacy of the extract as a weight loss aid is not currently available.[76-78]

The 78 citations for this monograph are located under Ephedra on the CD at the back of the book.

Feverfew

Botanical Name: *Tanacetum parthenium* (L.) Schultz Bip.
Pharmacopoeial Name: Tanaceti partheni herba.
Synonyms: *Matricaria parthenium* L.; *Chrysanthemum parthenium* (L.) Bernh.; *Leucanthemum parthenium* (L.) Gren. and Godron; *Pyrethrum parthenium* L. Sm.
Common Name: Feverfew.

HERB DESCRIPTION

Family

Asteraceae.

Parts Used

Aerial herb.

Common Forms

Fresh leaf.
Dried leaf, freeze-dried leaf.
Tincture: 1:5 25% ethanol.[1]
Standardized Extract: Not less than 0.2% parthenolide content.

INTERACTIONS REVIEW

Strategic Considerations

The modern use of feverfew as a specific for migraines followed its adoption by physicians at the London Migraine Clinic in the early 1980s, who investigated anecdotal reports of the effectiveness of the fresh leaf as a migraine prophylactic and treatment.[2,3] Following initial studies, its use spread rapidly to North America, and today the herb hovers in the lower ranks of the top-20 best-selling botanicals in the United States, partly because of the large number (29 million) of migraine sufferers seeking effective treatment for the often-refractory condition. This indication was never prevalent in Germany, and the herb is not mentioned by Weiss,[4] Wichtl,[5] or the German Commission E.[6] The first modern-use therapeutic monograph was in the *British Herbal Compendium*[1]; this has been superseded by a comprehensive monograph from the European Scientific Cooperative on Phytotherapy (ESCOP)[7] and recent reviews from Mills and Bone[8] and McKenna et al.[9]

Despite its current public popularity, recent systematic reviews of the available controlled trial data suggest that the effectiveness of feverfew for migraine prophylaxis is not conclusively established beyond reasonable doubt, although most trials favor the herb against placebo and suggest it has a good safety profile.[10,11]

Interpretations of the pharmacodynamics of feverfew extracts that stress only the sesquiterpene lactone *parthenolide* as the active constituent responsible for the anti-inflammatory and antimigraine actions of the herb have been described as controversial, particularly the so-called serotonin-parthenolide hypothesis of migraine prophylaxis.[12] The recent ESCOP monograph asserts that connections between the constituents of the herb and its migraine prophylactic action should be considered as complex and not definitively established.[7] However, a clearer picture may be emerging from recent studies.

Currently, the pharmacology of feverfew is being intensively reexamined after the discovery of the anti–nuclear factor kappa B (NF-κB) properties of parthenolide.[13-15] From an interactions perspective, given the pluripotent activities governed by this transcription factor, inhibition of NF-κB suggests several potentially valuable strategic interactions; these include modulation of adhesion molecule expression,[16] inhibition of inducible nitric oxide synthase (iNOS),[17,18] and possible targeting of antireperfusion injury,[19] as well as induction of apoptosis and modulation of drug resistance.[20,21] Parthenolide also appears to be a thiol depleter, which may be part of the mechanism underlying its antiaggregatory effect.[22,23] The induction of apoptosis by parthenolide also involves thiol antioxidant modulation.[21,24] The presence of NF-κB in platelets also suggest that this factor may have a role in aggregation, independently of gene regulation.[25]

Parthenolide has recently been shown to be a selective inducer of apoptosis in cells from chronic lymphocytic leukemia (CLL) patients at the relatively low median inhibitory concentration (IC_{50}) of 6.2 μmol.[26] Increasing research interest in the anticancer properties of feverfew and parthenolide are expanding the "herb for migraine" conception of the botanical that characterized feverfew in the late twentieth century.

The official ESCOP monograph lists no known interactions between feverfew and pharmaceuticals, and interactions reports are absent from the literature, although some secondary sources persistently assert an interaction between feverfew and warfarin[7,27] (see Theoretical, Speculative, and Preliminary Interactions Research). An interaction with drugs targeting hemostasis is theoretically more likely with antiplatelet thrombolytics, but depending on context and intent, such interactions are as likely to be beneficial as adverse. Protection against gastropathies induced by nonsteroidal anti-inflammatory drugs (NSAIDs) is a more than theoretically possible interaction, and although evidence for adjunctive interactions in oncological therapies (involving NF-κB–mediated activities) is preliminary, this may be an area of future interest as research evidence continues to emerge.

Pharmacokinetic data on the herb are meager; a recent report suggests that parthenolide and other sesquiterpene lactones exhibit a high degree of protein binding in human plasma.[28] The metabolic fate of parthenolide and its possible modulation of the cytochrome P450 (CYP450) system is unknown, but to date the herb does not appear to be associated with any obvious pharmacokinetic interactions.

HERB-DRUG INTERACTIONS

Indomethacin and Related Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Evidence: Indomethacin (indometacin; Indocin, Indocin-SR). Extrapolated, based on similar properties: Nonsteroidal anti-inflammatory drugs (NSAIDs):

COX-1 inhibitors: Diclofenac (Cataflam, Voltaren), combination drug: diclofenac and misoprostol (Arthrotec), diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), furbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen), combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen), indomethacin (indometacin; Indocin, Indocin-SR), ketoprofen

(Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Aleve, Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).

COX-2 inhibitor: Celecoxib (Celebrex).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **3. Possible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

The anti-inflammatory effects of feverfew may protect against gastropathic adverse effects of indomethacin and possibly other NSAIDs occurring with chronic use of these agents.

Research

In a rodent model of experimentally induced gastric ulceration by ethanol, oral pretreatment with either feverfew extract or parthenolide 24 hours before ethanol administration created protective effects ranging between 34% and 100% for the extract and 27% and 100% for parthenolide. At doses of 40 mg/kg body weight, the mean ulcer index declined from 4.8 (control) to 1.4 for the extract and 0.5 for parthenolide.[29] The researchers used *Tanacetum larvatum* (Grisb. ex Pant), a related feverfew species with a higher parthenolide content (1.1%) than *T. parthenium*, to examine the ulceroprotective effects of the herb against indomethacin-induced ulcers in rodents. They concluded that there was significant reduction of the ulcerogenic effect at 50 mg/kg orally, given after indomethacin (not pretreatment). The same extract significantly reduced NF-κB activation in two assay methods, at levels of 20 μg/mL. They also examined the anti-inflammatory effect of combining indomethacin and the herbal extract on the rat-paw carrageenan model and concluded that although there was slight synergy of effect for the combination, it was not significant.[29]

Previous studies on the ulceroprotective effects of dihydroleucodine, a sesquiterpene lactone from *Artemisia douglasiana*, support the hypothesis that the protective effects are caused by increased mucus secretion, which is significantly reduced by indomethacin.[30] More recently, unrelated investigations have shown that indomethacin markedly activates mucosal NF-κB 48 hours after administration, lending indirect support to the hypothesis that the therapeutic effects of feverfew are mediated through inhibition of this transcription factor.[31]

Integrative Therapeutics, Clinical Concerns, and Adaptations

The protective effectiveness of feverfew extracts in ameliorating NSAID-induced gastropathy is experimentally established, and positive data are available relating to indomethacin. In practice, unless feverfew is an agent of choice for therapeutic reasons, primarily migraine or arthritis, other botanical agents, such as licorice or aloe, may have a superior cost/risk profile to feverfew for this purpose. Toxicological data on possible mutagenicity of feverfew is controversial, although otherwise the extract has a good safety profile. In addition, additive or synergistic anti-inflammatory effects are therapeutically preferable, and in the case of feverfew and NSAIDs, this synergism has not been clearly demonstrated; a controlled trial of 50 migraine patients found no significant difference between placebo and control groups.[32] However, use of anti-inflammatory medications by patients in the feverfew group showed a decline over the 9-month trial period.

Taxanes: Paclitaxel, Docetaxel

Evidence: Docetaxel (Taxotere), paclitaxel (Paxene, Taxol), paclitaxel, protein-bound (Abraxane).

Extrapolated, based on similar properties: Chemotherapeutic agents that activate NF-κB:

Cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), daunorubicin (Cerubidine, DaunoXome), doxorubicin (Adriamycin, Rubex), doxorubicin, pegylated liposomal (Caelyx, Doxil, Myocet), epirubicin (Ellence, Pharmorubicin), etoposide (Eposin, Etopophos, Vepesid, VP-16), idarubicin (Idamycin, Zavedos), irinotecan (camptothecin-11, CPT-11; Campto, Camptosar), tamoxifen (Nolvadex), topotecan (Hycamtin), vinblastine (Alkaban-AQ, Velban, Velsar), vincristine (Leurocristine, Oncovin, Vincasar PFS), vinorelbine (Navelbine).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Parthenolide experimentally increases the sensitivity of breast cancer cells with constitutively active NF-κB expression to apoptosis-inducing effects of taxanes. This is likely a specific case of general chemosensitization by naturally occurring NF-κB inhibitors to chemotherapeutic agents known to have antiapoptotic effects of NF-κB. Clinical support for the interaction is not available.

Research

Parthenolide and feverfew extracts both exhibit NF-κB inhibitory actions.[13-15] This transcription factor is involved in multiple effects in cancer biology, including cell survival, adhesion, inflammation, proliferation, and metastasis, as well as chemoresistance, and its expression can be modulated by a range of chemopreventive natural compounds.[33,34] Paradoxically, a number of cytotoxic chemotherapeutic agents activate NF-κB, leading to chemoresistance.[35,36] Cory and Cory[37] found that parthenolide acted as an augmenter of apoptosis through NF-κB inhibition in a leukemia cell line, and later they studied an NF-κB–expressing subset of breast cancer cells that were chemoresistant to paclitaxel. The sensitivity to the chemotherapeutic agent could be increased in the malignant cells both by I-κB-α superrepressor and parthenolide. The effect was not replicated in nonmalignant cells. The authors suggest that the active ingredients of herbs may be useful in increasing the chemosensitivity of cancers with constitutively active NF-κB.[20,37]

An in vivo and in vitro study using three breast cancer lines found that parthenolide combined with docetaxel increased the antiapoptotic and antimetastatic effects of the taxane, and that the effect was accompanied by lower tumor levels of NF-κB.[38] Another NF-κB–related effect has been demonstrated with tamoxifen resistance reduction and parthenolide in MCF7 cells.[39] Thiol and redox status may also relate to the important differential effects of parthenolide on apoptosis between malignant and normal cells.[21,24] Parthenolide acted as an in vitro sensitizer to the NSAID sulindac in a pancreatic carcinoma

cell line. The effect of the combination was synergistic (greater than either agent alone), suggesting possible preclinical support for combining parthenolide with other NF-κB inhibitors in chemotherapy.[40] For example, parthenolide combined with dehydrocpiandrosterone (DHEA) attenuated tumor growth in vivo in a murine model compared to either agent alone.[41] Weak synergistic effects of parthenolide with other constituents of the whole herb on growth inhibition for two breast and one endometrial cancer cell lines were found in the case of the flavonoids apigenin and luteolin by Wu et al.[42]

Integrative Therapeutics, Clinical Concerns, and Adaptations

This potential interaction may be of considerable significance, although it currently lacks clinical support and must be regarded as preliminary. Incorporation into chemotherapy protocols at this time should be considered only by practitioners with solid clinical grounding in integrative oncology and may be specifically limited to issues related to chemotherapy-induced NF-κB activation.

Acetylsalicylic Acid, Clopidogrel, Ticlopidine, and Other Antiplatelet Thromboprophylactics

Evidence: Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal).
Extrapolated, based on similar properties: Cilostazol (Pletal), clopidogrel (Plavix), dipyridamole (Permole, Persantine), ticlopidine (Ticlid), combination drug: ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability:
5. Improbable

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

Aspirin (acetylsalicylic acid, ASA) is a well-documented antiplatelet agent acting through inhibition of cyclooxygenase production of thromboxane A_2 (TXA_2). Ticlopidine interacts with glycoprotein IIb/IIIa to inhibit fibrinogen binding to activated platelets and has been used for prevention of thrombosis when aspirin is poorly tolerated. Because of reports of hematological adverse effects associated with ticlopidine, clopidogrel (Plavix) is currently the preferred antiplatelet agent in such cases. As with ticlopidine, clopidogrel is another irreversible antiplatelet drug operating through adenosine diphosphate (ADP) receptor antagonism. The potential interaction is thus a theoretical additive pharmacodynamic increase in antiplatelet activity. Such an additive effect may theoretically increase the likelihood of bleeding disorders related to disturbances of primary hemostasis.

Research

In vitro investigations have demonstrated antiaggregatory actions of feverfew extracts and isolated parthenolide. Several aggregatory stimuli are inhibited by parthenolide, including ADP, collagen, and arachidonate.[43-46] Platelet secretory activity is also inhibited by parthenolide, reducing 5-hydroxytryptamine (5-HT, serotonin) release.[44,47,48] Thiol depletion plays a significant role in the mechanism.[22,49,50] Interestingly, the antiaggregatory effects of feverfew extracts and isolated parthenolide appear to be equivalent in magnitude.[51]

In a comprehensive review of antiplatelet activity of plant compounds, Venton et al.[52] stressed that because the relevant assay technologies are currently quite straightforward, many plant extracts and isolated compounds have been screened in vitro for platelet-inhibiting properties. Although many potentially active compounds that inhibit activation by one or more agonists have been identified, none has yet been transformed into a clinically effective antithrombotic drug.[52] Other than the pharmacokinetic modeling studies by Boik,[33] there has been little attempt to create meaningful algorithms to extrapolate in vitro IC_{50} values from the different study methods into meaningful estimates of likely therapeutic levels of the compounds after therapeutic oral doses of herb.

Reports

There are no preclinical studies or clinical reports confirming this interaction. On the contrary, the original clinical investigators of feverfew at the London Migraine Clinic reported to the *Lancet* in 1982 that they had tested 10 patients who had taken feverfew for 3½ to 8 years and assayed dose–aggregatory response curves to several platelet agonists, including ADP, thrombin, serotonin, and a prostaglandin analog (U46619). Aggregation responses to ADP and thrombin were identical to controls who had not taken feverfew for 6 months.[53] This was in direct conflict with in vitro findings of Makheja and Bailey[43] published earlier in 1982, confirming that extrapolation from in vitro activity to in vivo effects is problematic.

Clinical Implications and Adaptations

At present, this potential interaction can be considered clinically insignificant, if in fact it exists. Monitoring migraine or arthritis patients who may be combining substantial doses of feverfew chronically with antiplatelet drugs for signs relating to disturbances of primary hemostasis may be prudent (e.g., petechiae, ecchymoses, superficial bleeds at mucous membranes).

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

5-Hydroxytryptamine Receptor Agonists (Triptans)

Almotriptan (Axert), eletriptan (Relpax), frovatriptan (Frova), naratriptan (Amerge), rizatriptan (Maxalt), sumatriptan (Imitrex), zolmitriptan (Zomig).

There is no evidence of interaction between feverfew and the triptan drugs used for prophylaxis and treatment of migraine. Triptans are potent 5-HT agonists, and most triptans undergo metabolism by either monoamine oxidase A or CYP450 1A2 or 3A4. The serotonin hypothesis of feverfew pharmacology is no longer considered credible, and although direct evidence is lacking, obvious effects of the herb on CYP450 enzymes appear unlikely, therefore currently ruling out plausible pharmacokinetic and pharmacodynamic mechanisms for a feverfew-triptan interaction.

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar), warfarin (Coumadin, Marevan, Warfilone).

Although denied by authoritative secondary sources, a warfarin-feverfew interaction has been suggested by some derivative sources, based on in vitro antiplatelet activity previously discussed. Clinical evidence for this interaction is currently lacking.

The 53 citations for this monograph are located under Feverfew on the CD at the back of the book.

Garlic

Botanical Name: *Allium sativum* L.
Pharmacopoeial Name: Alii sativi bulbus.
Synonym: Porvium sativum Rehb.
Common Names: Garlic, stinking rose.

SUMMARY

Drug/Class Interaction Type	Mechanism and Significance	Management
Acetaminophen ⊕⊕⊕/☼	Potential pharmacokinetic interaction caused by garlic inhibition of cytochrome P450 2E1 may reduce hepatotoxic metabolite NAPQI formation. Not clinically demonstrated.	Not applicable for management of acute acetaminophen toxicity.
Dipyridamole Antiplatelet thromboprophylactics ⊕✗/✗/⊕	Possible additive increased antiplatelet activity with dipyridamole. Not established with other antiplatelet agents. Clinical significance not established; increased risk of bleeds likely overstated.	Avoid or adopt and monitor bleed times. Combine garlic in antithrombotic protocols.
Doxorubicin Anthracycline chemotherapy ⊕/☼	Garlic protects against and reduces drug-induced cardiotoxicity through multiple mechanisms, including increasing myocardial antioxidant status. Not clinically demonstrated.	Pretreat, coadminister, and continue herb postchemotherapy in cardioprotective protocols.
HMG-CoA reductase inhibitors (statins) ⊕/☼	Additive inhibition of HMG-CoA theoretically allows lowered statin dose and reduction of drug adverse effects. Plausible but not clinically established.	Consider adopting if statin-induced ADRs (myalgias, fatigue, etc.); trial if symptomatic.
Methotrexate Fluorouracil (5-FU) Chemotherapy associated with mucositis ⊕/☼	Garlic may prevent and reduce chemotherapy-induced mucositis through anti-inflammatory and antioxidant mechanisms. Not clinically established.	Consider incorporating garlic with other agents in protective protocols for chemotherapy-induced mucositis.
Saquinavir Protease inhibitor antiretrovirals ✗/◇◇	Possible pharmacokinetic interaction with saquinavir; reduces drug bioavailability; does not occur with ritonavir. Unknown significance and applicability to related protease inhibitors.	Monitoring serum drug levels advisable if coadministered.
Warfarin Oral vitamin K antagonist anticoagulants ✗/⊕	Theoretical additive effects on hemostasis caused by possible platelet inhibition. Clinical studies suggest interaction insignificant.	If coadministered, monitor INR and check for peripheral bleed symptoms.

HMG-CoA, Hydroxymethylglutaryl coenzyme A; *ADRs*, adverse drug reactions; *INR*, international normalized ratio.

HERB DESCRIPTION

Family

Liliaceae.

Related Species

Allium cepa L. (onion), *Allium schoenoprasum* L. (chives).

Habitat and Cultivation

Originally native to central Asia; commercially cultivated for 5000 years as a food and medicinal herb worldwide.

Parts Used

Fresh or dried bulb.

Common Forms

Fresh bulb.
Dried bulb.
Dried powder (allicin-stabilized).
Aged garlic extract (AGE).
Garlic oil (steam-distilled).
Garlic oil (macerated).

HERB IN CLINICAL PRACTICE

Overview

Garlic dietary supplements consistently occupy second or third place of the top-selling botanical products in the United States, quite apart from the widespread availability and use of garlic cloves as a dietary/culinary herbal ingredient. Scientific studies and numerous clinical trials support the following three primary areas of use in modern practice:

1. For cardiovascular disease prevention and treatment as a hypolipidemic, antiatherosclerotic, hypotensive, antiplatelet, and fibrinolytic agent.
2. For infectious conditions as a broad-spectrum antibiotic, antifungal, antiviral, and anthelmintic agent.
3. As a chemopreventive and anticancer agent; antioxidant and immunostimulant properties impact each of these areas.

The pharmacology of the herb derives from its organosulfur constituents (OSCs), although the chemistry of these is extremely complex and has not been fully characterized. Importantly, different garlic preparations may have significantly different constituent profiles; the principal compounds in the intact bulb are gamma-glutamyl cysteine peptides and the cysteine sulfoxide alliin. The enzyme allinase (released by damage to intact cells) converts alliin to the thiosulfinate allicin. Allicin is unstable and degrades to various volatile sulfide congeners, depending on the conditions applied.

Steam distillation converts water-soluble thiosulfinates to oil-soluble diallyl sulfides, whereas oil maceration produces ajoenes and vinyldithins.

Similarly, pharmacokinetic differences exist among the various preparations and their components. Metabolic transformation of various sulfides leads to the formation of compounds that have modulating effects on the cytochrome P450 (CYP450) system. Enteric-coated preparations have been shown to release only a fraction of their active allicin content.

These differences complicate attempts to compare data from various experimental and clinical trials using different garlic preparations. More than 45 randomized clinical trials have been conducted with garlic preparations. Metastudies have concluded that these trials show positive, although limited, short-term benefits of garlic on serum cholesterol and some coagulation parameters, but no significant effect on hypertension or blood glucose levels.[1-4] Some authors have criticized the meta-analyses, noting the lack of equivalence between preparations and inadequate definition or characterization of active principles in the trials, which seriously limits the clinical conclusions that can be drawn from the majority of trials to date.[5,6] Epidemiological studies of the cancer-protective effects of garlic consumption have also been subject to meta-analysis, and positive effects were found for stomach and colon cancers from raw and cooked garlic consumption.[7,8]

Garlic has not been official in the *U.S. Pharmacopoeia* since 1900, but it is listed in the 2002 edition of the *National Formulary* as "fresh or dried compound bulbs containing not less than 0.5% alliin." The German Commission E approved the use of "fresh or carefully dried bulbs" as "supportive to dietary measures at elevated levels of lipids in the blood" and as a "preventative for age-dependent vascular changes."[9] The European Scientific Cooperative on Phytotherapy (ESCOP) monograph indicates garlic for "treatment of elevated blood lipid levels insufficiently influenced by diet" and mentions the traditional indication for upper respiratory tract infections and catarrhal conditions while also noting that these lack trial support.[10] The World Health Organization (WHO) also includes mild hypertension as an indication.[11] Both ESCOP and McKenna et al.[12] provide comprehensive reviews of the recent scientific literature.

Historical/Ethnomedicine Precedent

In Europe, garlic has been used for millenia. It was a staple of the Roman army, Pliny recorded more than 60 uses for garlic, and Galen first recorded its use as a disinfectant before and after surgery. More recent folk use centers on respiratory conditions, including coughs, colds, flus, sinus and bronchial infections, pneumonia and tuberculosis, and the elimination of worms and other parasites. As an external treatment, garlic has been used as a "counterirritant" for rheumatic and arthritic conditions, as well as for earache, skin infections, and snakebites. Topical applications are also used in respiratory conditions. Garlic has been employed in all major world systems of medicine for many years. In China, garlic use was recorded in texts from the fifth century CE, principally as an antidote for poisons as well as a treatment for infectious and parasitical intestinal conditions such as diarrhea, dysentery, and diphtheria.

Known or Potential Therapeutic Uses

Antimicrobial, antifungal, atherosclerosis, bronchial and upper respiratory conditions, catarrh, colds, coughs, flu, gastric and colon carcinomas (prevention), hyperlipidemia, hypertension, hyperviscosity, immunostimulation, peripheral arterial occlusive disease, rhinitis, sinusitis, thrombosis.

Key Constituents

Organosulfur compounds (OSCs), principally alliin [(+)-*S*-allyl-L-cysteine sulfoxide] and gamma-L-glutamyl peptides. Alliin is transformed into allicin by allinase, and depending on physicochemical conditions, various derivatives may be formed. Flavonoids and saponins are also present.

Therapeutic Dosing Range

Fresh Garlic: 2.7 to 4.0 g daily.
Dried Powder: 0.4 to 1.2 g daily.
Tincture (1:5): 20 mL daily.
Oil: 2 to 5 mg daily.
Standardized Extracts:
- Garlic powder (Kwai): 200 to 300 mg three times daily.
- Aged garlic extract (AGE, Kyolic): 300 to 800 mg three times daily.
- Other preparations: Corresponding to 4 to 12 mg alliin, or 2 to 5 mg allicin-equivalent daily.

INTERACTIONS REVIEW

Strategic Considerations

The German Commission E did not list any known interactions for garlic in its 1998 monograph.[9] However, the later monographs by WHO and ESCOP both list a possible interaction between garlic and warfarin.[10,11] Although garlic consumption is usually assumed to be a risk to anticoagulated patients, reliable reports of such interactions are not available.[13]

As with ginkgo, garlic and several of its constituents have established antiplatelet activity in vitro. Using aggregometry in response to platelet-stimulating factors such as collagen and adenosine diphosphate (ADP), three clinical trials have demonstrated modest effects on platelet aggregation in vivo by AGE extracts[14,15] and garlic powder.[16,17] Bleed times and international normalized ratio (INR) were not measured, and the clinical significance of the antiaggregatory effects of garlic remains to be established. Three reports associate garlic alone with spontaneous bleeding, but none of these allows causality to be attributed to the herb[18-20] (see later discussion on garlic and antiplatelet thromboprophylactics). Cessation of high levels of garlic consumption before elective surgery may be prudent, but on the basis of currently available evidence, the risk of garlic-induced bleeding and interactions with drugs affecting hemostasis appears to be very low.[21]

On the other hand, inclusion of garlic in protocols for patients at risk of thrombosis, particularly those with history of atherosclerotic disease, offers multiple "collateral" benefits due to the pleiotropic actions of the herb on several cardiac risk factors.[22-27] The lipid-lowering effect of garlic extracts operates by several mechanisms, including the inactivation of hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase. This has led at least one author to suggest the potential value of combining garlic with pharmaceutical HMG-CoA reductase inhibitors for hyperlipidemia to reduce the risk of adverse effects such as rhabdomyolysis in sensitive populations, such as renal transplant patients.[28] This potentially beneficial interaction is proposed later, although previously undefined in the literature.

Effects on Drug Metabolism and Bioavailability

Experimental, animal, in vitro, and ex vivo human data suggest that garlic OSCs may be substrates, inducers, and/or inhibitors of various CYP450 enzymes. As with the pharmacodynamic effects of garlic, there are differences in effect among the different OSCs, different dose/duration regimens, and different species (mouse, rat, rabbit, human). The full spectrum of effects of OSCs on drug metabolism in humans is not well understood, but in vivo evidence is compelling for an inhibition of CYP450 2E1 by OSCs.

Diallyl sulfide (DAS) is converted by CYP2E1 to diallyl sulfoxide (DASO) and sequentially to diallyl sulfone ($DASO_2$).[29] These derivatives are competitive inhibitors of 2E1, and $DASO_2$ is also an irreversible (suicide) inhibitor of 2E1.[30,31] This is a typical example of 2E1 activity, which shares with CYP450 1A1 and 1A2 the role of metabolizing potentially carcinogenic aromatic hydrocarbons, and which may also bioactivate certain substrates to toxic or reactive intermediates (e.g., acetaminophen; see later discussion).[32,33] Loizou and Cocker[34] found that both DAS and garlic oil extract showed significant inhibition of 2E1 in eight healthy human volunteers with the 2E1 probe chlorzoxazone. Gurley et al.[35] also found significant inhibition of 2E1 after 28 days of garlic oil administration in healthy human volunteers using the same chlorzoxazone probe methodology. Davenport and Wargovich[36] found that single-dose in vivo OSCs in a rodent model decreased 2E1 protein but not its messenger ribonucleic acid (mRNA) levels. They also noted a slight increase in 1A1 and 1A2 levels.

Inhibition of CYP450 2E1 is considered one of the major mechanisms by which garlic consumption reduces mutagenesis and carcinogenesis and exerts hepatoprotective effects.[37,38] Other mechanisms may be involved, including OSC induction of glutathione transferases as well as scavenging of carcinogenic free-radical species.[39,40] Recent studies suggest that a number of complex effects on signal-transduction pathways may be involved in the chemopreventive effects of garlic OSCs.[41] Garlic-drug interactions with 2E1 substrates caused by inhibition by garlic OSCs have not yet appeared to be a clinically significant issue, and case reports are lacking. Drug substrates that theoretically may be affected by inhibition of 2E1 are verapamil, the halogenated anesthetics, and (a minor pathway) theophylline. In a clinical study restricted to older volunteers (mean age, 67 years), Gurley et al.[42] found a 22% inhibition of 2E1 by garlic oil administered for 28 days. The authors suggested that age-related changes in CYP450 activity are significant and should be factored into drug dose and potential interactions calculations.

Garlic is not the only dietary substance to modulate 2E1 expression. Inducers include ethanol, lettuce, and above all, increased body weight or obesity, whereas inhibitors include watercress and elements of *Camellia sinensis* (both green tea and black tea), especially epigallocatechin-3-gallate. If polymorphisms are taken into account, the total contribution of these variables to individual response variation in 2E1-mediated clearance of the probe substrate chlorzoxazone is 73%, with body weight alone accounting for 43% of the phenotypical variability in 2E1 activity.[43,44]

The effect of garlic on CYP450 enzymes other than 2E1 is less clear. A "before and after" probe study with healthy volunteers examined the effect of Kwai (aged) garlic consumption (600 mg three times daily for 14 days) on probe drugs for CYP3A4 (alprazolam) and CYP2D6 (dextromethorphan) pharmacokinetics and found no significant effects after garlic administration.[45] The authors concluded that aged (Kwai) garlic is unlikely to cause 3A4-modulated or 2D6-modulated drug interactions. Gurley et al.[35] found no effect of garlic oil on 3A4, 2D6, or 1A2 in healthy volunteers using a midazolam, debrisoquin, and caffeine cocktail in the study previously mentioned that demonstrated 2E1 inhibition.

Foster et al.[46] conducted an in vitro study using recombinant human CYP450 enzymes that investigated the effects of 10 different garlic products (including aged, odorless, oil, freeze-dried, and three fresh forms: common, Chinese, and elephant) on enzyme activity. The authors found that 2D6 was unaffected, but that 2C9*1, 2C19, 3A4, 3A5, and 3A7 were all inhibited by fresh garlic, whereas 2C9*2 was actively stimulated by fresh garlic. These authors concluded that pharmacokinetic interactions with narrow-therapeutic-range drugs may result from garlic consumption, affecting metabolism of drug substrates mediated by 2C9, 2D6, and 3A4. The same extracts were tested against an in vitro model of P-glycoprotein (P-gp) based on an adenosinetriphosphatase (ATPase) colorimetric assay, using verapamil as a positive control. (Stimulation of the ATPase assay is correlated with increased inhibitory activity of P-gps.) Aqueous extracts of aged garlic preparations exerted a very low to moderate inhibition of P-gp in the assay used.[46] In another in vitro model based on human KB-C2 cells, Nabekura et al.[47] found no effect of OSCs on the P-gp–mediated transport of daunorubicin and rhodamine 123. Greenblatt et al.[48] used an in vitro human hepatocyte model to test possible activity of different water-soluble compounds in garlic for CYP inhibitory activity and found negligible effect, except for high concentrations (100 μmol/L) of *S*-methyl-L-cysteine and *S*-allyl-L-cysteine, both of which produced modest inhibition of CYP3A. The authors concluded that CYP3A interactions with garlic and prescription drugs were unlikely.

Pharmacokinetic data for garlic (other than those related to drug-metabolizing systems) are minimal. However, one rodent study examined the effect of the saponin constituents of garlic and concluded that these compounds may contribute to the lipid-lowering activity of garlic by reducing lipid absorption levels at the intestinal wall.[49] Studies are required to delineate human pharmacokinetics of garlic and OSC preparations in order to determine the extent to which many of the important effects of OSCs described in vitro in animal models can be replicated in vivo at micromolar concentrations that correspond to those employed in the experimental models. Further research is also required to establish the full spectrum of effects of different forms of garlic and OSCs on drug metabolism and potential pharmacokinetic interactions. Inconclusive data are available relating to garlic and the human immunodeficiency virus type 1 (HIV-1) protease inhibitors, saquinavir and ritonavir (discussed later). Patients with HIV infection are likely to take garlic products or preparations, and physicians specializing in this patient population are usually aware of the complexities of managing polypharmaceutical regimens and empirically monitoring possible interactions. Other than this clinically circumscribed area, currently no compelling data exist on adverse pharmacokinetic interactions between pharmaceuticals and garlic preparations. The established inhibition of CYP450 2E1 underlies a major part of the hepatoprotective and chemoprotective benefits of garlic consumption.

HERB-DRUG INTERACTIONS

Acetaminophen

Acetaminophen (APAP, paracetamol; Tylenol); combination drugs: acetaminophen and codeine (Capital with Codeine;

Phenaphen with Codeine; Tylenol with Codeine); acetaminophen and hydrocodone (Anexsia, Anodynos-DHC, Co-Gesic, Dolacet, DuoCet, Hydrocet, Hydrogesic, Hy-Phen, Lorcet 10/650, Lorcet-HD, Lorcet Plus, Lortab, Margesic H, Medipain 5, Norco, Stagesic, T-Gesic, Vicodin, Vicodin ES, Vicodin HP, Zydone); acetaminophen and oxycodone (Endocet, Percocet 2.5/325, Percocet 5/325, Percocet 7.5/500, Percocet 10/650, Roxicet 5/500, Roxilox, Tylox); acetaminophen and pentazocine (Talacen); acetaminophen and propoxyphene (Darvocet-N, Darvocet-N 100, Pronap-100, Propacet 100, Propoxacet-N, Wygesic).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **3. Possible**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

This is primarily a pharmacokinetic interaction, whereby garlic extracts inhibit the CYP450 2E1 isoform that mediates the production of the hepatotoxic metabolite of acetaminophen (NAPQI). Although experimentally validated, the clinical significance of the interaction is not established.

Research

Acetaminophen is extensively metabolized through glucuronidation and sulfation as well as oxidation by CYP450 1A2, 3A4, and 1E2.[50-52] Oxidative metabolism by 2E1 forms the reactive intermediate NAPQI (*N*-acetyl-*p*-benzoquinone imine), which is subsequently conjugated by glutathione. Under normal circumstances, little NAPQI is formed, but if 2E1 undergoes induction, typically by alcohol consumption, NAPQI may be formed in greater-than-usual quantities. In turn, if glutathione capacity is exceeded at the same time, clinical hepatoxicity may result, with significant risk of fulminant hepatic failure. Deliberate overdose with acetaminophen is the major cause of drug-related liver failure and emergency liver transplants in the United States and until recently in the United Kingdom (when measures to restrict OTC availability of the drug were implemented).[53,54] Emergency treatment of acetaminophen poisoning with *N*-acetylcysteine (NAC) can help regenerate glutathione stores and prevent further NAPQI formation, but NAC is usually effective only in the earliest stages of intoxication.

Extensive in vitro and in vivo evidence exists for the ability of garlic preparations in the form of fresh garlic, garlic oil, and AGE to inhibit human CYP450 2E1[30,35,46] (see also pharmacokinetics earlier). A number of rodent studies have established that pretreatment with different garlic preparations exerts a protective effect against single-dose–induced acetaminophen toxicity according to a number of endpoints, including hepatic histology, aminotransferase and lactate dehydrogenase levels, 2E1 levels, reduced glutathione levels, and cataracts.[55] Studies have been performed with ajoene,[56] *S*-allylmercaptocysteine (SAMC),[57,58] DAS and fresh garlic,[37,39] $DASO_2$,[59] and diallyl disulfide (DADS)[60] and garlic oil.[61] Although the animal evidence appears substantial, doses in these experimental studies are often high, from 5 g/kg body weight for fresh garlic extracts to between 25 and 200 mg/kg for isolated OSCs. These do not translate into typical dietary doses of garlic or normal supplemental or therapeutic intake using garlic extracts.

The only available human study, conducted by Gwilt et al.,[62] examined the effects of 3 months' pretreatment with AGE at a dose equivalent to six to seven cloves of garlic daily in healthy volunteers. A 1-g dose of acetaminophen was given before garlic treatment, and at the end of each month for 3 months, urinary and plasma measurements levels of acetaminophen and its conjugates were taken. A slight increase in sulfate conjugates was found, but no significant reduction in acetaminophen or its metabolites was noted. This study did not directly examine toxic doses of acetaminophen, but rather was seeking to determine effects of garlic on subtoxic levels of the drug, which may be different from effects at higher exposure levels.

Further human studies are required to establish whether the data from rodent experiments can be extrapolated to clinical practice.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Despite the experimental demonstration of garlic-acetaminophen interaction in animal models and the known inhibition of CYP450 2E1 in humans by garlic OSCs, garlic's clinical and therapeutic significance is not established. Disulfiram, a pharmaceutical inhibitor of 2E1, has been shown to reduce the formation of NAPQI in healthy volunteers pretreated with a single dose, 10 hours before receiving 500 mg acetaminophen toxicity from overdose or from chronic alcohol consumption.[50] In the study previously described, Gwilt et al.[62] failed to find similar effects exerted by garlic in healthy volunteers. Given that acetaminophen poisoning is a serious condition requiring intensivist management, garlic use as an acute management strategy would be inappropriate in this context. For alcoholic patients with any degree of compliance, however, the addition of garlic by diet or supplementation would appear to be a logical counter to the chronic effects of alcohol on 2E1 induction.

Dipyridamole and Related Antiplatelet Thromboprophylactics

Evidence: Dipyridamole (Permole, Persantine).

Extrapolated, based on similar properties: Antiplatelet thromboprophylactics: Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal); cilostazol (Pletal), clopidogrel (Plavix), ticlopidine (Ticlid); combination drug: ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Interaction Type and Significance

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Garlic extracts and OSC compounds have established antiaggregatory effects. Coadministration of garlic with dipyridamole results in synergistically increased antiplatelet effects. Although related antiplatelet agents may operate through different mechanisms, net disabling of platelets is likely to be increased. Professional monitoring and management of this theoretical additive interaction are required.

Research

A number of in vitro and animal experiments suggest that garlic and certain garlic OSCs, particularly ajoene, exert significant antiplatelet activity through a variety of routes, including inhibition of ADP-induced aggregation.[63-70] Multiple mechanisms are involved and include membrane fluidity changes, inhibition of phospholipase C, inhibition of calcium mobilization, increase in nitric oxide and cyclic adenosine monophosphate (cAMP) production, and inhibition of thromboxane A_2 (TXA_2), all of which are antiaggregatory in effect.[71,72] Human studies have demonstrated antiaggregatory and antithrombotic activity in vivo with various forms of garlic, in healthy individuals as well as patients with atherosclerotic disease.[15-17,63,67,73-75]

Apitz-Castro et al.[76] employed ajoene, a garlic OSC found in oil preparations but not in AGE or powdered garlic, in an aggregometric investigation of the effects of the garlic compound on collagen-evoked platelet aggregation on the blood of healthy volunteers. The investigators also examined the effects of indomethacin, dipyridamole, and forskolin alone, as well as in combination with the ajoene. The effects of coadministration were found to be a synergistic (i.e., greater than additive) increase in aggregation for the combinations. In the case of dipyridamole, the median inhibiting dose ID_{50} was decreased fourfold with garlic. Harenberg et al.[77] found that although fibrinolysis increased after 4 weeks of garlic consumption in healthy volunteers, collagen-evoked and ADP-evoked aggregation remained unchanged.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Dipyridamole is primarily used in conjunction with coumarin anticoagulants in cardiac valve replacement patients and seldom used as a primary antiplatelet drug, compared with the commonplace "baby aspirin" or clopidogrel, as well as the emerging oral glycoprotein IIb/IIIa receptor–binding drugs. Although direct clinical data on the interaction are lacking for most antiplatelet agents, extrapolation appears warranted by the existing pharmacological data. Determination of context will define whether coadministration should be adopted or avoided within specific patient populations. For example, within an integrative therapeutic context, hyperlipidemic patients with or without a history of thrombosis or coronary artery disease (CAD) would benefit from addition of garlic consumption, with monitoring of the levels of coadministered antiplatelet pharmaceuticals and close attention to symptoms, including peripheral bleeds and INR increases. Patients at risk of thromboembolism invariably receive several drugs in combination to achieve anticoagulation and thromboprophylaxis. With professional management, the addition of garlic to these regimens may improve overall outcomes, as well as enable lower doses of the drugs, which may decrease the likelihood of adverse drug effects.[78,79]

Doxorubicin and Related Anthracycline Chemotherapy Agents

Evidence: Doxorubicin (Adriamycin, Rubex).

Extrapolated, based on similar properties: Daunorubicin (Cerubidine, DaunoXome), epirubicin (Ellence, Pharmorubicin), idarubicin (Idamycin, Zavedos), mitoxantrone (Novantrone, Onkotrone).

Similar properties but evidence indicating no or reduced interaction effects: Doxorubicin, pegylated liposomal (Caelyx, Doxil, Myocet).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:	Evidence Base:
3. Possible	○ **Preliminary**

Effect and Mechanism of Action

Anthracyclines generate free radicals that cause oxidative damage, particularly microsomal lipid peroxidation, through an iron-dependent process, which results in cardiotoxicity and adverse effects on other tissues, distinct from their antitumor actions. Garlic extracts exert a protective effect against cardiotoxicity from doxorubicin by specific enhancement of endogenous myocardial antioxidants and possibly by additional, unknown mechanisms. The interaction has been demonstrated in animal experiments; clinical studies and reports are unavailable to date.

Note: Cardiotoxicity is similar between equipotent doses of doxorubicin and daunorubicin, slightly lower for epirubicin, and only one-sixth that of doxorubicin for equipotent doses of mitoxantrone. Doxil (liposome-encapsulated doxorubicin) has negligible cardiotoxicity, presumably because of negligible cardiac exposure to the active drug with the pharmacokinetics of the liposome-encapsulated preparation.

Research

Doxorubicin is a highly effective antineoplastic agent, but acute and chronic cardiotoxicity is an adverse effect occurring in up to one third of the patients treated after a cumulative dose of 300 mg/m^2, and increasing sharply beyond a cumulative dose of 360 mg/m^2. The resultant irreversible and dose-dependent cardiomyopathy limits its clinical usefulness. The chronic form of anthracycline-induced cardiotoxicity may only manifest years after initial exposure, after an apparently asymptomatic interval, and has been documented two decades after treatment.[80] Cardiotoxicity of anthracycline chemotherapy agents is multifactorial and partly involves oxidative stress mediated by an iron-catalyzed Fenton reaction; iron-chelating agents such as dexrazoxane have been shown to decrease doxorubicin cardiac toxicity. The mechanisms of cardiotoxicity are considered to be distinct from the tumoricidal activity of the compounds.[81]

Several animal studies have examined the effects of garlic and OSCs on doxorubicin-induced cardiotoxicity. Intraperitoneal administrations of AGE[82] and DADS[83] were found to exert cardioprotective effects. Oral doses of garlic extracts (20 and 100 mg/kg) induced significant changes in the redox status of mouse red blood cells (measured by MDA generation and glutathione peroxidase activity) after doxorubicin exposure.[84] Mukherjee et al.[85] used fresh garlic homogenate administered to rats at oral does of 250 and 500 mg/kg daily for 30 days, followed by a single dose of Adriamycin, 30 mg/kg. Cardiotoxicity was reduced according to histopathological criteria. In addition, myocardial redox

enzyme activity (catalase, superoxide dismutase, glutathione peroxidase) was increased, and tumor necrosis factor alpha (TNF-α) expression was reduced.

These experimental studies provide preliminary support for the potential interaction, but it remains to be established whether oral doses of garlic extracts or purified OSCs in humans can generate sufficient concentrations in vivo to correspond to the micromolar levels employed in the in vitro and animal models. Research into garlic and OSC pharmacokinetics in vivo is required to establish dose parameters for the interaction in clinical practice. Nonetheless, the multifactorial antioxidant effects of garlic are being increasingly understood, with extensive implications for inflammatory and cardiovascular diseases as well as cancer.[41,86]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Acute cardiotoxicity can be evaluated by creatine kinase, particularly the cardiac specific MB isoenzyme. Chronic cardiotoxicity can be monitored using electrocardiography and left ventricular performance monitored by computerized M-mode echocardiography measuring the ejection fraction and/or MUGA scan (nuclear medicine technique for measuring cardiac ejection fraction), both of which are reliable and highly sensitive noninvasive parameters for evaluating myocardial contractility.

Anecdotal clinical experience has indicated that therapeutic benefit can be obtained in patients with existing doxorubicin-induced cardiomyopathy and clinical congestive heart failure using L-carnitine, coenzyme Q10, taurine, fish oil, magnesium, and hawthorn *(Crataegus)* leaf/flower and berry extracts, at least in some cases. Given the additional pluripotent effects of garlic OSCs on signal transduction in cancer cells, including cell cycle arrest, induction of apoptosis, and inhibition of inflammatory cytokines, as well as inhibition of multidrug (P-gp) resistance, there would appear to be good grounds for incorporating garlic extracts into prechemotherapy protocols for prophylaxis of anthracycline-induced cardiotoxicity.[41,87,88] Integrative management with these nutrients, botanicals, and appropriate pharmaceuticals may be of greatest clinical benefit, when applied by health care professionals trained and experienced in both nutritional therapeutics and conventional medicine. Randomized controlled clinical trials in this area would be of great interest.

Hydroxymethylglutaryl Coenzyme A (HMG-CoA) Reductase Inhibitors (Statins)

Atorvastatin (Lipitor), fluvastatin (Lescol, Lescol XL), lovastatin (Altocor, Altoprev, Mevacor), combination drug: lovastatin and niacin (Advicor), pravastatin (Pravachol), rosuvastatin (Crestor), simvastatin (Zocor), combination drug: simvastatin and extended-release nicotinic acid (Niaspan).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

The mechanism of garlic-induced hypocholesterolemic activity is multifactorial but includes inhibition of cholesterol synthesis at the level of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase. Coadministration of garlic with pharmaceutical HMG-CoA reductase inhibitors may enable lower statin drug doses, resulting in reduced risk of drug-related adverse effects.

Research

The pharmacology of garlic's cholesterol-lowering action is multifactorial, and remains to be fully characterized.[89] In vitro studies with rodent and human hepatocyte models of cholesterol synthesis have demonstrated that HMG-CoA reductase inhibition is a significant but not the sole mechanism.[90-93] More recent data implicate inhibition of sterol-4α-methyl oxidase as being the major enzyme involved.[94]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Although efficacy has been established by numerous clinical trials, the magnitude and clinical significance of the hypocholesterolemic effects of garlic extracts are controversial, according to meta-analyses of the available trial data.[1,3,95] In clinical practice, however, incorporation of garlic and garlic extracts into integrative hypolipidemic protocols with a variety of nutritional and botanical agents is commonplace. The increasingly widespread prescription of HMG-CoA reductase inhibitors by primary health care providers for relatively moderate cholesterol elevations (or previously normal-range values) has raised concerns about the potential long-term effects of depletion of coenzyme Q10 by these agents, particularly in populations with history of serious CAD and myocardial infarction.[96] Degree of coenzyme Q10 depletion by statins depends on several factors, including patient age, but a positive correlation exists between level of dosage and level of depletion (see Coenzyme Q10 monograph).

For patients experiencing adverse effects of statin drug therapy, such as myalgias and fatigue, it is possible that drug dose levels may be lowered without loss of efficacy by combination with garlic. For patients with a previous history of cardiac disease also prescribed statin therapy, prudence would suggest that prophylaxis of cardiomyopathy should not only include coadministration of coenzyme Q10 to appropriate levels, but also incorporate integrative hypocholesterolemic protocols that may allow exposure levels to statins to be lowered or, in some cases, the drug to be replaced by non-pharmaceutical interventions. Other groups at specific risk, such as renal allografts, may also be considered for this approach.[28]

Mucositis-Inducing Chemotherapeutic Agents, Including Fluorouracil, Bleomycin, Doxorubicin, and Ethanol

Evidence: Fluorouracil (5-FU; Adrucil, Efudex, Efudix, Fluoroplex), methotrexate (Folex, Maxtrex, Rheumatrex). Extrapolated, based on similar properties: Bleomycin (Blenoxane), doxorubicin (Adriamycin, Rubex), and others.

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
4. Plausible

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

Mucositis (oral and intestinal) can be a dose-limiting adverse effect of certain chemotherapies. Preliminary evidence

suggests that garlic extracts may exert a protective activity at the mucosa, which may reduce mucositis and increase ability to sustain required doses of chemotherapy. The clinical significance of the interaction remains to be established. A possible ulceroprotective effect against ethanol-induced gastropathy has been noted, which may be considered a related interaction.

Research

Garlic and OSCs are known to have antioxidant and anti-inflammatory effects. Recent evidence has indicated garlic modulates of inflammatory cytokines in various tissues, including intestinal epithelia. Spontaneous secretion of TNF-α in Caco-2 cells was inhibited by allicin, which also suppressed interleukin-8 (IL-8) and interleukin-1 (IL-1), while inhibiting degradation of INF-κ (thus increasing NF-κ inhibition).[97] Together with multiple effects of OSCs on redox status and eicosanoid metabolism, several plausible mechanisms underlie the potential protective effects against chemotherapy-induced mucositis, as demonstrated in animal models for both methotrexate and 5-FU using dietary AGE.[98,99] Related oxidative mechanisms are involved in ethanol-induced gastric ulceration. Another rodent study observed that an oral garlic oil preparation (0.25 and 0.5 mg/kg) administered 30 minutes before ingestion of ethanol (1 mL) reduced the ulcer index, increased antioxidant enzyme levels, and reduced lipid peroxidation compared with controls.[100] Extrapolation from these studies to in vivo human oral consumption ultimately depends on a fuller understanding of OSC pharmacokinetics than is currently available.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Treatment of chemotherapy- or radiation-induced mucositis (oral and intestinal) is particularly amenable to integrative strategies employing combinations of botanicals agents (see also Aloe and Licorice Root monographs) and nutrients such as glutamine, vitamin E, and beta-carotene. Combination protocols are often used in integrative oncology environments, despite the lack of published trial support at present. The possible inclusion of garlic/OSC extracts in such protocols is an interesting possibility because similar to capsicum, the herb is popularly considered to have a gastroirritant potential, and as with capsaicin, garlic in fact can exert gastroprotective effects. Additionally, garlic OSCs interact with a number of molecular targets with a resultant anticancer action. At present the optimal form and dose of garlic extracts in any such protocol need to be established empirically; ultimately, clinical trials are required to establish the benefits of adding garlic for treatment of chemotherapy-related mucositis.

Saquinavir and Related Antiretroviral Protease Inhibitors

Evidence: Saquinavir (Fortovase, Invirase).
Extrapolated, based on similar properties: Amprenavir (Agenerase), atazanavir (Reyataz), brecanavir, darunavir (Prezista), fosamprenavir (Lexiva), indinavir (Crixivan), nelfinavir (Viracept), tipranavir (Aptivus); combination drug: lopinavir and ritonavir (Kaletra).
Similar properties but evidence indicating no or reduced interaction effects: Ritonavir (Norvir).

Interaction Type and Significance

✗ Potential or Theoretical Adverse Interaction of Uncertain Severity

◇◇ Impaired Drug Absorption and Bioavailability, Precautions Appropriate

Probability:
3. Possible

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

Saquinavir, like all protease inhibitors, is a cosubstrate of CYP3A4 and P-gp. A pharmacokinetic interaction has been demonstrated in healthy volunteers, in whom garlic significantly reduced drug bioavailability. Further data are needed to establish the precise mechanism and clinical significance before extrapolations to other antiretrovirals and to HIV-1 patient populations are fully warranted.

Research

Piscitelli et al.[101] administered garlic extracts, with an allicin content equivalent to four to six garlic cloves per day, to 10 healthy volunteers for 3 weeks. Before and after the garlic treatment period, saquinavir was administered for 3 days (1200 mg three times daily), and blood samples were taken to measure pharmacokinetic parameters. After a 10-day washout period, the saquinavir dose was repeated and a further sample measured. Peak concentration and AUC (area under curve) of saquinavir were reduced by 54% and 51%, respectively, and after the washout period, levels did not return to baseline but were approximately 60% to 70% of the pretreatment values. The authors suggested that either induction of intestinal 3A4 reduced the bioavailability or P-gp may be involved, rather than changes in systemic clearance. Failure to return to baseline levels after the washout period is unexplained. A further finding that complicates interpretation of this study was the separation of the small number of subjects into two distinct groups. The first group had no significant change in saquinavir AUC with garlic, but exhibited a drop in AUC after the washout period. The other group had a significant drop in saquinavir AUC with garlic, but postwashout AUC was less than baseline. This bimodal pharmacokinetic result awaits a satisfactory explanation.

Garlic administration does not significantly affect the single-dose pharmacokinetics of the related protease inhibitor ritonavir in healthy volunteers after 4 days of acute dosing with garlic, according to a study by Gallicano et al.[102] However, the dose of garlic in this study was relatively low (10-mg odorless capsules daily), and a trend was noted to decreased bioavailability. Ritonavir powerfully inhibits and induces CYP3A4, and a single dose cannot be extrapolated to steady-state kinetics of therapeutic administration. Available experimental studies implicate both P-gp and intestinal 3A4 in ritonavir and saquinavir clearance modulation. An in vitro investigation using a MDR1-transfected MDCK cell model for assaying P-gp efflux activity found that allicin inhibited P-gp–mediated efflux of ritonavir in a dose-dependent fashion.[103] Mouly et al.[104] used another in vitro model, the Caco-2 cell, to examine the kinetics of saquinavir in relation to 3A4, P-gp, and serum protein binding and implicated both 3A4 and P-gp, but not serum albumin, in saquinavir availability.

Case reports are lacking.

Clinical Implications and Adaptations

Patients with HIV/AIDS are likely to use garlic preparations. Such use, if self-prescribed, should be disclosed to the prescribing physician or specialist team managing the patient's drug regimen. However, blanket cautions regarding dangers of

herbal modulation of antiviral drug therapy for HIV patients are arguably inappropriate, although frequently made in the literature. It is well known that long-term retroviral agents in HIV-infected patients exhibit kinetic differences that are not necessarily revealed by short-term studies in healthy volunteers. Both saquinavir and ritonavir are known to exhibit decreases in AUC over several months of administration in infected patients.[108] The interactivity of the antiretroviral drugs with each other and with unrelated drugs is well known among HIV/AIDS specialist providers and most patients. Polypharmacy is common, and viral load is invariably monitored as an indicator of antiviral therapeutic efficacy. Serum drug levels should be monitored directly; serum dosage, timing of administration, and drug combinations may need to be adjusted accordingly and frequently. (See also St. John's Wort monograph, Indinavir section.)

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), fluindione, nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar), warfarin (Coumadin, Marevan, Warfilone).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:
4. Plausible

Evidence Base:
▽ **Mixed**

Effect and Mechanism of Action

A theoretical additive effect between coumarin anticoagulants and garlic upon hemostasis is hypothesized to increase INR and/or increase risk of bleeding. Reliable reports of the interaction are unavailable, and direct pharmacodynamic interaction is contradicted by the clinical data.

Research

Substantial data suggest that garlic and OSC components of garlic exert in vitro and in vivo antiaggregatory effects (see Antiplatelet Thromboprophylactics earlier). However, data demonstrating effects of garlic on coagulation proper (i.e., secondary hemostasis), through interference with the production or action of soluble coagulation factors, are unavailable.

Reports of bleeding induced by garlic alone are rare, and of the three reports available, none appears to demonstrate a causal link between garlic consumption and hemorrhagic episodes. Spontaneous spinal epidural hematoma in an 87-year-old man who consumed an average of four garlic cloves daily for an unstated duration was attributed to garlic.[19] In their review of the evidence for interactions between warfarin and garlic, however, Vaes and Chyka[13] noted that such epidural hematomas are rare, and the cause is unknown in 40% of cases.[13] Another anecdotal report involved postoperative bleeding following mammoplasty; atypical "bloody oozing" was noted during surgery, and a 200-mL hematoma developed postoperatively and was later evacuated. The patient had apparently had a "heavy garlic intake" preoperatively, although preparation, dose, and duration of intake were not specified. At a second, later mammoplasty, after discontinuation of garlic, the bleeding did not recur.[20] A third case involved a 72-year-old man who experienced postoperative hemorrhage after a standard transurethral prostate resection procedure. He required transfusion with 4 units of blood. The patient later admitted habitual garlic consumption, the preparation and dose of which were not stated.[18]

A warfarin-garlic interaction is suggested by authoritative secondary sources, such as the ESCOP[10] and WHO[11] therapeutic monographs, both of which base this claim on a single anecdotal report by Sunter in 1991. The report underlying this apparent interaction was a short letter from Sunter containing inadequate information that failed to mention the form, preparation, dose, duration of administration, comedications, or case history details, or even the magnitude of the apparent INR change.[106] This report has been challenged as "unreliable," scoring zero in the scale of report reliability devised by Fugh-Berman and Ernst.[107] Meanwhile, unsupported claims that garlic prolongs INR are repeated by derivative sources without substantiation.[108] A controlled trial using AGE at 1200 mg/day for 4 weeks versus placebo in eight patients, all stable taking warfarin, found no significant changes between garlic and placebo when INR was compared to baseline levels after garlic administration.[109] Another trial with 48 patients monitored potential bleeding and thromboembolic episodes during anticoagulant therapy with warfarin while consuming AGE at 5 mL twice daily for 12 weeks. No adverse events or changes in hemostatic or platelet parameters were noted.[21]

Reports

Pathak et al.[110] reported a case in which garlic tablets consumed at 600 mg/day for 12 days apparently reduced the INR of an 82-year-old patient previously stable taking fluindione. The case reporting seems reliable, and the report is somewhat unexpected because fluindione is an indanedione derivative similar to phenindione, which is used as vitamin K antagonist anticoagulant, mainly in France. Cessation of garlic tablets restored the INR within 4 days. The authors suggested a possible pharmacokinetic induction by garlic compounds of the CYP450 enzymes responsible for metabolizing the drug, or a possible effect on serum protein binding.[110] Assessment of the case is problematic; fluindione is known to exhibit extreme individual variation in pharmacokinetics, and the pathways of its metabolism are not definitely established.[111]

Clinical Implications and Adaptations

The 4-hydroxycoumarin compound warfarin is the most widely used anticoagulant drug in the Western world. It is known for a high variability in interindividual and intraindividual response. The primary individual factors affecting response variability are age and polymorphisms of CYP450 2C9.[112] The incidence of warfarin-related bleeding complications is difficult to estimate because of methodological issues surrounding data collection and interpretation. Recent calculations suggest that improved anticoagulation control has reduced the serious adverse drug reaction (ADR) category of "major bleeds, non-fatal" incidence to approximately 2.5% to 8.0%, with a "minor bleed" incidence of about 15% per year. Fatal bleed estimates vary from 1% to 4.8% per year.[113] Warfarin interacts with a wide range of drugs, including antibiotics, central nervous system agents, and cardiac drugs, as well as many dietary ingredients, most of which increase anticoagulation.[114]

All this confounds the already-complex situation of determining the medical appropriateness, form, and level of anticoagulation, especially in older individuals with multiple risk

factors for bleeding, such as unstable INR, comorbidities (especially bleeding related), polypharmacy (especially with NSAIDs), advanced age, and difficulty in compliance with requirements of coagulation control.

Synergistic or additive interaction between warfarin and garlic is effectively unproven. It has been well argued that anticoagulation and antithrombotic therapy exemplifies the methodological and theoretical limits that pervade the discussion of interactions in general; in particular, the development of more precise tools to test for potential interactions is needed.[115,116] Meanwhile, candidates for garlic coadministration with warfarin might best be reviewed on a case-by-case basis before using garlic extracts, and if appropriate, they should be monitored for signs of increased peripheral bleeding after initiating coadministration.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Chlorzoxazone

Chlorzoxazone (Paraflex, Parafon Forte, Relaxazone, Remular-S).

Several pharmacokinetic studies examining the effect of garlic and its OSCs on CYP450 2E1 have used chlorzoxazone probe methodology (see Effects on Drug Metabolism and Bioavailability). Because a degree of 2E1 inhibition has been established by these studies, this finding is "reversed" by some authors into a presumed or purported interaction. However, the therapeutic index of chlorzoxazone is not such to warrant a particular caution, and in practice, drug dose levels and frequency of this antispasmodic are often adjusted to the required level of symptom relief. Given the lack of reports of the interaction and its likely minimal significance, it is currently classified here as "overstated."

Isoproterenol

Isoproterenol (Isoprenaline; Isuprel, Medihaler-Iso).

The nonselective beta-adrenergic receptor agonist isoprenaline was originally used in inhalant form for asthma and parenterally for cardiac resuscitation. In most applications, it has now been replaced by more selectively acting agents. Coadministration of garlic with isoprenaline in animal models has shown that garlic may reduce the proarrhythmic adverse effects associated with the drug, as well as minimize or prevent ischemic and necrotic damage to the heart (and other organs) that can result from exposure to excessively high doses of the drug.[117-119] Some secondary sources list this as an established interaction, based on the animal evidence.[120] In everyday practice, the drug is little used, and in any event it is improbable that isoproterenol would be administered at doses that might induce necrotic organic toxicities. Of interest, however, are related animal studies that have demonstrated an antiarrhythmic activity in garlic extracts in experimentally induced models of ventricular and supraventricular arrhythmias.[121-123]

Oral Hypoglycemic Agents and Insulin

Buformin (Andromaco Gliporal, Buformina), chlorpropamide (Diabinese), glimepiride (Amaryl), glipizide (Glucotrol; Glucotrol XL), glyburide (glibenclamide; Diabeta, Glynase, Glynase Prestab, Micronase, Pres Tab), insulin (animal-source insulin: Iletin; human analog insulin: Humanlog; human insulin: Humulin, Novolin, NovoRapid, Oralin), metformin (Dianben, Glucophage, Glucophage XR); combination drugs: glipizide and metformin (Metaglip), glyburide and metformin (Glucovance); tolazamide (Tolinase), phenformin (Debeone, Fenformin), tolbutamide (Orinase, Tol-Tab).

A handful of early studies conducted in the 1960s and 1970s suggested hypoglycemic activity in experimental or animal models, and these data have been used to suggest a speculative interaction with insulin.[124,125] Of the few human investigations that examined blood sugar parameters in response to garlic or OSCs, most have failed to detect significant hypoglycemic activities resulting from garlic consumption, although some trials have noted trends toward lowered blood glucose levels.[2,16,74] One study noted bimodal gender differences in glycemic responses to garlic, with females experiencing elevation and males reduction of blood sugar.[126] Recent evidence suggests that garlic extracts may be protective against diabetes-induced sequelae by inhibiting glycation.[127,128] Antioxidant cardioprotective and vasodilatory effects are also relevant in diabetic patients. However, significant reduction of blood glucose levels does not appear to be a viable therapeutic strategy in management of diabetes, and interactions with oral hypoglycemics would seem to be speculative based on current data.

Surgery

The literature contains two reports of postoperative bleeding purported to be associated with garlic use, as discussed earlier under Warfarin and related Oral Vitamin K Antagonist Anticoagulants. However, the data in both cases are inadequate to ascribe causality to the herb. Given the lack of reports of either spontaneous or postoperative bleeding associated with garlic use, it would appear that moderate garlic use is generally safe for those undergoing elective surgery. Preoperative measurement of bleed times or temporary cessation of garlic consumption may be prudent management strategies, depending on individual circumstances. It is axiomatic that herb and nutrient intake are disclosed before surgery; however, the general risk associated with garlic appears to be overstated in the secondary and derivative literature.

The 128 citations for this monograph are located under Garlic on the CD at the back of the book.

Ginger

Botanical Name: *Zingiber officinale* Roscoe.
Pharmacopoeial Name: Zingeribis rhizoma.
Synonym: *Amomum zingiber* L.
Common Names: Ginger, zingiber.

SUMMARY

Drug/Class Interaction Type	Mechanism and Significance	Management
Anesthesia, general ⊕⊕/☼	Herb reduces postoperative nausea and vomiting (PONV) caused by anesthetic. Possible alternative to pharmaceuticals in moderate PONV. Insufficient activity for emetic rescue in acute cases.	Consider pretreatment in elective surgery patients. Postoperative treatment may help moderate cases.
Antiplatelet agents ✗	Theoretical interaction based on "NSAID-like" properties of ginger. Clinical occurrence and significance not established. Increased risk of bleed negligible.	Preferably avoid; if coadministration compelling, professional monitoring advised.
Cisplatin Emetogenic chemotherapy ⊕⊕/☼	Ginger reduces acute nausea associated with cisplatin and other emetogenic antineoplastic chemotherapies.	Consider pretreatment, and posttreatment (up to 24 hours) for nausea.
Nonsteroidal anti-inflammatory drugs (NSAIDs) Antiarthritic analgesics ⊕⊕⊕/☼	Herb used as adjuvant with antiarthritic NSAIDs increases symptom relief and reduces side effects of drug by allowing lower doses.	Consider coadministration in appropriate populations.
Phenprocoumon Oral vitamin K antagonist anticoagulants ✗	Theoretical additive effects on hemostasis (similar to aspirin/warfarin combinations). One case report, conflicts with clinical data; suggests risk generally overstated.	Preferably avoid; if coadministered, maintain stable regimen and monitor INR.

PONV, Postoperative nausea and vomiting; *INR*, international normalized ratio.

HERB DESCRIPTION

Family

Zingiberaceae.

Habitat and Cultivation

Perennial, with tuberous rhizomes, native to Southeast Asia, and cultivated in tropical regions, including India, West Indies, Jamaica, Africa, and China.

Parts Used

Rhizome.

Common Forms

Fresh or Dried Rhizome: considered different agents in Chinese practice.
Dried Powdered Rhizome.
Tincture (1:5), Fluid Extract (1:1), 90% ethanol, fresh or dried rhizome.
Standardized Extracts: Various, including EV.EXT 33 (Ferrosan) standardized to hydroxy-methoxy phenols; Zintona standardized to 1.4% volatiles and minimum of 2.0 mg gingerols and shogoals per 250-mg capsule.

HERB IN CLINICAL PRACTICE

Overview

Best known as a pungent spice and dietary ingredient, ginger is among the top-20 dietary supplements in retail sales in the United States. Primarily viewed by conventional medicine as an antiemetic for motion sickness, the nausea of pregnancy, and postoperative nausea, the herb has many more, diverse therapeutic applications in both Western and Asian botanical medicine. It has potent anti-inflammatory effects on eicosanoid metabolism, circulatory and digestive tonic actions, and metabolic, endocrine, antimicrobial, antipyretic, antioxidant, and antineoplastic activities. Toxicity is minimal, and ginger is free of adverse effects at therapeutic doses.

Therapeutic monographs for ginger generally limit the indications to recent clinical trial–driven applications. Ginger was approved by the German Commission E in 1988 for dyspepsia and motion sickness, although not for morning sickness.[1] The European Scientific Cooperative on Phytotherapy (ESCOP)[2] recently reviewed much of the research but also suggested only motion sickness and postoperative nausea prevention as clinical uses. Broader authoritative surveys of the herb can be found in literature reviews by Mills and Bone[3] and McKenna et al.[4] Recent interest in the cancer chemopreventive properties has provided a new emphasis in pharmacological research into ginger and its constituent compounds.[5,6]

Historical/Ethnomedicine Precedent

Ginger has been used for centuries in Ayurvedic and Chinese medicine, where it is a major ingredient in innumerable formulae for many treatment indications. In India, ginger is not only widely used as a spice and meat preservative and antimicrobial digestive tonic, but also considered to have aphrodisiac and cognitive-enhancing effects, especially on memory, and has also been used as a narcotic antagonist. In classical Chinese medicine, the fresh rhizome *(Sheng Jiang)* is distinguished from the dried and processed rhizome *(Gan Jiang)*. In light of modern precautions suggesting elevated risk of bleeding with ginger consumption, an interesting Chinese medical use

of dried ginger is to arrest bleeding, especially bleeding associated with "Deficiency" and "Cold."[7] Doses of the herb in Chinese practice are considerably higher than in modern phytotherapy, maximum dosage for Sheng Jiang is 30 g.[7] Traditional Western botanical medicine considers ginger to be a "diffusive stimulant," to be added to formulae to enhance the bioavailability of other herbs, as well to support diffusive physiological processes (e.g., expectoration, diaphoresis).[4]

Known or Potential Therapeutic Uses

Appetite stimulation, dyspepsia, flatulence, digestive/choleretic secretory stimulation, increasing bioavailability of foods and medicines, ulceroprotection, circulatory stimulation, thermogenesis, menstrual flow irregularities, colds, influenza, fevers, atherosclerosis, hypercholesterolemia, hyperviscosity, hepatic protection, pain relief in osteoarthritis and rheumatoid arthritis, Kawasaki's disease, antiemesis in nausea of motion, pregnancy, drug withdrawal, and chemotherapy; antineoplastic adjuvant.

Key Constituents

Pungent oleoresin containing phenolic gingerols and their dehydration derivatives, shogoals (formed by drying); volatile oil (variable composition of monoterpenes and sesquiterpenes depending on botanical chemotypes and physical methods of preparation).

Therapeutic Dosing Range

Fresh or Dried Rhizome: 2 to 4 g daily.
Tincture 1:5 (90% ethanol): 1.25 to 3.0 mL three times daily.
Fluid Extract 1:1 (90% ethanol): 0.25 to 0.75 mL three times daily.
Standardized Extract: Dose equivalent to 2 to 4 g dried rhizome daily.

INTERACTIONS REVIEW

Strategic Considerations

The available therapeutic monographs on ginger minimize suggestions of herb-drug interactivity. The German Commission E listed ginger interactions under "none known,"[1] ESCOP[2] mentions only the possible increase in bioavailability of sulfaguanide, and the World Health Organization (WHO)[8] monograph suggests an "enhancement" of pharmaceutical anticoagulant therapy, adding that the clinical significance of the possible interaction has not been evaluated. By contrast, secondary literature and commentators in both professional and popular press emphasize potential anticoagulant effects of ginger and freely extrapolate to hypothetical interactions with drugs affecting hemostasis.

The presumed mechanism of interference with normal hemostasis by ginger is based on in vitro studies that suggest the herb may affect platelet aggregation, primarily through inhibition of eicosanoid metabolism and specifically reduction of thromboxane levels.[9] However, the experimental support is inconclusive, and to date the balance of in vivo studies suggest a lack of effect of ginger on thromboxane-induced platelet aggregation in humans.[10–15] Until recently, clinical reports were based only on a questionable single case report of platelet aggregation inhibition apparently attributed to the consumption of ginger marmalade.[16] A recent single report of elevated international normalized ratio (INR) and epistaxis in a patient previously stable on phenprocoumon anticoagulant therapy is discussed later.[17] However, no pharmacological data show that ginger affects the coagulation pathways reflected by the INR, so this case remains an isolated and unexplained interaction, its significance unclear. The existence of only two somewhat controversial reports in a quarter century suggests that portentous warnings about risks of combining ginger with anticoagulants may be overstated.

The activity of the herb as an anti-inflammatory, analgesic, and circulatory stimulant has led to its incorporation in protocols for arthritis. Coadministration of ginger in combination regimens with nonsteroidal anti-inflammatory drugs (NSAIDs) or analgesics for arthritis has been examined indirectly in trials that permitted NSAID/analgesic rescue or in one trial where patients added ginger to an existing NSAID regimen.[18–20] Although further investigations are warranted, there may be neither significant additive effect between NSAIDs and ginger alone in arthritis nor any significant difference between NSAIDs and ginger alone for arthritic symptom relief. However, ginger's adverse effect profile is superior to conventional NSAID drugs, and ginger could be incorporated into combination protocols for botanical cyclooxygenase-2 (COX-2) inhibition in arthritis and related inflammatory conditions to maintain integrity of the protective, constitutive gastric cyclooxygenase and prostaglandin E_2 (PGE_2). Common compound formulations with ginger include herbs such as rosemary, *Boswellia*, and the plant-derived compound resveratrol, which act as COX-2 inhibitors at the receptor level and also downregulate inducible COX-2 transcription. Ginger extracts have been shown to exert an ulceroprotective effect against aspirin and indomethacin, implying the pharmacology of ginger-containing combination protocols targeting COX-2 could be applied to a variety of inflammatory conditions, including malignancy.[21]

The established antiemetic effects of ginger, well proven for motion sickness and morning sickness of pregnancy, have also been found to be helpful in drug-induced nausea and vomiting. The strong association of certain antineoplastic chemotherapies (e.g., cisplatin) with acute nausea, as well as postoperative nausea and vomiting (PONV) associated with emetogenic anesthetics, constitute beneficial interactions with ginger (see anesthetics and chemotherapies later). Ginger may well find application in the treatment of other cases of drug-induced nausea when symptom occurrence is not inevitable; one report suggests that it can be used for nausea relating to symptoms of disequilibrium after discontinuation of serotonin-inhibiting drugs.[22]

Effects on Drug Metabolism and Bioavailability

An experimental study found that ginger enhanced the absorption of sulfaguanidine across the small intestine in rodents.[23] Secretory increases by the pancreas and bile are also associated with ginger administration.[24] An early study suggests glucuronide conjugation and renal and biliary excretion are involved in elimination of the volatile component zingerone.[25] In rats, [6]-gingerol was eliminated partly by hepatic metabolism, and the gingerol was more than 90% bound to serum protein.[26]

Traditionally, ginger has been used to promote the absorption of herbs in multiherb botanical prescriptions. The Ayurvedic *Trikatu* formula is a mixture of ginger with long-pepper and black pepper that has been shown to increase the bioavailability of several pharmaceuticals.[27] A more recent study of the effect of Trikatu on the kinetics of sodium

diclofenac found the opposite effect: a significant reduction of bioavailability.[28] These studies are not applicable directly to ginger alone, and the piperine ingredient of the other herbs in the formula are known to have modulating effects on several cytochrome P450 isoforms.[29]

Data on potential effects of ginger and its constituents on drug-metabolizing enzymes are largely unavailable at this time. Although traditional botanical prescribing conventions may use ginger for increasing bioavailability of other herbs, the effects on pharmaceutical drug absorption are not predictable on the basis of the current data. One study has documented an inhibitory effect on P-glycoprotein (P-gp). Accumulation of daunorubicin was increased in a multidrug-resistant cell line in the presence of [6]-gingerol, which also appeared to increase the cytotoxicity of vinblastine, suggesting an inhibition of P-gp–mediated efflux of the cytotoxic drug from the cells.[30] Until further data are available, the prediction of P-gp–mediated drug-ginger interactions remains speculative, if theoretically possible.

HERB-DRUG INTERACTIONS

Anesthesia, General

Evidence: Atracurium (Tracrium), fentanyl (Actiq Oral Transmucosal, Duragesic Transdermal, Fentanyl Oralet, Sublimaze Injection), hyoscine hydrobromide, combination drug: morphine hydrochloride, codeine hydrochloride, and papaverine hydrochloride (Papaveretum); suxamethonium (scoline, succinylcholine; Anectine), thiopentone (Thiopental), vecuronium (Norcuron).
Extrapolated, based on similar properties: Emetogenic anesthetics.

Interaction Type and Significance
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **3. Possible**
Evidence Base: **▽ Mixed**

Effect and Mechanism of Action
Anesthesia-induced PONV may be reduced by pretreatment with ginger extracts, which probably act at both central serotonergic and peripheral gastric levels to inhibit emesis.

Research
Six trials performed over 15 years specifically examined the effects of ginger pretreatment on the severity and incidence of PONV.[31-36] All trials involved gynecological settings, and the majority (five of six) involved laparoscopic outpatient procedures, with a total of 668 subjects across all the studies. Powdered ginger in capsules was used in all cases, with oral doses ranging from 0.5 to 2.0 g of herb, administered 1 to 3 hours before the procedure, although one trial also administered ginger both before and after the procedure.

In a meta-analysis of only three of the trials, Ernst and Pittler[37] concluded that the evidence for ginger efficacy in PONV was positive. However, a more recent meta-analysis by Morin et al.[38] that included all six trials available to date concluded that the antiemetic effects of ginger were insufficient to consider the incorporation of the herb into the PONV clinical setting.

Visalyputra et al.[35] examined 111 women undergoing laparoscopic gynecological diagnostic procedures, divided into placebo, ginger-only, droperidol, and droperidol/ginger groups. The dose of ginger was divided into 1.0 g before the procedure and another 1.0 g 30 minutes before discharge. No significant differences were found between placebo and the other groups.[35] The only notably positive study was by Phillips et al.,[36] who used 1 g ginger 1 hour before anesthesia. The ginger appeared to be equally effective to metoclopramide (10 mg) in reducing nausea, both being significantly better than placebo.[36]

A recent meta-analysis of these trials concluded that there was definite evidence for a positive effect of ginger at 1.0 g per day for PONV.[39]

Integrative Therapeutics, Clinical Concerns, and Adaptations
Although the trial evidence is not conclusive, there would appear to be reasonable grounds for patients undergoing elective procedures who may prefer nonpharmaceutical options, when available, to utilize ginger pretreatment before procedures involving anesthesia. Data are not available for emetic rescue, and conventional use of metoclopramide or dexamethasone may be required after exposure to emetogenic anesthetics. The risks of bleeding to anticoagulant effects of the herb are discussed in the following sections on antiplatelet agents and phenprocoumon. Theoretical cautions against combining ginger with anesthetics have also been made on the basis of a single rodent study in which administration of isolated [6]-gingerol and [6]-shogoal at doses of 3.5 mg/kg induced increases in hexobarbital sleep time in rats.[40] Equivalent human doses of ginger powder or fresh ginger would be orders of magnitude higher than normal therapeutic dose levels of the herb.

Antiplatelet Agents

Antiplatelet thromboprophylactics: Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin), ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal); cilostazol (Pletal), clopidogrel (Plavix), dipyridamole (Permole, Persantine), ticlopidine (Ticlid); combination drug: ASA and extended-release dipyridamole (Aggrenox, Asasantin).
Monoclonal antibody antiplatelet agents: Abciximab (ReoPro), eptifibatide (Integrelin), tirofiban (Aggrastat).

Interaction Type and Significance
✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability: **6. Unknown**
Evidence Base: **▽ Mixed**

Effect and Mechanism of Action
A theoretical interaction extrapolated from the "NSAID-like" activity of ginger and its active compounds through inhibition

of thromboxane-evoked platelet aggregation, creating an assumed additive disabling of platelets. The interaction has not been clinically demonstrated to date.

Research

Equivocal results have been obtained in experimental and in vitro studies attempting to characterize effects of ginger extracts and isolated ginger compounds on platelet aggregation, although there is evidence for a dual inhibitory effect on eicosanoid synthesis, with lipoxygenase as well as cyclooxygenase subject to inhibition.[14,15,41-43] COX-2 effects may be mediated by the effect of [6]-gingerol on nuclear factor kappa B (NF-κB) activation. Kim et al.[44] used a mouse skin model and found evidence of the ginger compound blocking phosphorylation of I-κBα as well as p65. This was reversed by a p38 mitogen-activating protein (MAP) kinase inhibitor, implicating the p38 MAP kinase signaling pathway of NF-κB as the upstream mediator of COX-2 downregulation.[44]

Four human studies have investigated the effects of ginger on platelet aggregation. Verma et al.[45] examined the effects of a fatty diet (100 g butter for 7 days) on platelet aggregation in 20 healthy volunteers. Ten individuals also consumed 5 g dried ginger with the fatty meal. Adenosine diphosphate (ADP) and epinephrine-induced platelet aggregation was significantly lower in the butter-plus-ginger group than in the butter-only group. Lumb[12] conducted a small, double-blind randomized trial with eight healthy volunteers who consumed 2 g ginger or placebo. No effect was found on any parameters of platelet activity (samples taken 3 and 24 hours after ginger administration), including bleed time, aggregometry, and platelet count. Srivastava[10] measured platelet thromboxane in human volunteers before and after 7 days consumption of 5 g/day fresh garlic or 70 g/day raw onion. Thromboxane B_2 (TXB_2) levels (measured after sample clotted by incubation for 1 hour) were reduced by approximately one third in the ginger group ($n = 7$). The small sample size was statistically underpowered ($p < 0.1$). The onion-consuming group exhibited a trend to increased TXB_2 after clotting.

Another study investigated the effects of ginger on TXB_2 with higher doses of ginger administered by vanilla custard, with 15 g raw ginger daily or 40 g cooked stem ginger for 2 weeks, in 18 healthy volunteers of both genders. There was no washout period in the crossover design, and when venous blood samples were taken on both day 12 and day 14, no significant change in TXB_2 levels was detected between either form of ginger and placebo. In contrast, an earlier pilot study by the same researchers had detected significant (39%) TXB_2 reduction after only 3 mg/day administration of acetylsalicylic acid (ASA).[13] Bordia et al.[11] used a placebo-controlled trial to examine the effects of powdered ginger administered at 4 g daily for 3 months in 60 patients with a history of coronary artery disease. Blood lipids and glucose, plasma fibrinogen, and fibrinolytic activity, as well as ADP and epinephrine-induced platelet aggregation, were measured at 1½ and 3 months. No significant differences were found between the placebo and ginger groups in any of the parameters measured. However, a single 10-g dose of ginger did produce significant reduction in platelet aggregation evoked by the two test agonists measured 4 hours after ginger administration.

Jiang et al.[46] conducted a small, open-label trial (12 healthy male volunteers) and examined a range of pharmacokinetic and hemostasis parameters after administration of ginger or ginkgo, alone or with warfarin. Aggregation, INR, warfarin enantiomer concentrations in plasma and urine, and warfarin enantiomer binding were all measured at day 1 and day 7. The dose of ginger was three tablets of 0.4 g powdered rhizome three times for 1 week. Neither ginger nor ginkgo produced significant effect on clotting status or the pharmacokinetics and pharmacodynamics of warfarin.

Clinical Implications and Adaptations

The quality of the evidence is variable, partly because of small sample sizes, different forms of ginger tested (or different purified compounds), and differing doses used. However, the balance of available data suggests that the effects of ginger compounds on cyclooxygenase and lipoxygenase inhibition do not appear to have detectable clinical effects on primary hemostasis. By extension, it appears that ginger can be safely utilized at therapeutic doses along with antiplatelet and anticoagulant medications. Theoretically, for certain individuals with unique pharmacogenomic susceptibility or subclinical platelet disorders, ginger preparations might interact adversely with either antiplatelet or anticoagulant agents.

Cisplatin and Emetogenic Antineoplastic Chemotherapies

Evidence: Cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox).
Extrapolated, based on similar properties: Carboplatin (Paraplatin), mechlorethamine (nitrogen mustard; Mustargen), oxaliplatin (Eloxatin), phenylalanine mustard (Melphalan), uracil mustard (uramustine).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Evidence Base:
○ Preliminary

Effect and Mechanism of Action

Nausea and vomiting are predictable adverse effects of certain chemotherapies, typically cisplatin and nitrogen mustards, and often occur with various other agents. The established antiemetic activity of ginger may be effective against acute (<24 hours) chemotherapy-induced nausea and vomiting, possibly through serotonergic mechanisms.

Research

Morrow[47] surveyed 442 oncology outpatients receiving consecutive chemotherapy and found that 16% who reported susceptibility to motion sickness were more likely to experience nausea and vomiting after chemotherapy than matched controls. Ginger has been investigated in numerous trials for the treatment of various kinds of nausea, including motion sickness, postoperative nausea, and morning sickness. The majority of studies have been positive, and a meta-analysis of six randomized double-blind placebo-controlled trials concluded that ginger was a "promising antiemetic remedy" in 2000, although more data are required to draw firm conclusions.[37] Sharma et al.[48,49] investigated preadministration of acetone and alcoholic extracts of ginger in rodent and canine models of cisplatin-induced emesis. Cisplatin inhibits gastric emptying, and the endpoint used is the delay in gastric emptying associated with the antiemetic agent. Acetone ginger extracts (200 and 500 mg/kg orally) were more significantly effective

than the 5-hydroxytryptamine (5-HT_3) receptor antagonist ondansetron in delaying gastric emptying in rodents. In canines, researchers using a similar procedure, but with the ginger extracts (25-200 mg/kg) given 30 minutes after cisplatin, also caused a dose-dependent reduction in emesis and increase in emetic latency compared with controls. Aqueous extracts were ineffective. The acetone extract of ginger was more effective than the alcoholic extract, preventing emesis in 20% of dogs, compared to none for the alcoholic extract. Yamahara et al.[50] found that oral administration of [6]-gingerol (25 or 50 mg/kg orally) or an acetone extract of ginger (150 mg/kg orally) pretreatment could completely prevent cyclophosphamide-induced emesis in a rodent model.

The antiemetic mechanisms of ginger compounds were investigated by Abdel-Aziz et al.[51] using three different molecular models. They concluded that although an effect on 5-HT_3 receptor ion-channel complex was definitely implicated, there were also indirect effects, possibly through substance P and muscarinic receptors.[51] Finally, in a wider context but still within the oncology setting, a rodent model was used to demonstrate that ginger may also be effective in radiation-induced taste aversion.[52]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Three temporal phases of chemotherapy-induced nausea are distinguished: *anticipatory* (occurring before exposure), *acute* (onset within or lasting up to 24 hours of exposure), and *delayed* (onset more than 24 hours after exposure, typically 48 to 72 hours, with variable duration). The anticipatory type is independent of the specific agent of both the type of cancer and the chemotherapy regimen, essentially a conditioned response. The acute form is most susceptible to treatment with antiemetic agents, whereas delayed symptoms are less susceptible to antiserotonergic agents, suggesting that different mechanisms may be involved.[53,54] Although human studies are lacking, ginger extracts have been used clinically by practitioners versed in botanical medicine to prevent and treat the acute phases of chemotherapy-induced nausea typified by the emetic effects of cisplatin.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) and Analgesic Antiarthritics

COX-1 inhibitors: Diclofenac (Cataflam, Voltaren), combination drug: diclofenac and misoprostol (Arthrotec), diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), furbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen); combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen); indomethacin (indometacin; Indocin, Indocin-SR), ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Aleve, Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).
COX-2 inhibitors: Celecoxib (Celebrex).

Interaction Type and Significance

⊕⊕⊕ **Beneficial or Supportive Interaction, Not Requiring Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
2. Probable

Evidence Base:
○ Preliminary

Effect and Mechanism of Action

Ginger and ginger extracts exert anti-inflammatory effects through multiple mechanisms, including cyclooxygenase and lipoxygenase inhibition. Adjuvant combination of ginger with NSAIDs for arthritis leads to increased symptom relief and allows the NSAID dose to be lowered and in some cases discontinued. Ginger has a superior adverse effect profile to known NSAIDs, and coadministration reduces adverse effects through lower NSAID dose or eventual substitution.

Research

In vitro evidence has established that ginger and some of its constituent compounds are effective inhibitors of cyclooxygenase and lipoxygenase and may downregulate transcription of cyclooxygenase and inducible nitric oxide synthase (iNOS) by inhibition of NF-κB.[21,42-44] Two randomized placebo-controlled clinical trials have demonstrated small but significant effects for ginger treatment of osteoarthritis, although in the study by Bliddal et al.[19] the effect was small compared with ibuprofen and was confined to a first period of treatment in a crossover design. The trial by Altman and Marcussen[20] showed a significant effect in 261 patients with osteoarthritis of the knee, although the ginger extract was administered in combination with the herb galangal *(Alpinia galangia)*. Acetaminophen was permitted as a rescue medication in both studies. The ginger group had less use of rescue medication than the placebo group. Additionally, several rodent experimental model studies have shown that ginger extracts are directly protective against NSAID-induced gastric ulcers in a rodent model.[55-58]

Reports

Srivastafa and Mustafa[59] reported a case series of seven patients who used ginger extracts combined with NSAIDs, but who were not taking other antiarthritic medications (e.g., gold) or steroids. Six patients were taking NSAIDs for 3 months but failed to experience symptom relief. After 3 months of oral ginger administration (up to 5.0 g fresh rhizome or 1.0 g powdered rhizome daily), while continuing NSAID therapy, the patients all experienced reduction in pain symptoms and improved range of motion, and two patients also experienced relief of myalgia. After 3 months of coadministration the NSAIDs were stopped; the patients continued with ginger alone and were able to maintain the same degree of symptom relief.

Integrative Therapeutics, Clinical Concerns, and Adaptations

The adverse effect profile of NSAIDs, including the COX-2 specific inhibitors, continues to present significant problems to the pharmaceutical anti-inflammatory strategies for arthritis. Ginger extracts may additively combine with NSAIDs and after a period of coadministration can substitute for them in some cases. Health care professionals versed in botanical medicine are more likely to incorporate ginger into polyherbal anti-inflammatory formulae rather than use it as a single agent. Typical associated ingredients might include curcumin, *Boswellia serrata*, resveratrol, and the salicylate-containing *Salix* spp.

Phenprocoumon and Related Oral Vitamin K Antagonist Anticoagulants

Evidence: Phenprocoumon (Jarsin, Marcumar).
Extrapolated, based on similar properties: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), warfarin (Coumadin, Marevan, Warfilone).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability: **4. Plausible**

Evidence Base: ▽ **Mixed**

Effect and Mechanism of Action

A theoretical additive effect between coumarin anticoagulants and ginger on hemostasis is hypothesized to increase INR and risk of bleeding. Unsupported by the currently known pharmacology of the herb, a single report of the possible interaction is available. The clinical significance of the proposed interaction is minimal.

Research

There are no human studies investigating pharmacodynamic effects of ginger on the vitamin K–dependent clotting factors II, VII, IX, and X. Weidener and Sigwart[60] conducted a series of experimental investigations with EV.EXT 33 ginger extracts on Wistar rats, including a study of the effects of oral warfarin (0.25 mg/kg daily) alone and in combination with the ginger extract. Warfarin significantly increased prothrombin time (PT) and activated partial thromboplastin time (APTT) compared with normal controls. Coadministration of ginger extract at 100 mg/kg for 4 days had no effect on warfarin-induced changes in PT and APTT and did not alter these coagulation parameters in a control group receiving no warfarin.[60]

In a recent study described earlier under Antiplatelet Agents, Jiang et al.[46] found that ginger and ginkgo had no significant effect on clotting status or the pharmacological profile of warfarin.

Pharmacokinetic data demonstrating any effect of the herb on drug-metabolizing enzymes mediating coumarin drug metabolism (cytochromes P450 1A2 and 2C9) are also unavailable. Further studies are required to establish definitively an absence of effect of ginger on coagulation, but the balance of currently available evidence suggests such effects are unlikely.

Reports

A single German case involving ginger and phenprocoumon was reported by Krüth et al.[17] in 2004. A 76-year-old woman with a history of mitral insufficiency, atrial fibrillation, congestive heart failure, and osteoporosis who was taking concurrent cholecalciferol, captopril, piretanide, digoxin, and a nitrate vasodilator was maintaining a stable INR (range, 2.0 to 3.0) while receiving long-term phenprocoumon therapy. Because of a peripheral bleed incident (epistaxis), she was admitted to hospital, and INR was greater than 10. Phenprocoumon was stopped, and she received three doses of vitamin K_1 (initially 10 mg intravenously, then 5.0 mg and 3.0 mg orally after 3 and 6 days, respectively). By day 6, the INR and PTT normalized and phenprocoumon was resumed, with INR maintained at normal levels by the same dose used before the bleeding episode. A detailed history revealed "a regular ginger intake (pieces of dried ginger and tea from ginger powder)" for several weeks before the bleeding incident occurred. The patient was advised to refrain from ginger use, and no further episodes of bleeding were noted. The authors note that the current pharmacological data on ginger do not provide any obvious mechanism for the observed effects.

The report, although complete in some respects, lacks vital information. The exact form, amount, dose, frequency, and duration of ginger administration are not given, making the incident impossible to evaluate. Further, "Dried ginger pieces" is an unusual form of ingesting the herb given its pungent and acrid taste, and "ginger tea" does not exclude the presence of nonginger ingredients. The ginger was apparently consumed for several weeks before the INR elevation. Case data show a rapid elevation of INR between two measurements 7 days apart. Relating this to an unstated dose of ginger consumed several weeks earlier does not constitute a reasonable association by timing for the INR effect to be causally associated with the herb consumption. The INR plots show values maintained within therapeutic range for more than a week before the bleed episode, presumably during the "several weeks" consumption of ginger. The observed INR increase might be explained by excessive phenprocoumon levels caused by inadvertent drug misadministration, a dietary pharmacokinetic interaction, or sudden decrease in dietary intake of vitamin K–containing foods, none of which was considered by the authors.[17]

Clinical Implications and Adaptations

The single available case report is insufficient to confirm the existence of a ginger–oral anticoagulant interaction, especially with the lack of a plausible pharmacological mechanism and inadequacies in the report data. In addition, some controlled trial evidence suggests that ginger has no measurable effect on warfarin pharmacokinetics or pharmacodynamics. Until further data are available, it cannot be assumed that moderate ginger consumption exerts clinically significant effects on the coagulation cascade and INR values. As normally occurs with coumarin-effected anticoagulation, monitoring of INR and alerting patients to report early signs of bleeding (e.g., epistaxis, ecchymoses) remain essential elements of vitamin K antagonist therapy. Possible antiplatelet activity cannot be ruled out completely at this time (see Antiplatelet Agents), but epistaxis or other serious bleeding episode would be expected with an INR higher than 10.

The use of cured ginger in Chinese medicine to arrest bleeding in certain conditions has already been mentioned. Anecdotal clinical experience also suggests that at normal therapeutic dose ranges for appropriate indications, ginger and ginger extracts present no significant risk of bleeding in patients on oral vitamin K antagonist anticoagulation.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Aminoglycoside Antibiotics

Amikacin (Amikin), gentamicin (G-mycin, Garamycin, Jenamicin), kanamycin (Kantrex), neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin), netilmicin (Netromycin), paromomycin (monomycin; Humatin), streptomycin, tobramycin (AKTob, Nebcin, TOBI, TOBI Solution, TobraDex, Tobrex).

A preliminary in vitro study by Nagoshi et al.[61] found a potential synergy between aminoglycoside antibiotics and [10]-gingerol against vancomycin-resistant enterococci. The authors suggested that this may be caused by detergent-like effect of the gingerol increasing membrane permeability. Whether this preliminary finding can be replicated in vivo remains to be established.

Sulfaguanidine

Sulfaguanidine

Using an experimental rat intestine model, Sakai et al.[28] demonstrated that ginger extracts enhanced the absorption of sulfaguanidine by 150% compared with controls. This has

been identified as the sole possible ginger-drug interaction by two authoritative secondary reviews.[2,62] Whether or not this is an example of general effects of ginger on intestinal absorption in rodents (see pharmacokinetics discussion earlier), the likelihood of this being a clinically significant interaction, given the limited contemporary use of this agent for enteric infections and the lack of human data, suggests that the interaction is overstated, particularly when identified as the only interaction of ginger with any pharmaceutical agent.

The 62 citations for this monograph are located under Ginger on the CD at the back of the book.

Ginkgo

Botanical Name: *Ginkgo biloba* L.
Pharmacopoeial Name: Ginkgo folium
Common Names: Ginkgo, maidenhair tree.

SUMMARY

Drug/Class Interaction Type	Mechanism and Significance	Management
Anesthesia, general ?	Possible increased sleeping time: mechanism unknown; significance unclear; inadequate data.	Management: same as surgery; eliminate potential interaction.
Acetylsalicylic acid/aspirin Ticlopidine, clopidogrel Antiplatelet agents ✗	Theoretical additive antiplatelet activity; significance not established, likely overstated. Ginkgo may allow lower dose of drug, reducing drug adverse effects.	Avoid or adopt and monitor bleed times.
Cisplatin ⊕⊕/☼	Ginkgo may help reduce platinum drug toxicities (renal, neural).	Consider coadministration.
Cyclosporine ⊕⊕/☼	Ginkgo may help reduce PAF-mediated drug nephrotoxicity. Potentially important for allograft patients.	Consider coadministration.
Doxorubicin Anthracycline chemotherapy ⊕/☼	Ginkgo protects against and reduces drug-induced cardiotoxicity through multiple mechanisms.	Pretreat, coadminister, and continue herb postchemotherapy.
Fluorouracil (5-FU) ?	Suggested additive therapeutic effect caused by increase in drug disposition by circulatory effects of ginkgo.	Coadministration could be beneficial, unlikely to be harmful. Professional advice mandatory.
Fluoxetine SSRI antidepressants ⊕⊕/☼	Ginkgo reduces sexual dysfunction adverse effects (including erectile dysfunction in men) of drug through multiple mechanisms; may have additive antidepressant effects.	Consider trial if symptomatic.
Gentamicin Aminoglycoside antibiotics ⊕/☼	Herb may reduce drug induced ototoxicity through neuroprotective and neuroreparative mechanisms.	Consider trial adoption. Continue herb if symptomatic after antibiotic therapy.
Haloperidol Neuroleptics ⊕/☼	Herb may reduce drug-induced tardive dyskinesia adverse effects through neuroprotective and neuroreparative actions.	Consider adopting. Continue herb if tardive dyskinesia symptoms persist.
Surgery ✗✗✗/⊕✗/⊕	Ginkgo may decrease hemostasis via antiplatelet effects presurgically. Anti-ischemic and neuroreparative postsurgically.	Stop ginkgo 1 week before surgery. Adopt postsurgically if indicated.
Trazodone ?	Mechanism unknown; significance unclear; inadequate data.	Avoid until further data available.
Warfarin Oral vitamin K antagonist anticoagulants ✗	Theoretical additive effects on hemostasis caused by potential platelet inhibition; similar to aspirin/warfarin combinations. Inadequate data; incidence and significance unknown. General risk overstated.	Audit elderly populations for undisclosed herb use. If coadministered, maintain regimen, monitor INR. Hold if INR supratherapeutic or signs of abnormal bleeding occur.

PAF, Platelet aggregation (platelet-activating) factor; *SSRI*, selective serotonin reuptake inhibitor; *INR*, international normalized ratio.

HERB DESCRIPTION

Family

Ginkgoaceae.

Habitat and Cultivation

Sole survivor of an ancient botanical taxon (Ginkgoales), the ginkgo tree is now widely cultivated as an urban ornamental because of its pollution resistance. Considered a "native" to China, large commercial plantations in the temperate areas of the United States and Western Europe provide most crude herb for medicinal extracts.

Parts Used

Leaf.

Common Forms

Dried Leaf: Powdered.
Tincture, Fluid Extract: 50% ethanol.
Standardized Dry Extract: 22% to 27.0% flavonoids and 5.0% to 7.0% terpene ginkgolides. Dry extract preparations usually stipulate maximum permitted levels of ginkgolic acid (< 5 ppm).

HERB IN CLINICAL PRACTICE

Overview

Ginkgo leaf extract is unusual in that its current use originates entirely from European pharmacological studies in the 1960s rather than a long history of traditional use. Notably, many secondary sources incorrectly claim ginkgo has been used for centuries; the fruit or nut, not the leaf, is the traditional

medicine in Chinese herbal practice. Positive clinical trials demonstrating efficacy of ginkgo leaf extract for Alzheimer's disease and other age-related dementias have helped position it as a consistent top-10 best seller throughout Europe and North America in recent years. In the United States, retail sales of ginkgo surpassed $36 million in 2002, and in the same year an estimated 1.375 billion *daily* single treatments of ginkgo were prescribed in Germany alone. This constitutes a substantial volume of post-marketing surveillance data, which generally confirms the minimal toxicity and adverse effect profile of the extract. Adverse effect incidence corresponds to the low levels noted in clinical trials (< 1.5%).

The chemistry of ginkgo leaf extract is complex and includes several unique terpenoid compounds. Research has centered on these compounds' pharmacology, including inhibition of platelet aggregation by ginkgolide B, which is an unusually high-affinity ligand for the platelet aggregation (platelet-activating) factor (PAF) receptor. However, the known pharmacodynamics of the herb are generally considered a synergistic result of multiple constituents, including flavonol glycosides and oligomeric proanthocyanidins, as well as the terpenoids. Almost all the clinical research has been conducted with the concentrated (50:1) standardized *Ginkgo biloba* extracts, EGb 761 and LI 1370. Partly because of interest in potential antiplatelet therapeutic agents, several studies have employed isolates of the diterpene trilactones, either ginkgolide B (BN 52021) alone or a combination of ginkgolides A, B, C, and J (BN 52063); however, these data may have limited application to whole-leaf dry extract. In turn, botanical practitioners often use hydroethanolic liquid extracts of whole leaf when preparing blended individual prescriptions. Such extracts have been poorly investigated compared to the standardized dry-extract material, to which they should not be regarded as therapeutically equivalent. Ginkgo folium has therapeutic monographs by the German Commission E (1998)[1] and World Health Organization (WHO, 1999)[2] and subsequent monographs (2003) by the European Scientific Cooperative on Phytotherapy (ESCOP)[3] and *American Herbal Pharmacopoeia*.[4] Longer works by DeFeudis[5] and van Beek[6] provide more comprehensive and in-depth reviews of the extensive literature.

Historical/Ethnomedicine Precedent

Traditional Western therapeutic indications for ginkgo leaf are absent because of its historically recent incorporation into the materia medica, although seeds have been used in Chinese medicine for centuries.

Known or Potential Therapeutic Uses

Altitude sickness, asthma, Alzheimer's disease and multi-infarct dementia; cerebral insufficiency and associated impairments of memory, learning, attention, and cognitive function (enhancement of these functions in healthy and in aging adult populations, as well as after head trauma); depression, dysmenorrhea, hypoxia; neuroprotection, ischemic protection (cardiac, cerebral, renal), and neurorestoration of disease and iatrogenic nerve damage; macular degeneration, neurosensory deficits including tinnitus, cochlear hearing impairment, oxidative stress, peripheral vascular disorders including intermittent claudication and Raynaud's disease; reduced retinal blood flow, vertigo.

Key Constituents

Terpenes: Ginkgolides A, B, C, and J (diterpene trilactones); bilobalide (sesquiterpene).

Flavonoids: Glycosides of quercitin, kaempferol, and isorhamnetin; (+)-catechin, (−)-epicatechin, (−)-epigallocatechin, and (+)-gallocatechin; oligomeric and polymeric procyanidins.
Phenolic acids, including ginkgolic acid; essential oil.

Therapeutic Dosing Range

Fluid Extract: 1:1, 3.0 to 8.0 mL/day.
Standardized Extract: 120 to 240 mg/day in divided doses.

Note: Unless otherwise stated in this monograph, ginkgo leaf and ginkgo leaf extract refer to the standardized solid extract preparations that have formed the basis of almost all studies of ginkgo leaf.

INTERACTIONS REVIEW

Strategic Considerations

The consensus of the authoritative botanical monographs is that there are no established interactions between ginkgo leaf (or its standardized extracts) and prescription drugs. Some secondary sources suggest that interaction with anticoagulants is theoretically possible.[3,4] From the conventional side, *Stockley's Drug Interactions* cites several herbs that interact with anticoagulants, but does not include ginkgo.[7] Given the widespread use of ginkgo and its multisystem actions, classified by DeFeudis[5] into four broad categories (vasoregulation, cognition-enhancement, stress alleviation, gene regulation), the range of possible interactions may be larger and more complex than suggested by the current literature and reports.

The literature is uneven in quality, leading to interpretive problems. Botanical monographs have distinguished between effects of traditional forms of ginkgo leaf preparations (and the properties of the 50:1 standardized extracts) and effects of isolated constituents (e.g., terpenoid ginkgolides). Conventional sources frequently fail to distinguish form, dose, and duration of administration of ginkgo extracts in their reporting; often also misspelling the name of the herb as "gingko."[8-10] Despite the low quality of reports, some trends emerge when reviewing secondary literature.

A tendency of ginkgo extract alone to induce spontaneous bleeding (i.e., in healthy individuals) is often assumed in mainstream reports of ginkgo interactions; this is controversial. Relative to its high level of use, very few reports of spontaneous bleeding are actually attributable to ginkgo use.[16-19] The poor standard of adverse event reporting of ginkgo-associated bleeds has been criticized both in journal correspondence and in several review articles.[20,21] The apparent consensus of the reports on bleeding is that although ginkgo leaf extracts may have been associated with some hemorrhagic episodes, particularly ophthalmic neurovascular bleeds, causality is not established, and the general risk is probably overstated. At least three trials in healthy volunteers have failed to demonstrate any significant effect of ginkgo on platelet and coagulation parameters in healthy humans.[22-24] Larger-scale trials are needed to investigate potential hematological effects of the extract, particularly in older populations. Several reports of postoperative bleeding are described later in the discussion of surgery.

Coadministration of ginkgo extracts with drugs affecting hemostasis presents questions with no simple evidence-based answers at present. Careful individual assessment and monitoring, with case-by-case therapeutic choices, remain the best practice. Given that the herb has been confirmed by meta-analysis of clinical trials to be effective for peripheral arterial

disease, the precise populations that may choose gingko self-prescription may also be those more at risk of potential interactions because of their use of prescription drugs affecting hemostasis. (See further discussion later in the sections on interactions involving antiplatelet agents and warfarin.)

A number of the beneficial interactions of ginkgo listed later relate to its anti-ischemic, antioxidant, neuroprotective/neuroreparative, and chemoprotective effects. Typically, these interactions involve reduction of drug-induced toxicities, such as nephrotoxicity or neurotoxicity, through multiple mechanisms. these protective effects against drug toxicities most likely apply to numerous medications other than those for which preliminary evidence already exists; see doxorubicin, cyclosporine, gentamicin, and haloperidol later. Integrative oncological applications for ginkgo may include radiation sensitization as well as chemoprotection.[25] The role of ginkgo extracts in integrative oncological protocols is a new area of study.[5,26]

Pharmacokinetics

There are some pharmacokinetic data on ginkgo extracts in both animal models and humans. Bioavailability of both the triterpene lactones and flavonol glycosides is high, with figures up to eighty per cent for some ginkgolide fractions. The flavonol glycosides are rapidly absorbed, but are extensively metabolized in humans, whilst the terpenoids are excreted unchanged, with overall half-life of about six hours.[27-30] There is animal and human evidence that the extract constituents can cross the blood-brain barrier.[31-33] The ginkgo flavonoids quercitin, kaempferol, and isorhamnetin are themselves substrates of P-glycoprotein (P-gp).[34]

Effects on Drug Metabolism and Bioavailability

Until recently, the question of whether *Ginkgo biloba* extracts significantly affect drug-metabolizing systems had not been systematically investigated. Initial data from in vitro studies was typically inconclusive or conflicting, but results of more recent in vivo human trials now suggest minimal effects of the herb on cytochrome P450 (CYP450) activity.

Gurley et al.[35,36] studied the effects of ginkgo in both young adults and, interestingly, older populations (60-76 years) using the probe–drug cocktail methodology they helped establish as a standard technique for evaluating CYP450 induction and inhibition effects. They found no significant effects of ginkgo extracts on CYP450 1A2, 3A4, 2E1, or 2D6. This corroborates the previous results of Duche et al.,[37] as well as Markowitz et al.,[38] who found no in vivo effect of ginkgo on CYP2D6 or CYP3A4. A negative study with donepezil (Aricept) and ginkgo coadministration in human volunteers failed to find any effects of ginkgo on the pharmacokinetics of the cholinesterase inhibitor.[39] Donepezil is metabolized by 2D6 and 3A4 and is conjugated by uridine glucuronosyltransferase (UGT) enzymes. Two different trials with separate probe substrates have demonstrated a lack of effect on CYP2C9, the warfarin *S*-enantiomer–metabolizing enzyme.[40,41] This corroborates Jiang et al.,[24] who found a lack of pharmacokinetic interaction between warfarin and ginkgo[24] (see warfarin discussion later). A subsequent in vivo trial did detect effects of ginkgo administration on phenotyped variants of CYP2C19 using omeprazole as a substrate; however, this drug is also a potent inhibitor of 2C19, so the general applicability of these results is problematic.[42] At this stage, the possibility of 2C19 interactions remains to be corroborated.

Reliable case reports suggestive of pharmacokinetic interactions between ginkgo and prescription drugs mediated by CYP450 effects are unavailable. Meanwhile, in vitro studies on ginkgo and CYP450 using various models, including rodent and human hepatocytes as well as recombinant enzymes, continue to provide prospective data for in vivo investigations. however, the in vitro models do not correlate well with in vivo data.[43-47]

The issue of possible ginkgo effects on drug transporters has not been well studied to date. Absence of any observed effect of the herb on digoxin levels suggests a probable lack of effect on P-gp.[48] Certain ginkgo flavonoids such as quercitin and kaempferol, which are ubiquitous ingredients, have been shown to inhibit P-gp in vitro, as well as being substrates for P-gp themselves.[49,50]

HERB-DRUG INTERACTIONS

Anesthesia, General

Anesthesia, General

Interaction Type and Significance

? **Interaction Likely but Uncertain Occurrence and Unclear Implications**

Probability:
6. Unknown

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

Anesthetic-induced sleeping time may be altered by pretreatment with ginkgo. The mechanism of action is unknown.

Research

Ginkgo leaf extracts are known to cross the physiological intact blood-brain barrier (BBB) in a rodent model. A shortening effect on narcosis-induced sleeping times was demonstrated when a single intraperitoneal dose of EGb 761 at 25 and 50 mg/kg body weight or ginkgolide B at 1 and 5 mg/kg was administered before sodium barbital–induced narcosis.[51] Ginkgolide A was ineffective. A similar study also found shortening of sleeping time after intraperitoneal administration of hexobarbital, α-chloralose, and urethane in mice.[52] However, these researchers found that ginkgolide A isolate and bilobalide isolate could reproduce the shortening effects of the whole-leaf extract. A human study using quantitative electroencephalographic (EEG) data established that a single 240-mg dose of EGb 761 induced a significant increase in EEG activity 3 hours later, corresponding to that associated with "cognitive activator drugs." This suggests effective penetration of the human BBB.[53]

Clinical Implications and Adaptations

In the absence of reports, and given the small number of rodent studies, this interaction cannot be characterized clearly at this time. The pharmacological evidence for a mechanism is circumstantial, but the prospect that EGb 761 extracts may cross the intact BBB and interact with medications affecting neurotransmission is finite. More research is required to understand the effects of ginkgo extracts on increasing brain activity in opposition to anesthesia.

Given the additional possibility of antiplatelet effects on primary hemostasis during surgical procedure (see surgery), elective surgery patients should be carefully questioned regarding disclosure of self-administered herb use and advised to refrain from ginkgo consumption before surgery, to prevent possible interactions with anesthetics.

Antiplatelet Thromboprophylactics

Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal).
Clopidogrel (Plavix), Ticlopidine (Ticlid)
Extrapolated, based on similar properties: Cilostazol (Pletal), dipyridamole (Permole, Persantine); combination drug: ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability:
3. Possible

Evidence Base:
▽ **Mixed**

Effect and Mechanism of Action

A theoretical pharmacodynamic convergence exists between the inhibitory effects of ginkgo leaf dry extracts on platelet aggregation and the antiplatelet effects of drugs affecting primary hemostasis at the platelet level. The significance of the interaction is unknown but appears to be both overstated and controversial. It may also be regarded as a "contraindication" rather than an interaction, depending on circumstances.

The presumed mechanism is a suggested convergence on platelet disabling by various pathways. Acetylsalicylic acid (aspirin/ASA) is a well-documented antiplatelet agent acting through inhibition of cyclooxygenase production of thromboxane A_2 (TXA_2). Ticlopidine (Ticlid) interacts with glycoprotein IIb/IIIa to inhibit fibrinogen binding to activated platelets and has been used to prevent thrombosis when aspirin is poorly tolerated. After reports of hematological adverse effects associated with ticlopidine, clopidogrel (Plavix) is currently the preferred antiplatelet agent in such cases. As with ticlopidine, clopidogrel is an irreversible antiplatelet drug operating through adenosine diphosphate (ADP) receptor antagonism.

Research

Experimental evidence indicates that the components of ginkgo leaf extract can cause in vitro and ex vivo inhibition of platelet aggregation, probably through several mechanisms. These include increase in endogenous aggregation inhibitors such as nitric oxide (NO) and prostaglandin I_2 (PGI_2), as well as direct inhibition of PAF.[51] However, the evidence for clinically significant effects of ginkgo extracts on platelet aggregation in humans is not available. In fact, Koch[52] showed that the concentrations of ginkgolides required to inhibit human (vs. rabbit) aggregation induced by PAF were more than 100 times greater than the levels demonstrated by pharmacokinetic measurements in humans after normal dosing at 120 to 240 mg EGb 761 daily. In other words, inhibition of PAF (itself a weak aggregatory factor) requires such high concentrations of ginkgolides that clinical effects of ginkgo consumption on platelet aggregation mediated by PAF seem improbable.

Preclinical investigations by European manufacturers of their ginkgo leaf extracts, as part of the toxicological and related regulatory requirements for medicinal product licensing, have been accessed and reported indirectly by DeFeudis[5] and in the 2003 *American Herbal Pharmacopoeia* monograph of the dry extract.[4] Unpublished preclinical studies by Schwabe apparently failed to find any effect of EGb 761 on bleed times at 240 mg/day for 7 days in healthy volunteers, either alone or in combination with acetyl salicylate. The Beaufort-IPSEN-Pharma group sponsored a double-blind trial with 32 healthy volunteers and found no effect on bleed time or other hemostatic parameters after administration of 120 to 480 mg/day for 2 weeks.

A small preclinical study in France administered EGb at three dose levels (120, 240, and 480 mg/day) to 23 normal males for 2 weeks and found no effect on platelet function or coagulation.[23] Another study with healthy volunteers examined the effect of ginkgo extract administration on peripheral microcirculation in normal volunteers with a variety of red blood cell (RBC) and platelet parameters. No effect on platelet aggregation was noted, but a significant increase in RBC aggregation was found.[53] A study with 50 healthy volunteers found no significant effects on coagulation or clotting parameters after 240 mg/day EGb 761 versus placebo for 7 days in a crossover design trial.[22] The same study group continued the investigation into a second phase using the same subjects and assays and found no discernible effect of ginkgo when combined with aspirin, this time versus ASA alone in the same crossover design.

A brief report compared the arterial antithrombotic effect of EGb 761 and aspirin in an animal model using laser-induced emboli. Both aspirin and EGb 761 pretreatment reduced the number and duration of emboli compared with controls. They were not significantly different from each other in antiembolic effect.[54] A rodent study found a potentiation of the effect of ticlopidine by coadministering ginkgo in thrombosis-induced rats, such that 50 mg/kg ticlopidine with 40 mg/kg oral ginkgo was equivalent to 200 mg/kg ticlopidine in inhibition of ADP-dependent platelet aggregation.[55]

Jiang et al.[24] conducted an open-label trial (12 healthy male volunteers) and examined a range of pharmacokinetic and hemostasis parameters after administration of ginger or ginkgo, alone or with warfarin (see later section). Aggregation, international normalized ratio (INR), warfarin enantiomer concentrations in plasma and urine, and warfarin enantiomer binding were all measured at day 1 and day 7. The dose of ginkgo was two tablets of EGb 761 standardized 24/6 three times daily for 1 week. Ginkgo had no significant effect on clotting status or the pharmacokinetics and pharmacodynamics of warfarin.

Reports

Only one report of bleeding associated with aspirin and ginkgo concurrent administration is available. A case of hyphema (retinal bleed) reported in a 70-year-old man with a history of coronary bypass and 3 years of aspirin use at 325 mg/day. One week after commencing standardized ginkgo at 40 mg twice daily, he had a spontaneous bleed in the anterior chamber of the right eye. This resolved on cessation of ginkgo, and there was no recurrence after cessation.[17] This case was classified as a "possible" interaction by Fugh-Berman and Ernst.[20]

Although not involving aspirin, in a related report a 71-year-old man in Germany had taken 40 mg ginkgo extract twice daily for 30 months and started to take 600 mg ibuprofen daily for osteoarthritic pain. After 4 weeks of concurrent use, the patient was found comatose and died the next day from a massive intracerebral bleed. The authors suggest that TXA_2-dependent platelet aggregation was inhibited by the ibuprofen, and that this combined with the antiplatelet effect of ginkgo. Concurrent medications were not recorded.[56]

Integrative Therapeutics, Clinical Concerns, and Adaptations

The frequent suggestions in both professional and consumer literature that the ginkgo-aspirin combination is responsible for significant incidence of major hemorrhagic adverse events are unsubstantiated at this time. A single report and the failure to demonstrate any effects of the combination on bleed times in preclinical studies suggest that potential clinical problems associated with interaction are considerably overstated. Recent trial evidence demonstrating no effects of EGb 761 alone on hemostasis in healthy volunteers suggests that the potential interaction should probably be reclassified as "speculative."[22] However, pending large-scale trials, prudence may warrant a degree of caution.

The mechanism of prophylaxis of cerebrovascular accident (CVA, stroke) by antiplatelet agents is poorly understood. Certain individuals may exhibit "aspirin resistance";[57,58] one study suggested the incidence may be as high as 40%.[59] Also, any prophylactic benefit of aspirin may be caused by secondary rather than primary mechanisms, because hyperactivity of the anucleated platelet is predetermined to a degree at the megakaryocyte level during hematopoiesis.[60,61]

Given the favorable profile of ginkgo extract effects on ischemic reperfusion injury, as well as the demonstrated neuroprotective and neuroreparative properties, there is a supportable argument for the benefits of ginkgo leaf extract as a prophylactic for stroke in *healthy* elderly populations. For those subpopulations with definite indications for prophylactic ASA administration, the combination with ginkgo is unlikely to disrupt hemostasis and may permit the lower dose range of aspirin to be administered, thereby reducing the incidence and severity of gastric mucosal damage. Definitive consensus on the dose of ASA required for effective thromboprophylaxis is not available, but the lower dose of 75 mg/day may suffice in combination with concurrent ginkgo extract use, with less potential gastric mucosal irritation and damage than the higher doses of ASA monotherapy.[62,63] Recent epidemiological evidence suggests that the 75-mg dose of ASA is responsible for the largest number of drug/adverse drug reaction (ADR)–related hospital admissions in the United Kingdom.[64] In this light, the recent (animal) evidence that ginkgo exerts ulceroprotective and cytoprotective effects against inflammation and duodenal ulcers is particularly relevant.[65,66]

Cisplatin and Related Platinum Chemotherapy Compounds

Evidence: Cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ).
Extrapolated, based on similar properties: Carboplatin (Paraplatin), oxaliplatin (Eloxatin).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Platinum compounds have well-documented neurological and renal toxicities. Pretreatment, coadministration, and posttreatment use of ginkgo extracts with platinum chemotherapy may exert protection against drug toxicities. The interaction is unsupported by human evidence.

Research

Two preliminary experimental studies have investigated whether the established neuroprotective and renal-protective properties of ginkgo might be active against platinum toxicity. One rodent study demonstrated that pretreatment with ginkgo reduced cisplatin ototoxicity, as measured by compound action potential–determined auditory threshold and reduced hair cell damage on scanning electron microscopy, compared with cisplatin alone. Blood urea nitrogen (BUN) and creatinine levels were also lower in the pretreatment group, and histological renal damage was lower than in the nonginkgo group. Finally, rates of tumor growth were unaffected by ginkgo-pretreatment versus cisplatin-alone animals inoculated with squamous cell carcinoma SCC-158 line.[67] Another study examined the effects of coadministration (rather than pretreatment) with ginkgo and cisplatin in mice. Sensory nerve conduction velocity and the growth of dorsal root ganglia neurons in culture were superior in the ginkgo coadministration group.[68]

Integrative Therapeutics, Clinical Concerns, and Adaptations

In both animal studies, oral ginkgo dose was moderately high, approximately 100 mg/kg. Assuming known interspecies pharmacokinetic scaling algorithms, this is approximately equivalent to a daily human dose of 1000 mg, which is higher than the normal therapeutic range for ginkgo extracts. However, acute toxicity of ginkgo is low, and the interaction is plausible. Thrombocytopenia should be monitored because the antiplatelet effects of high doses of ginkgo have not been studied. However, human studies are needed to determine the effectiveness of ginkgo against platinum-induced toxicity.

Cyclosporine

Cyclosporine (Ciclosporin, cyclosporin A, CsA; Neoral, Sandimmune, SangCya).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Nephrotoxicity is the principal adverse effect of cyclosporine. Ginkgo may significantly ameliorate cyclosporine-induced nephrotoxicity. In addition, acute rejection responses in cyclosporine-immunosuppressed patients may lead to ischemic damage to the graft organ. Ginkgo offers an additional degree of protection from such damage, which is also mediated in part through PAF.

Research

Cyclosporine is known to increase PAF. Rodent studies with ginkgolide B in cyclosporine-immunosuppressed animals have

shown that the hemodynamic renal damage induced by the drug can be reversed by BN 52021 administration.[69] A rodent study of skin allograft in mice found that whole-leaf ginkgo extract could reproduce the effect of BN 52021 in prolonging allograft survival, although the effect was less than with the ginkgolide B isolate.[70] Animal studies have also suggested a protective effective for cardiac allografts and against cardiac ischemic-reperfusion injury.[71,72] A Japanese in vitro study of the interaction between cyclosporine and BN 52021 in human monocytes from asthma patients suggested that the two agents may be synergistic in reducing inflammatory cytokine production.[73] Another in vitro study, using human liver microsomes, found that EGb 761 abolished cyclosporine-induced lipid peroxidation.[74]

A double-blind pilot study ($n = 20$) examined the effects of pretreatment with BN 52021 both in renal graft donors before harvesting and in recipients before grafting, versus placebo. Immunosuppression was with cyclosporine and prednisone. Posttransplant renal failure was 33% in the placebo group and 0% in the BN 52021 group, who also had better serum creatinine values after transplantation than the controls.[75]

Integrative Therapeutics, Clinical Concerns, and Adaptations

The pharmacological data, although mostly experimental, suggest several potential benefits from the concurrent administration of ginkgo with cyclosporine in immunosuppressed graft patients. The mechanisms underlying improved graft survival and protection against ischemic-reperfusion injury are likely multifactorial. Renal graft patients must confront the paradox that cyclosporine, as well as tacrolimus, is nephrotoxic. Naturopathic physicians and other practitioners of botanical medicine have incorporated ginkgo, along with related renal-protective herbs, into protocols for protective support of renal graft patients.[76] Cyclosporine being a substrate of CYP3A4 should not cause concern in that the pharmacokinetic effects of ginkgo on this enzyme are not considered significant.[36,37] This infrequently discussed interaction could be of great potential value to renal allograft patients, whether using cyclosporine or unrelated immunosuppressants.[77] On a cautionary note, one transplant team reported undisclosed use of ginkgo as being responsible for postoperative bleeding after a hepatic transplant.[14]

Doxorubicin and Related Anthracycline Chemotherapy

Evidence: Doxorubicin (Adriamycin, Rubex).
Extrapolated, based on similar properties: Daunorubicin (Cerubidine), epirubicin (Ellence, Pharmorubicin), idarubicin (Idamycin, Zavedos), mitoxantrone (Novantrone, Onkotrone). Similar properties but evidence lacking for extrapolation: Daunorubicin, liposomal (DaunoXome); doxorubicin, pegylated liposomal (Caelyx, Doxil, Myocet).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Doxorubicin is known to induce dose-related cumulative cardiotoxicity (short term and long term). This may be reduced by concurrent ginkgo administration.

Research

Few studies have directly examined the possibility that ginkgo and its constituents may ameliorate anthracycline-associated cardiopathy. One rodent study examined the effects of concurrent EGb 761 and doxorubicin administration in mice, one group of which was also pretreated with ginkgo before induction of gastric tumors with benzo(a)pyrene. The ginkgo-pretreated animals had a lower tumor incidence and had higher hepatic glutathione and glutathione-*S*-transferase levels. Concurrent doxorubicin and oral EGb 761 did not additively increase the antitumor effect, compared with doxorubicin alone, but reduced cardiotoxic markers, both histological damage and lipid peroxidation levels.[78] Another study examined the effects of EGb 761 on various parameters of doxorubicin cardiotoxicity in otherwise-normal animals. The EGb-treated animals had significantly lower mortality, ascites, myocardial lipid peroxidation, normalization of antioxidant enzymes, reversal of electrocardiographic (ECG) changes, and minimal ultrastructural damage of the heart, compared with doxorubicin alone.[15] In unrelated studies, ginkgo has been shown to ameliorate the adverse effects of bleomycin.[79,80] Antioxidant protectant effects have also been shown for other drugs, including acetaminophen and vancomycin.[81,82]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Doxorubicin is one of the most widely used antineoplastic agents, but its effectiveness is limited by well-documented cardiotoxic adverse effects, which can manifest decades after cessation of treatment.[83] The pathogenetic mechanisms of anthracycline cardiotoxicity are not fully understood, although the ultimate clinical presentation is indistinguishable from typical congestive heart failure. Although an early toxicity may be observed, shortly after commencement of administration (especially in elderly patients), the symptoms of progressive heart failure can appear months or even years after conclusion of the treatment, and the cardiomyopathy initially may be quite asymptomatic. Several possible cardiac protection agents have been examined, but none has been found effective, including vitamin E and *N*-acetyl cysteine. The iron-chelating agent dexrazoxane (Zinecard) reduces cardiotoxicity but has been associated with possible reduction in antitumor effects; part of the doxorubicin toxicity may be caused by FeII-dox-complex free-radical formation.[84]

Based on the preliminary animal evidence, and considering the known pharmacology of ginkgo, patients receiving doxorubicin may benefit from a cardioprotection protocol incorporating ginkgo extracts, together with related herbal agents such as hawthorn and nutritional supplements such as coenzyme Q10 and acetyl-carnitine. Further studies are required to examine the potential benefits of this interaction.

Fluorouracil

Fluorouracil (5-FU; Adrucil, Efudex, Efudix, Fluoroplex).

Interaction Type and Significance

? **Interaction Possible but Uncertain Occurrence and Unclear Implications**

Probability:
6. Unknown

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

A possible effect of EGb 761 on fluorouracil administration in combination with immediate ginkgo pretreatment has been

proposed. This may enhance distribution of the chemotherapeutic agent to tumor sites and reduce side effects.

Research

Ginkgo and 5-FU have been concomitantly administered on colorectal patients[85] and pancreatic cancer patients.[86] These studies used a parenteral preparation (EGb 761-ONC) as a 30-minute intravenous-push pretreatment before administration of 5-FU (500 mg/m^2/day) for 6 days. These were effectively phase II trials. No adverse effects of the combination were noted, and some improvement was recorded in two patients, with a cessation of cancer progression in several who had previously failed the 5-FU. Quality-of-life parameters and median survival times were not altered. The authors suggest further combination investigation may be warranted. The present studies suggest that the combination is safe and does not lead to increased toxicity.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Although the data are preliminary, corresponding to a phase II trial, the effects of ginkgo extracts as a combination agent in chemotherapy not only have the potential to ameliorate drug-induced toxicities (see Doxorubicin), but also may have anticancer effects. This is a promising topic for integrative oncology that requires research and clinical investigation.[87]

Fluoxetine and Related Selective Serotonin Reuptake Inhibitor (SSRI) Antidepressants

Evidence: Fluoxetine (Prozac).
Extrapolated, based on similar properties: Citalopram (Celexa), escitalopram (*S*-citalopram; Lexapro), fluoxetine (Prozac, Sarafem), fluvoxamine (Faurin, Luvox), paroxetine (Aropax, Deroxat, Paxil, Seroxat), sertraline (Zoloft).
Similar properties but evidence lacking for extrapolation: Serotonin-norepinephrine reuptake inhibitor (SSRI/SNRI) antidepressants: Duloxetine (Cymbalta), venlafaxine (Effexor).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **3. Possible**
Evidence Base: ▽ **Mixed**

Effect and Mechanism of Action

Sexual dysfunction is a well-documented adverse effect of SSRI antidepressant therapy. Ginkgo leaf extract may be useful in ameliorating such adverse effects by various mechanisms, including NO-dependent vasorelaxation.

Research

A small number of studies have investigated this possible beneficial interaction, but the evidence is mixed. In a negative study, Kang et al.[88] found an unusually large placebo effect in a 2-month double-blind randomized controlled trial of SSRI-induced sexual dysfunction after ginkgo administration in increasing doses up to 240 mg/day for 8 weeks total. There was no difference between the EGb 761 and control groups, both reporting significant decrease in symptoms of dysfunction. An open trial of men and women using a variety of antidepressant medications with an unspecified ginkgo extract for 4 weeks at an average dose of 209 mg/day reported effectiveness in reducing SSRI-related symptoms, more so in women (n = 33) than men (n = 30).[89] The study was subsequently criticized for methodological weaknesses and inadequate statistical analysis by more than one correspondent.[90,91] A small (n = 22), positive study by Ashton et al.[92] found a slight but incomplete reversal of SSRI-induced sexual dysfunction in men and women after higher-dose ginkgo administration, although the extract product details were not disclosed.

Report

A single case report exists of a woman taking fluoxetine who experienced relief from fluoxetine-induced genital anesthesia after concurrent administration of EGb 761, 180 to 240 mg/day for 2 weeks.[93]

Integrative Therapeutics, Clinical Concerns, and Adaptations

This interaction is plausible but cannot be regarded as firmly substantiated. However, the prevalence of SSRI-related sexual dysfunction and excellent safety and toxicological profile of ginkgo leaf extract, whether alone or in combination, may prompt integrative practitioners to conduct an empirical trial with affected patients. Circumstantial support for this approach derives from the known antidepressant effects of ginkgo and its general effectiveness in combination with a variety of antidepressant medications.[94]

Gentamicin and Related Aminoglycoside Antibiotics

Evidence: Gentamicin (G-mycin, Garamycin, Jenamicin), amikacin (Amikin).
Extrapolated, based on similar properties: Kanamycin (Kantrex), neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin), netilmicin (Netromycin), paromomycin (monomycin; Humatin), streptomycin, tobramycin (AKTob, Nebcin, TOBI, TOBI Solution, TobraDex, Tobrex).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **3. Possible**
Evidence Base: ▽ **Mixed**

Effect and Mechanism of Action

Gentamicin and the aminoglycoside antimicrobials have well-documented adverse effects of ototoxicity and nephrotoxicity. Concurrent administration of ginkgo leaf extract may modulate these toxicities, through multiple mechanisms.

Research

The same researchers who examined protective effects of ginkgo leaf extract against Adriamycin-induced cardiotoxicity (see Doxorubicin) also performed a rodent study to investigate the effects of ginkgo on gentamicin-induced nephrotoxicity. After 2 days of pretreatment with EGb 761 (300 mg/kg op) and 8 days of concurrent administration with 80 mg/kg gentamicin, serum markers of kidney function and histopathology in Wistar rats demonstrated significant protective effects for the ginkgo-combination versus gentamicin-alone group.[95] Another animal study examined neurosensory cochlear damage induced by gentamicin using both electrosensory and histopathological criteria in guinea pigs. Pretreatment with ginkgo extract reduced the level of acute toxic changes.[96] However, in conflict with these studies, another rodent study of ototoxicity induced by the related aminoglycoside alizarin (amikacin, Amikin) suggested that ototoxicity may be

increased by concurrent administration of EGb 761 and alizarin versus alizarin alone.[97]

Integrative Therapeutics, Clinical Concerns, and Adaptations

This potential interaction is an extrapolation from the known neuroprotective and neuroreparative effects of ginkgo extracts. Protection against the neurosensory toxicity and nephrotoxicity of gentamicin is a plausible beneficial interaction with some evidence from animal experiments, but clinical reports and studies are not available. The rodent studies are also open to methodological criticism, particularly the high dosage levels of EGb 761 used, which do not readily translate to normal human dose schedules for the extract.

Based on current data, concurrent administration of gentamicin or aminoglycoside and ginkgo cannot be recommended without qualification. However, if clinical symptoms of cochlear toxicity or vestibular toxicity persist after cessation of aminoglycoside therapy, subsequent ginkgo leaf extract administration likely would be beneficial in helping reverse the symptoms, although in some cases, certain forms of damage (i.e., to hair cells) may be irreversible. Nephrotoxicity caused by aminoglycosides is considered more reversible than ototoxicity, although the evidence from other forms of drug-induced nephrotoxicity would support the use by extrapolation of ginkgo leaf extract in this context. Until further data are available, firm clinical directions about this interaction are not possible.

Haloperidol and Related Antipsychotics

Evidence: Haloperidol (Haldol).
Similar properties but evidence lacking for extrapolation: Chlorpromazine (Largactil, Thorazine), clozapine (Clozaril), fluphenazine (Permitil, Prolixin, Prolixin Decanoate, Prolixin Enanthate), olanzapine (Zyprexa), prochlorperazine (Compazine, Stemetil), quetiapine (Seroquel), risperidone (Risperdal).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **4. Plausible**
Evidence Base: ☐ **Inadequate**

Effect and Mechanism of Action

Haloperidol is a heterocyclic antipsychotic drug associated with adverse effects of akathisia and tardive dyskinesia common to the thorazine group of neuroleptics. A beneficial reduction in adverse effects and an increase in drug efficacy, possibly associated with antioxidant activity of the ginkgo extract, may take place with concomitant administration.

Research

A double-blind trial with refractory schizophrenia patients (n = 109) compared haloperidol, 25 mg/day, alone to the same dose of haloperidol with EGb 761, 360 mg/day, for 12 weeks. Both groups showed some improvement in psychobehavioral scores, although the ginkgo group improved more than the haloperidol-only group. Extrapyramidal symptoms were significantly reduced in the combination group.[98] In two related studies, the same authors repeated these findings and also measured the levels of superoxide dismutase (SOD) before and after treatment with the combination; SOD levels were maintained in the ginkgo group more than the controls. The improvements in psychobehavioral assessment scores were positively correlated with SOD levels.[99,100]

Integrative Therapeutics, Clinical Concerns, and Adaptations

The initial studies by one group of researchers provide an intriguing insight into the possible benefits of combining ginkgo with antipsychotic drugs. The prominent extrapyramidal adverse effects of these agents have long been a cause for concern, particularly during long-term neuroleptic administration, during which tardive dyskinesia symptoms may become irreversible. This has caused some controversy in psychiatric circles, with critics such as Breggin[101] and others suggesting that the *modus operandi* of the neuroleptics in psychotic patients is "brain disabling" by causing cellular damage at the neuronal level.

Although the newer neuroleptic drugs have less severe adverse effects than haloperidol and the thorazine-related heterocyclics, the problem remains significant. The possibility that the established neuroprotective and neuroreparative effects of ginkgo leaf extracts may minimize drug toxicity deserves further investigation. Until more data are available, this must be classed as a "theoretical but plausible" beneficial interaction.

Surgery

Surgery

Interaction Type and Significance

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**
⊕✗ **Biomodal or Variable Interaction, with Professional Management**
⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **3. Possible**
Evidence Base: ☐ **Inadequate**

Effect and Mechanism of Action

Perioperative administration of ginkgo leaf is suggested to increase the likelihood of surgery-related and postoperative bleeding. Ginkgo leaf concentrated extracts have inhibitory effects on platelet aggregation in vitro and ex vivo. Antiplatelet activity may operate not only through inhibition of PAF, but also through other aggregation inducers such as thrombin, ADP, collagen, and arachidonic acid. However, clinically significant in vivo antiplatelet effects have not been established in vivo.

Research

Epidemiological and survey data suggest that consumption of herbal and dietary supplements among preoperative patients is common.[11] Failure to disclose herbal medicine usage may be as high as 70% of patients.[10] Norred et al.[102] surveyed 500 elective surgery patients, of whom 51% used herbal and nutritional products in the 2 weeks before surgery. Of surveyed patients, 24% consumed 50 different herbs; classification by potential adverse effects revealed that 27% of surgical patients consumed natural pharmacological agents that may inhibit coagulation, affect blood pressure (12%), cause sedation (9%), have cardiac effects (5%), or alter electrolytes (4%). Direct studies of ginkgo use in the preoperative scenario are unavailable.

Reports

Several case reports of excessive postoperative bleeding are available, varying in quality from low to unassessable. Fessenden et al.[12] reported a case after laparoscopic cholecystectomy in a patient using an unidentified "gingko" (sic) peparation.[12] The patient was apparently also taking a "multivitamin," the ingredients of which were not disclosed.

The report is impossible to evaluate due to lack of information about the form and dose of the herb.

A report by Norred and Finlayson[103] of postsurgical bleeding following mastectomy after use of high doses of ginkgo extract (375 mg four times daily) involved polypharmacy and thus confounds simple interpretation. The patient was also taking vitamin E (800 IU/day for 10 years) and ginseng (300 mg four times daily for 6 weeks), along with bilberry, astragalus, and several prescription medications, although none that directly affects coagulation.[103] Although a typical "real life" scenario, the case report is difficult to evaluate, particularly the role of ginkgo extract in the adverse event.

Bebbington et al.[104] also reported a case of apparently persistent postoperative bleeding after a hip arthroplasty. The 77-year-old woman was concurrently taking aspirin and "simple anti-inflammatories." Allegation of ginkgo use (120 mg/day) was made by a relative, and the authors attribute the excessive bleeding to the herb. Given the concurrent use of ASA and unspecified anti-inflammatory medications, any single causal attribution seems unwarranted.

Destro et al.[105] report two similar histories of 50-year-old women undergoing plastic surgery who both experienced diffuse perioperative bleeding and subsequent bilateral hematoma after their rhytidoplasty and blepharoplasty procedures. Medical history, concurrent medications, and validation of ginkgo involvement were not given, although apparently both cases were "linked by chronic auto medication with a commercial extract of ginkgo."

Yagmur et al.[106] made a better-documented report of postoperative bleeding with thorough assessments of various coagulation parameters. A 75-year-old woman was taking an 80-mg/day dose of a commercial preparation for more than 1 year before an ambulatory procedure that was followed by extensive bleeding. Postoperative aggregation tests showed a decreased level of aggregation in response to collagen, although ADP, adrenaline, and ristocetin stimuli all resulted in normal aggregation. The patient discontinued the ginkgo postoperatively. Bleed times in response to collagen were reduced from 228 seconds to 168 seconds at 10 days after cessation of the ginkgo.

Clinical Implications and Adaptations

Dire warnings about the dangers of postoperative bleeding with concomitant use of ginkgo extracts are controversial. Norred and Brinker[107] noted that given the established reluctance of patients to disclose herbal medication usage, overzealous admonitions to "discontinue all herbs prior to surgery" may have the effect of further encouraging clandestine herb use by surgical patients, thus hindering patient communication and rapport and compromising patient safety.

Patient safety mandates a preoperative screening for herb-nutrient-drug interactions as a required element of admission. Ginkgo should be included in advisories to elective surgery patients about potential adverse effects of herbs and nutritional supplements on hemostasis, particularly older women undergoing plastic surgery involving ocular areas, based on the limited case reports. The potential interaction should be presented as a possibility that can be sensibly averted by avoiding ginkgo leaf extract consumption preoperatively. However, the stress-alleviating aspects of ginkgo could also be of therapeutic benefit in the postoperative period, and the acute stress of surgery may be ameliorated by ginkgo administration.[87,108]

Trazodone

Trazodone (Desyrel).

Interaction Type and Significance

? Interaction Likely but Uncertain Occurrence and Unclear Implications

Probability:
6. Unknown

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

Trazodone, an antidepressant 5-hydroxytryptamine ($5\text{-}HT_2$) receptor blocker, can cause heavy sedation at antidepressant doses of approximately 400 mg/day. Concurrent ginkgo use could potentiate sedation. The interaction cannot be considered established.

Report

An 80-year-old patient with Alzheimer's disease taking nonsedative doses (20 mg at night) of trazodone commenced ginkgo (form unspecified) at 80 mg twice daily. After 3 days the patient became comatose and was revived by 1 mg of intravenous flumazenil. Both the ginkgo and the trazodone were being used at low levels; concurrent medications were not disclosed. The authors suggest that because of the flumazenil response, benzodiazepine mechanisms were involved (since flumazenil is often used to reverse benzodiazepine-induced intoxication).[9] This single report is insufficient basis to consider the interaction between trazodone and ginkgo extract as established. From the known pharmacodynamics of trazodone, concurrent ginkgo must have been potentiating trazodone effects by at least twentyfold because the patient was taking a nonsedating dose. Some sources include this report under a heading of "possible interactions with benzodiazepines," which is also difficult to justify.[4]

Research

Current research data do not help elucidate the mechanism or likelihood of this interaction. In vitro effects on neuronal transmission and activity remain poorly understood and are undoubtedly complex, as well as unknown in vivo.[109,110] Also, the antidoting mechanism of flumazenil and its principal active metabolite 1-methyl-chlorophenyl-piperazine (mCPP) on benzodiazepines is not fully understood, although it may be independent of the benzodiazepine site.[111] Extrapolations from the available data to support the interaction report are speculative.

Clinical Implications and Adaptations

These are unclear at this time. For older patients (> 75 years) using central nervous system drugs, cautious commencement of ginkgo administration would be prudent. Titration of ginkgo dose toward the desired end-dose range can be made gradually over weeks while monitoring for adverse effects.

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Evidence: Warfarin (Coumadin, Marevan, Warfilone).
Extrapolated, based on similar properties: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar).

Interaction Type and Significance

✗ Potential or Theoretical Adverse Interaction of Uncertain Severity—Avoid

Probability:
3. Possible

Evidence Base:
▽ Mixed

Effect and Mechanism of Action

Theoretical pharmacodynamic convergence occurs between the inhibitory effects of ginkgo leaf dry extracts on platelet aggregation and the hypoprothrombinemic effects of warfarin. The interaction is theorized to increase overall risk of bleeding, although no compelling evidence exists for the clinical occurrence of the interaction, and a single isolated report is contradicted by limited available trial evidence, which suggests the risk may be overstated.

Research

Experimental evidence indicates that the components of ginkgo leaf extract can cause in vitro and ex vivo inhibition of platelet aggregation, probably through several mechanisms, including increase in endogenous aggregation inhibitors such as NO and PGI_2, as well as direct inhibition of PAF.[51] However, the evidence for clinically significant effects of ginkgo extracts on platelet aggregation in humans is mixed.

As discussed under Clopidogrel, preclinical investigations by European manufacturers of their ginkgo leaf extracts for medicinal product licensing have been reviewed by DeFeudis[5] and in the *American Herbal Pharmacopoeia* monograph.[4] Schwabe (the German producers of EGb 761) failed to find any effect on bleed times at 240 mg EGb 761 daily for 7 days in healthy volunteers, either alone or in combination with acetyl salicylate. The Beaufort-IPSEN-Pharma group's double-blind trial with 32 healthy volunteers found no effect on bleed time or other hemostatic parameters after 2 weeks of 120 to 480 mg/day.

In the French study cited earlier (see Clopidogrel), EGb at 120, 240, or 480 mg/day in 23 normal males for 2 weeks had no effect on platelet function or coagulation.[23] A trial of 50 healthy volunteers found no significant effect of ginkgo on clotting and bleed time parameters when administered alone for 7 days, versus placebo in a crossover design.[22] Another study with healthy volunteers examined the effect of ginkgo extract on peripheral microcirculation and found no effect on platelet aggregation but a significant increase in RBC aggregation.[53]

A small clinical study examined the effects of ginkgo on INR in warfarin-anticoagulated patients. The small crossover trial examined the effects of ginkgo leaf dry extract (100 mg/day orally) and coenzyme Q10 on INR values in 14 outpatients (average age, 64.5 years) maintained on warfarin anticoagulation. INR was not affected, and the mean warfarin dose remained unchanged.[112]

Also as previously discussed, Jiang et al.[24] conducted a open-label trial with 12 healthy male volunteers and examined pharmacokinetic and hemostasis parameters after administration of ginger or ginkgo, alone or with warfarin. Aggregation, INR, warfarin enantiomer concentrations in plasma and urine, and warfarin enantiomer binding were measured at days 1 and 7. The ginkgo dose was two tablets of EGb761 standardized 24/6 three times daily for 1 week. Neither ginger nor ginkgo produced any significant effect on clotting status or on the pharmacokinetics and pharmacodynamics of warfarin.

Report

A single report is available that associates concurrent warfarin and ginkgo use with intracerebral hemorrhage. A 78-year-old woman with a history of dementia, myocardial infarction, hypertension, and atrial fibrillation had used warfarin for 5 years since a coronary bypass procedure. She also had a pacemaker. Sudden-onset apraxia was followed by a computed tomography (CT)–based diagnosis of left parietal hemorrhage; her prothrombin time (PT) was 16.9 and partial thromboplastin time (PTT) 35.5. Ginkgo use was discovered (dose, form, and regimen unstated) for the preceding 2 months. Anticoagulation reversed after cessation of warfarin and ginkgo, without vitamin K administration; however, the patient remained apraxic.[113] Fugh-Berman and Ernst[20] characterized this case as "possible," but a single-point score above "unevaluable."

Clinical Implications and Adaptations

The 4-hydroxycoumarin compound warfarin is the most widely used anticoagulant drug in the Western world. It is known for a high variability in interindividual and intraindividual response. The primary individual factors affecting response variability are age and polymorphisms of CYP450 2C9.[114] The incidence of warfarin-related bleeding complications is difficult to estimate because of methodological issues surrounding data collection and interpretation. Recent calculations suggest that improved anticoagulation control has reduced the serious ADR category of "major bleeds, non-fatal" incidence to approximately 2.5% to 8.0%, with a "minor bleed" incidence of about 15% per year. Fatal bleed estimates vary from 1% to 4.8% annually.[63] Warfarin interacts with a wide range of drugs, including antibiotics, central nervous system agents, and cardiac drugs, as well as dietary substances, many of which increase anticoagulation.[115]

All this confounds the already-complex situation of determining the medical appropriateness, form, and level of anticoagulation, especially in older individuals with multiple risk factors for bleeding, such as unstable INR, comorbidities (especially bleeding related), polypharmacy (especially with NSAIDs), advanced age, and difficulty in compliance with requirements of coagulation control.

From an integrative perspective, the patient populations who might benefit most from the neuroprotective and antiischemic effects of ginkgo, such as older (>75 years) individuals with a history of dementia or cerebral ischemia, are also much more likely to be anticoagulated with warfarin.[116] Because no way currently exists to identify those who might be at risk of a ginkgo-induced adverse event, let alone a warfarin-ginkgo interaction, integrative practitioners are arguably confronted by a more complex choice than their conventional care counterparts. This includes whether to switch to different forms of antithrombotic therapy, including strategies based on natural agents such as garlic and nattokinase, to gain benefits from ginkgo administration against possible ischemic damage. (Use of warfarin alternatives is normally restricted to those who have a demonstrated intolerance for the drug.) A case-by-case evaluation, coupled with vigilant monitoring, is essential. Recently available laboratory tests that examine genetic parameters of hypercoagulability, as well as soluble fibrin monomer and dimer, can provide useful information in this regard.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Anticonvulsant Medications

Carbamazepine (Carbatrol, Tegretol), clonazepam (Klonopin), clorazepate (Tranxene), divalproex semisodium, divalproex

sodium (Depakote), ethosuximide (Zarontin), ethotoin (Peganone), felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), levetiracetam (Keppra), mephenytoin, mephobarbital (Mebaral), methsuximide (Celontin), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), phenobarbital (phenobarbitone; Luminal, Solfoton), phenytoin (diphenylhydantoin; Dilantin, Phenytek), piracetam (Nootropyl), primidone (Mysoline), sodium valproate (Depacon), topiramate (Topamax), trimethadione (Tridione), valproate semisodium, valproic acid (Depakene, Depakene Syrup), vigabatrin (Sabril), zonisamide (Zonegran).

Some secondary reviewers recommend avoidance of ginkgo with anticonvulsants because of the presence of a "neurotoxin" in the seed and the extracts.[117,118] This refers to a specific anti–vitamin B_6 compound, 4′-*O*-methylpyridoxine (MPN), present only in the seeds and thought to be responsible for causing convulsions after intoxication following seed (nut) consumption in China and Japan.[119] Levels of MPN in ginkgo leaf (1-5 µg per leaf) are much lower than in seed (80 µg per seed), and neurotoxic effects, including convulsions, occur at oral levels of 11 mg/kg (LD_{50} of 50 mg/kg) in guinea pigs. The amount of MPN in a typical human therapeutic daily dose of EGb 761 would be about 10 to 50 µg/day, suggesting that intoxication and interaction are unlikely.[4] Van Beek has reviewed MPN toxicity in depth.[6] Clinical reports of MPN intoxication from ginkgo leaf consumption are absent. A recent speculative case report alleging fatal ginkgo-induced seizures, possibly from MPN intoxication or pharmacokinetic interaction with valproate and phenytoin, was unreliable. The authors failed even to confirm the use of the herb, much less mention dose, frequency of administration, and so on, while including comments about ginkgo nut toxicity and suggesting unproven pharmacokinetic interactions with anticonvulsants through CYP450 2C9 induction.[120]

Monoamine Oxidase (MAO) Inhibitors

MAO-A inhibitors: Isocarboxazid (Marplan), moclobemide (Aurorix, Manerix), phenelzine (Nardil), procarbazine (Matulane), tranylcypromine (Parnate).

MAO-B inhibitors: Selegiline (deprenyl, L-deprenil, L-deprenyl; Atapryl, Carbex, Eldepryl, Jumex, Movergan, Selpak); pargyline (Eutonyl), rasagiline (Azilect).

Evidence from in vitro and ex vivo rodent studies on MAO-A and MAO-B inhibitory activity does not suggest central MAO inhibition by ginkgo. A human study using radiolabeled l-deprenyl and clorgyline (which inactivate MAO-A and -B isoforms, respectively) after 1 month of pretreatment with 60 mg EGb 761 twice daily in 10 normal subjects showed no effect on MAO activity in any brain region imaged by positron emission tomography (PET).[121] Peripheral MAO inhibition is not precluded by these studies.

Oral Hypoglycemic Agents and Insulin

Buformin (Andromaco Gliporal, Buformina), chlorpropamide (Diabinese), glimepiride (Amaryl), glipizide (Glucotrol, Glucotrol XL), glyburide (glibenclamide; Diabeta, Glynase, Glynase Prestab, Micronase, Pres Tab); insulin (animal-source insulin: Iletin; human analog insulin: Humanlog; human insulin: Humulin, Novolin, NovoRapid, Oralin), metformin (Dianben, Glucophage, Glucophage XR); combination drugs: glipizide and metformin (Metaglip), glyburide and metformin (Glucovance); phenformin (Debcone, Fenformin), tolazamide (Tolinase), tolbutamide (Orinase, Tol-Tab).

Data are conflicting on the possible effects of ginkgo on pancreatic beta-cell activity, as well as on oral hypoglycemic agents. In a study on the effects of EGb 761 in patients with non-insulin-dependent diabetes mellitus (NIDDM, diet and medication controlled), Kudolo[122] suggests that hyperinsulinemic (insulin-resistant) patients should avoid EGb 761 because of an increase in insulin level on an oral glucose tolerance test (OGTT). Kudolo et al.[123] performed a later study that found no effect of EGb 761 on pancreatic beta-cell activity. A Japanese group performed several rodent studies that suggest possible biphasic effects of ginkgo extracts on 2C9, the p450 enzyme that metabolizes sulfonylurea and "glitazone" oral hypoglycemic agents.[46,124] The relevance of these data to humans is unknown. Suggestions of clinically significant interactions between oral hypoglycemics and ginkgo extracts are not warranted by the available data at this time.

Thiazide Diuretics

Bendroflumethiazide (bendrofluazide; Naturetin), combination drug: bendrofluazide and propranolol (Inderex); benzthiazide (Exna), chlorothiazide (Diuril), chlorthalidone (Hygroton), cyclopenthiazide (Navidrex), combination drug: cyclopenthiazide and oxprenolol hydrochloride (Trasidrex); hydrochlorothiazide (Aquazide, Esidrix, Ezide, Hydrocot, HydroDiuril, Microzide, Oretic); combination drugs: hydrochlorothiazide and amiloride (Moduretic); hydrochlorothiazide and captopril (Acezide, Capto-Co, Captozide, Co-Zidocapt); hydrochlorothiazide and enalapril (Vaseretic); hydrochlorothiazide and lisinopril (Prinzide, Zestoretic); hydrochlorothiazide and losartan (Hyzaar); hydrochlorothiazide and metoprolol (Lopressor HCT); hydrochlorothiazide and spironolactone (Aldactazide); hydrochlorothiazide and triamterene (Dyazide, Maxzide); hydroflumethiazide (Diucardin), methyclothiazide (Enduron), metolazone (Zaroxolyn, Mykrox), polythiazide (Renese), quinethazone (Hydromox), trichlormethiazide (Naqua).

A paradoxical report in a secondary source suggests that a hypertensive patient receiving a thiazide diuretic took ginkgo (unspecified) and experienced a rise in blood pressure, which was reversed only by cessation of both agents.[125] Given the vasorelaxant effects of ginkgo extracts, this interaction appears improbable, and the report is not reinforced by any other data at this time.

The 125 citations for this monograph are located under Ginkgo on the CD at the back of the book.

Ginseng

Botanical Name: *Panax ginseng* C.A. Meyer.
Pharmacopoeial Name: Radix ginseng.
Synonym: *Panax ginseng* T. Nees.
Common Names: Ginseng, Korean ginseng, Chinese ginseng, Asian or Oriental ginseng.

SUMMARY

Drug/Class Interaction Type	Mechanism and Significance	Management
Amoxicillin Beta-lactam antibiotics ⊕⊕⊕	Ginseng increases T helper cell typ. 1 (Th1) immunity and may enhance effectiveness of many antimicrobial agents, although evidence of interaction is specific to amoxicillin. Clinical significance: possibly widely applicable, although currently unknown.	Consider coadministration, especially in antibiotic-resistant conditions or immunocompromised patients.
Chemotherapy Radiotherapy ⊕/☼	Ginseng may decrease drug toxicities and increase drug efficacy through multiple mechanisms, including immunomodulation, chemosensitization, and specific toxicity reduction. Western clinical trial support negligible, despite anecdotal clinical support.	Pretreatment and coadministration with chemotherapy and radiation recommended, with appropriately experienced professional management.
Ethanol Antiarthritic analgesics ◈/☼/⊕⊕⊕	Clearance of alcohol may be increased by herb pretreatment. Interaction of questionable clinical value.	None.
Narcotics, opioids, central stimulants ?	Ginseng may reduce drug-induced tolerance development and decrease adverse effects of drug use. Clinical significance not established.	Consider possible use as additional support for adverse effect reduction in analgesia or withdrawal from narcotic/opioid abuse.
Phenelzine Monoamine oxidase inhibitors (MAOIs) ✗	Ginseng effect on neurotransmitters not considered physiologically significant. Current low use of nonselective MAOIs renders clinical significance marginal. Interaction overstated.	Normal precautions regarding nonselective MAOI advice for patients adequate.
Vaccine immunotherapies ⊕	Ginseng extracts may increase antibody response and effectiveness of some vaccine therapies by enhancing antigen-presenting cell (APC) activity. In particular, ginsenosides may be a useful pretreatment and adjuvant for improving potency and immunogenicity of vaccines.	Pretreatment and coadministration worthy of consideration.
Warfarin Oral vitamin K antagonist anticoagulants ✗	International normalized ratio (INR) reduction in a single report, probably idiosyncratic. Significance unknown, likely minimal.	Observe normal INR monitoring, especially if adding or removing any drug/herb to stable anticoagulation.

HERB DESCRIPTION

Family

Araliaceae.

Related Species

Panax quinquefolius L. (American ginseng) or *Xi Yang Shen*.

Habitat and Cultivation

Slow-growing woodland perennial native to northern China and Korea, now widely cultivated in those countries and in Japan.

Parts Used

Main and lateral roots.

Common Forms

Dried peeled root (white ginseng); steamed dried root (red ginseng) by decoction, or infusion if powdered.
Tincture or Fluid extract.
Standardized Extract: Dried concentrates, typically standardized to 4% to 5% ginsenosides (with ginsenosides Rg1/Rb1 ratio ≥ 0.5).

HERB IN CLINICAL PRACTICE

Overview

Ginseng is economically the most important herb in world commerce and has generated more scientific studies and a larger general literature than any other herb. Although used in Asia for more than 2000 years, ginseng has now become widely incorporated into consumer products as well as the herbal materia medica in the West. Ginseng is the archetypal adaptogenic herb. *Adaptogens* have no equivalent among conventional pharmaceutical agents. The term was coined by Soviet researcher Lazarev in 1947 and subsequently defined by Brekhman in terms of three salient qualities. Adaptogens are *nonspecific* (in relation to a wide range of stressor stimuli), *nontoxic* (cause minimal disturbance to normal physiological function), and *normalizing* (direction of action varies depending on the prior state of response to stressor and always normalizes).[1] The general properties of adaptogens have been reviewed by Panossian et al.[2] and Wagner and Norr.[3] As with its companion adaptogen eleuthero (see Eleuthero monograph), ginseng and its constituent ginsenosides have a broad range of immunomodulating, chemopreventive, neuroendocrine, and antineoplastic activities, as well as behavioral effects on athletic, sexual, and cognitive performance.

The literature on ginseng is voluminous; recent accessible Western resources include therapeutic monographs by the World Health Organization (WHO),[4] British Herbal Medical

Association (BHMA),[5] and European Scientific Cooperative on Phytotherapy (ESCOP),[6] as well as literature reviews by McKenna et al.[7] and Court.[8] Recent monographs from the Chinese medicine perspective include Bensky et al.[9] and Chen and Chen.[10] *Ren shen* is a transliteration of the Chinese name for "peeled, dried root," also known as "white ginseng." *Hong shen*, or "red ginseng," is the root steamed before drying. Red ginseng is considered more *Yang* (i.e., warmer and stronger) than white ginseng. The ginsenoside profile of the two forms is different. The separate species *Panax quinquefolius* L. (American ginseng or wild American ginseng) is known as *Xi Yang Shen* and is regarded as closer to Japanese-cultivated *Panax ginseng*, or *Dong Yang Shen*, and has less warming properties than *Ren shen*.[10] The Western literature does not usually observe these energetic distinctions, although *P. quinquefolius* and *P. ginseng*, despite similarities, are not considered interchangeable by most authoritative Western sources, and the scientific literature on *P. quinquefolius* is considerably less than that for *P. ginseng*.

In consumer product marketing, the term "ginseng" has been confusingly used to refer to related species such as American ginseng *(P. quinquefolius)* as well as unrelated species such as Siberian ginseng (now known as eleuthero). Correct recording of the Latin binomial is always essential to identify an herb accurately, and failure to properly identify the species is a persistent defect of mainstream medical discussions of ginseng-related adverse events and drug interactions. A further problem, endemic to the dietary supplement market, is the variable quality and composition of commercial products containing, or claiming to contain, ginseng.[11] Because of the high price of the root, adulteration can occur, and several contaminating species have been identified in China.[9]

Historical/Ethnomedicine Precedent

In classical Chinese medicine, ginseng is a major *qi* tonifying herb, addressing general deficiencies of *yuan qi* ("source qi") to replenish *jing* ("vital essence"), as well as deficiencies of blood *(xue)*, spleen *(Pi)*, lung *(Fei)*, and kidney *(Shen) qi*. As a *shen* herb, it also calms the "Spirit/Mind" and improves mental function. Ginseng has been progressively integrated into Western use in the last 30 years, primarily as an adaptogenic tonic herb to treat fatigue and neurasthenia, enhance general wellness, and improve physical, sexual, and cognitive performance. As in China, ginseng is now increasingly seen as a potentially valuable agent in Western integrative cancer protocols.[12,13]

Known or Potential Therapeutic Uses

Stress reduction and neuroendocrine balancing (dysglycemia, adrenal insufficiency); fatigue, chronic fatigue immune dysfunction syndrome (CFIDS); convalescence; enhancement of exercise, athletic and work capacity, and performance; increasing mental alertness and cognitive performance; adjunct to radiation and chemotherapy treatment; immunoprotection and immunomodulation, chemoprevention, cardiotonic, hepatoprotective, hyperlipidemic, hypoglycemic.

Key Constituents

Steroidal saponins, known as *ginsenosides* (up to 3.0%). The ginsenosides are based on three sapogenin aglycones: 20(S)-protopanaxodiol, 20(S)-protopanaxotriol, and oleanic acid. Ginsenosides are designated by the letter "R" followed by various subscripts. The total number of ginsenosides has not been definitively determined; more than 30 have been described. Ginsenosides are present as a complex mixture, and the composition may vary with conditions of cultivation and processing.

Polyacetylene compounds, peptidoglycans, volatile oil, polysaccharides, and lipids.

Therapeutic Dosing Range

Dried root: Western—up to 2 g daily; Chinese—up to 9 to 10 g daily.

Tincture/Fluid extract: Up to 3 mL/day, 1:1 equivalent.

Standardized Extract: 100 mg 5:1 4% ginsenosides (e.g., G115, Pharmaton S.A.) solid extract twice daily, i.e., 8 mg ginsenosides total daily.

INTERACTIONS REVIEW

Strategic Considerations

The "normalizing" effect of ginseng on homeostatic parameters, coupled with a broad spectrum of activities and minimal toxicity, underlies a lack of pronounced pharmacodynamic drug interactions with the herb at therapeutic doses. In a recent review of the safety and toxicity of ginseng, including adverse drug interactions, Coon and Ernst[14] concluded that the herb was rarely associated with adverse events or drug interactions. Authoritative monographs either report no interactions (German Commission E)[15] or cite the often-repeated but unlikely adverse interaction with phenelzine (see later discussion) and a possible interaction with warfarin (WHO, ESCOP).[4,6]

Secondary sources often suggest theoretical or speculative interactions based on extrapolations from the pharmacology of the herb. However, pharmacological data for ginseng often reveal apparently opposing effects, such as hypertensive/hypotensive, central nervous system (CNS) stimulant/CNS depressant, and antihistamine/histamine-like actions.[16] These opposing effects extend to genomic activity.[17] Such apparently conflicting data and the correlation of the direction of many ginseng effects with baseline physiological state before consumption are explained partly by the opposing action of the separate ginsenoside components of the herb.[18] This also applies to more complex processes, such as angiogenesis; ginseng can promote angiogenesis in wound healing but inhibit it in tumorigenesis.[19,20] As with steroidal hormones, the ginsenosides are capable of exerting complex actions at genomic and proteomic levels, exhibiting membrane intercalation and nuclear localization, as well as more rapid actions at a signal transduction and second-messenger level.[18] Many of the observed downstream effects of ginsenosides may result from these levels of activity. There is evidence that ginsenosides may reverse the classic downregulation of glucocorticoid receptor (GR) by dexamethasone, although evidence for direct binding to the GR is equivocal.[21] This should not be read so much as evidence for a "dexamethasone-ginseng" interaction, but rather as an indication of the complexity of actions of the herb. For example, diverse effects of the ginsenosides may be downstream consequences of GR modulation, including several antineoplastic effects.[22] Similarly, putative estrogenic activity by some ginsenosides[23] may be caused by crosstalk between GR and ER,[24] rather than direct "phytoestrogen" effects, which have not historically been attributed to the herb, in contrast to recent data on isolated ginsenoside components.[25,26]

In conclusion, the documented literature on ginseng interactions largely fails to account for the complex, pleiotropic and

nonspecific effects of the herb, particularly on stress-related homeostasis and neuroendocrine and immune parameters. Practitioners versed in botanical medicine are likely to emphasize precisely these adaptogenic aspects in therapeutic practice, whereas the mainstream view continues to regard ginseng narrowly as some type of mild stimulant, although an exotic one.

Effects on Drug Metabolism and Bioavailability

The effects of ginseng (and isolated ginsenosides) on cytochrome P450 (CYP450) has not been fully characterized, but the balance of available data from rodent, in vitro, and preclinical in vivo studies suggests that the herb has minimal effects on the mixed-function oxidase system, lacking pronounced induction or inhibition effects that may contribute to metabolic drug interactions.[27] Two in vivo human CYP450 studies are available to date. Anderson et al.[28] found no effect of 14 days' administration of standardized (G115) ginseng in 20 healthy volunteers on urinary 6-β-OH cortisol/cortisol ratios, suggesting lack of induction of the herb on CYP3A4. Gurley et al.[29] used a probe cocktail methodology in 12 healthy volunteers to examine the effects of 28 days' administration of *Panax ginseng* at a high dose of 500 mg three times daily. They found no significant changes in CYP450 1A2, 2D6, 2E1, or 3A4.[29] Two recombinant human CYP450 enzyme studies suggest a possible weak inhibition of isoforms 1A1, 1A2, and 1B1 by G115 extract.[30] Another study using isolated component ginsenosides found that R_d, R_c, and R_f exerted a very weak effect on 1A2, 2C9, 2C19, 2D6, and 3A4. Ginsenosides R_c and R_f also exerted activation effects on 2C9 and 3A4, respectively, but only at concentrations of 200 μM. The authors concluded that these small effects would be unlikely to have in vivo effects on coadministered medications.[31] Rodent models have also failed to reveal significant effects on CYP450 enzymes 1A2, 2B1, and 3A23.[32-34]

In contrast to the Phase II drug metabolism, there is preliminary experimental evidence for a modulating effect of ginseng on P-glycoprotein (Phase III drug metabolism), and substrates of this transporter protein may be subject to pharmacokinetic interactions.[35] The mechanisms of drug resistance modulation have not been fully characterized; cell line evidence examining the effects of ginsenoside components on drug efflux with vinblastine and doxorubicin suggests a competitive inhibition mechanism rather than transcriptional induction/inhibition.[36-39] Confirmed clinical correlations of drug resistance modulation or other efflux pump-mediated interactions with ginseng or ginsenosides are not available to date, although doxorubicin (Adriamycin) cardiotoxicity was reduced in a rodent model when ginseng was coadministered with the drug.[40]

Finally, evidence suggests that in both rodents and humans, certain intestinal bacteria may hydrolyze ginseng saponins into novel ginsenoside metabolites with antineoplastic activity, suggesting a prodrug bioactivation aspect to the action of the herb under certain circumstances.[41,42] The clinical significance of this bioactivation mechanism has not been established.

HERB-DRUG INTERACTIONS

Amoxicillin and Related Beta-Lactam Antibiotics

Evidence: Amoxicillin (Amoxicot, Amoxil, Moxilin, Trimox, Wymox); combination drug: amoxicillin and clavulanic acid (Augmentin, Augmentin XR, Clavulin, Nuclav).

Extrapolated, based on similar properties: Beta-lactam antibiotics: Methicillin (Staphcillin); aztreonam (Azactam injection); carbapenem antibiotics: meropenem (Merrem I.V.); combination drug: imipenem and cilastatin (Primaxin I.M., Primaxin I.V.); cephalosporin antibiotics; penicillin antibiotics: ampicillin (Amficot, Omnipen, Principen, Totacillin); combination drug: ampicillin and sulbactam (Unisyn); bacampicillin (Spectrobid), carbenicillin (Geocillin), cloxacillin (Cloxapen), dicloxacillin (Dynapen, Dycill), mezlocillin (Mezlin), nafcillin (Unipen), oxacillin (Bactocill), penicillin G (Bicillin C-R, Bicillin L-A, Pfizerpen, Truxcillin), penicillin V (Beepen-VK, Betapen-VK, Ledercillin VK, Pen-Vee K, Robicillin VK, Suspen, Truxcillin VK, V-Cillin K, Veetids), piperacillin (Pipracil); combination drug: piperacillin and tazobactam (Zosyn); ticarcillin (Ticar); combination drug: ticarcillin and clavulanate (Timentin).

Interaction Type and Significance

⊕⊕⊕ **Beneficial or Supportive Interaction, Not Requiring Professional Management**

Probability:	Evidence Base:
2. Probable	○ **Preliminary**

Effect and Mechanism of Action

A synergistic effect between amoxicillin (plus clavulanic acid) and coadministered ginseng results in increased antibacterial effect. The mechanism is likely caused by increased cellular immunity (Th1) induction by ginseng.

Research

A group of 75 patients with acute bronchitis received 875 mg amoxicillin and 12 mg clavulanic acid twice daily for 9 days. They were then randomized into two groups; one received additional ginseng (G115, 200 mg/day) and the other antibiotic only for the 9 days. On days 4 to 7 the ginseng group had significantly lower bacteria counts than the antibiotic-only group, although this became a nonsignificant trend after day 8. The authors of this pilot study suggested that ginseng may be a particularly useful adjunct in cases of acute bronchitis.[43] (Arguably, however, most infectious disease experts would agree that antibiotic treatment of this condition is not necessary or indicated in patients who are not debilitated or immunosuppressed.)

Integrative Therapeutics, Clinical Concerns, and Adaptations

The effect of ginseng extracts in enhancing cell-mediated immunity, particularly natural killer (NK) cell activity, has been documented. The combination of natural compounds with beta-lactam antibiotics to deal with refractory conditions or bacterial resistance is also documented (e.g., see Green Tea monograph). The interaction identified by the previous study is more likely a specific instance of the general enhancement of immune responses by ginseng. Such an effect is probable in combination with a wide variety of antimicrobial agents, rather than as a specific interaction couplet between amoxicillin or beta-lactam agents, implying a broader clinical significance than suggested by the specific report.

Antineoplastic Chemotherapy and Radiotherapy

Bleomycin (Blenoxane), carboplatin (Paraplatin), cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), cytarabine (ara-C; Cytosar-U, DepoCyt, Tarabine PFS), dactinomycin (Actinomycin D, Cosmegen, Cosmegen Lyovac), daunorubicin (Cerubidine, DaunoXome), docetaxel

(Taxotere), doxorubicin (Adriamycin, Rubex), etoposide (Eposin, Etopophos, Vepesid, VP-16), mitomycin (Mutamycin), oxaliplatin (Eloxatin), paclitaxel (Paxene, Taxol), paclitaxel, protein-bound (Abraxane), vinblastine (Alkaban-AQ,Velban, Velsar), vincristine (Leurocristine, Oncovin, Vincasar PFS), vinorelbine (Navelbine).

Interaction Type and Significance

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Coadministered ginseng may potentially act as both a chemosensitizer and a protector against antineoplastic drug toxicities, particularly antitumor antibiotics and platinum compounds. Mechanisms may include multidrug resistance disabling, potentiation of cytotoxic activity with some drugs, protection of healthy cells, and enhancement of immune system activity during myelosuppression. These potential interactions have not been subject to Western clinical trials at this time, although they are supported by anecdotal clinical practice and preliminary pharmacological data.

Research

Experimental and animal data supporting the general use of ginseng extracts, particularly red ginseng, in association with antineoplastic agents are available. Most reports are in original Asian literature, which is only briefly summarized here.

Isolated triterpene (ginsenoside) fractions have been shown to reverse drug resistance to daunomycin, doxorubicin (Adriamycin), and vinblastine in resistant leukemia cell line P388/ADM, with Adriamycin sensitivity increasing the most.[36] Inhibition of leukemic progenitor cells cultured from bone marrow of patients with acute myelogenous leukemia (AML) increased significantly when cytotoxic drugs (homoharringtonine, cytarabine, Adriamycin, etoposide) were coadministered with a complete saponin extract of *Panax ginseng* (20 μg/mL); a total of 17 of 72 drugs tested exhibited resistance reversal.[44] A Chinese formula with ginseng as the main ingredient reduced the cardiotoxic effects of Adriamycin in rabbits compared with controls.[45] Combination treatment with a sapogenin metabolite of ginseng (50 mg/kg) in mice orally administered with doxorubicin (3 mg/kg) significantly reduced germ cell injury and other parameters (e.g., serum LDH, CPK) to the level of control animals.[46]

The effects of extracts of both red and white ginseng were compared in the activity of mitomycin C in vitro against Ehrlich ascites sarcoma cells. The ginsenosides Rh2 and Rg3 promoted mitomycin uptake by the tumor cells, and when an in vivo comparison was performed in mouse Ehrlich ascites sarcoma and rat ascites hepatoma, the red ginseng extracts showed a stronger effect in combination with mitomycin than the white ginseng extract.[47-49] Conducting in vitro studies with ginsenoside Rg(3), Kim et al.[39] showed that inhibition of multidrug resistance was caused by competitive inhibition of binding with P-glycoprotein (P-gp), rather than by transcription effects on MDR1 gene or P-gp levels. Ginsenoside Rh2 from red ginseng demonstrated a synergistic effect with cisplatin in vitro and in vivo (when inoculated into mice) against growth of a cell line derived from a human ovarian adenocarcinoma.[50] A cisplatin-resistant subline of human lung cancer cells was also shown to undergo resistance reversal in vitro when cisplatin was coadministered with IH-90 (intestinal metabolite of Rb1 and Rd).[37,51]

Shin et al.[52] used a rodent model to demonstrate that red ginseng polysaccharide had a synergistic effect with paclitaxel against the proliferation of implanted sarcoma and melanoma cancer cell lines. The extract also restored NK cell activity suppressed by the drug. Radioprotective effects of ginseng pretreatment have also been demonstrated in rodent models.[53-59] Immunomodulation effects of ginseng have been shown to preserve bone marrow function and CD4 cell activity during exposure to chemotherapeutic agents.[60] A small trial ($n = 42$) with stage III gastric cancer patients found that CD3/CD4 cell activity was preserved, with positive effects on survival, when red ginseng was combined with postoperative adjuvant chemotherapy.[61]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Clinical research is needed to corroborate these interactions in vivo. Given the pleiotropic anticancer effects of ginseng extracts, multiple rationales exist for incorporation of the herb into integrative protocols in the oncology setting. The antifatigue and immunomodulating effects of ginseng are likely to add to its usefulness, particularly for later-stage cancers. Modern Chinese medicine has incorporated herbal and conventional treatments to a higher degree than current Western practice, with ginseng a primary ingredient in compound formulations designed to address specific clinical circumstances.[62] At present, further clinical data are required to substantiate the use of ginseng in this context; however, its value as an adjuvant in oncology is beginning to be recognized in the West.[12]

Ethanol

Ethanol

Interaction Type and Significance

◇ **Impaired Drug Absorption and Bioavailability, Negligible Effect**

☼ **Prevention or Reduction of Drug Adverse Effect**

⊕⊕⊕ **Beneficial or Supportive Interaction, Not Requiring Professional Management**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Ginseng appears to increase the metabolic clearance of ethanol and lower blood alcohol level, possibly by delaying gastric emptying. The clinical significance of the interaction is low.

Research

A much-quoted but methodologically limited preclinical study used 14 healthy males in an open-label and uncontrolled design that compared blood alcohol levels 40 minutes after ingestion for alcohol given alone and for the same dose of alcohol combined with 3 g *Panax ginseng*. Blood alcohol levels were 32% to 51% lower when ginseng was coadministered. Full pharmacokinetic measurements were not made, with no data on maximum concentration (C_{max}) or area under curve (AUC).[63]

Animal experiments have confirmed the general finding that alcohol clearance is increased by ginseng coadministration. Pretreatment with ginseng in a rat model (200 mg/kg) reduced ethanol AUC by 21% compared with controls.[64] Pretreatment with ginseng and ginsenosides reduced the

onset of loss of the righting reflex in mice treated with ethanol, but did not affect ethanol-induced sleeping time in the animals.[65] Presence of a pharmacodynamic element in the effect of the ginseng/alcohol combination is uncertain. In a rodent model, however, red ginseng extracts reduced ethanol's impairment of a behavioral task, and administration of neurotropic agents suggested that this effect may be mediated by an adrenergic pathway.[66] Another rodent study found that an ethanol-induced decrease in brain weight in neonatal rats was reduced by administration of ginsenosides, suggesting a neuroprotective effect against alcohol damage.[67]

Integrative Therapeutics, Clinical Concerns, and Adaptations

The ramifications of pharmacokinetic lowering of ethanol blood levels by ginseng are arguably of less clinical significance than interest for recreational alcohol consumers. This interaction should be clinically distinguished from potential neuroprotective activities of the ginseng saponins that may partly underlie the beneficial effects of the herb on cognitive function.[68,69]

Narcotic Analgesics (Opiates) and Psychostimulants

Evidence: Cocaine, methamphetamine, morphine sulfate (Astramorph PF, Avinza, Duramorph, Infumorph, Kadian, MS Contin, MSIR, Oramorph SR, RMS, Roxanol, Roxanol Rescudose, Roxanol T).

Extrapolated, based on similar properties: Narcotic analgesics: Butorphanol (Stadol, Stadol NS), codeine, fentanyl (Actiq Oral Transmucosal, Duragesic Transdermal, Fentanyl Oralet, Sublimaze Injection), hydrocodone, hydromorphone (Dilaudid), levorphanol (Levo-Dromoran), meperidine (Demerol), methadone (Dolophine, Methadose), opium tincture, oxycodone (Endocodone, OxyContin, OxyIR, Percolone, Roxicodone), oxymorphone (Numorphan), paregoric, pentazocine (Talwin, Talwin NX), propoxyphene (Darvon, Darvon-N).

Combination drugs: buprenorphine and naloxone (Suboxone); codeine and acetaminophen (Capital with Codeine; Phenaphen with Codeine; Tylenol with Codeine); codeine and acetylsalicylic acid (Empirin with Codeine); codeine, acetylsalicylic acid, caffeine, and butalbital (Fiorinal); hydrocodone and acetaminophen (Anexsia, Anodynos-DHC, Co-Gesic, Dolacet, DuoCet, Hydrocet, Hydrogesic, Hy-Phen, Lorcet 10/650, Lorcet-HD, Lorcet Plus, Lortab, Margesic H, Medipain 5, Norco, Stagesic, T-Gesic, Vicodin, Vicodin ES, Vicodin HP, Zydone); hydrocodone and acetylsalicylic acid (Lortab ASA); hydrocodone and ibuprofen (Reprexain, Vicoprofen); opium and belladonna (B&O Supprettes); oxycodone and acetaminophen (Endocet, Percocet 2.5/325, Percocet 5/325, Percocet 7.5/500, Percocet 10/650, Roxicet 5/500, Roxilox, Tylox); oxycodone and acetylsalicylic acid (Endodan, Percodan, Percodan-Demi); pentazocine and acetaminophen (Talacen); pentazocine and acetylsalicylic acid (Talwin Compound); propoxyphene and acetaminophen (Darvocet-N, Darvocet-N 100, Pronap-100, Propacet 100, Propoxacet-N, Wygesic); propoxyphene and acetylsalicylic acid (Bexophene, Darvon Compound-65 Pulvules, PC-Cap); propoxyphene, acetylsalicylic acid, and caffeine (Darvon Compound).

Interaction Type and Significance

? Interaction Likely but Uncertain Occurrence and Unclear Implications

Probability: **3. Possible**

Evidence Base: **○ Preliminary**

Effect and Mechanism of Action

Ginseng extracts may interfere with analgesic effects of morphine and related opioids while preventing or reversing drug-induced tolerance, according to animal data. The mechanism and clinical significance of the interaction are not established, although theoretically the herb may be of value in preventing or modulating drug adverse effects, including drug tolerance.

Research

Investigators have conducted experimental studies into the effects of ginseng pretreatment and coadministration with psychostimulant and opioid drugs, principally morphine but also methamphetamine and cocaine, in rodent behavioral models (conditioned–place preference tests). The general conclusions were that drug-induced hyperactivity was reduced by ginseng, with ginsenosides fractions Rg1 and Rb1 being primarily responsible for the antiopioid activity. The effect may be related to dopaminergic pathway modulation but has not been established.[70-76]

Clinical Implications and Adaptations

At least one author has suggested that ginseng extracts hold the potential to prevent and treat the effects of abuse of cocaine, methamphetamine, and morphine.[77] These extrapolations from rodent models to drug abuse behavior and tolerance mechanisms in humans require supporting clinical data, which are unavailable at present.

Phenelzine and Other Monoamine Oxidase (MAO-A) Inhibitors

Evidence: Phenelzine (Nardil).

Extrapolated, based on similar properties, as MAO-A inhibitors: Isocarboxazid (Marplan), moclobemide (Aurorix, Manerix), procarbazine (Matulane), tranylcypromine (Parnate).

Interaction Type and Significance

✗ Potential or Theoretical Adverse Interaction of Uncertain Severity

Probability: **5. Improbable**

Evidence Base: **☐ Inadequate**

Effect and Mechanism of Action

Possible hypomania or hypermania and exacerbation of CNS adverse effects normally associated with phenelzine alone have been reported during ginseng coadministration. Report reliability is low, the mechanism unknown, and the existence of the interaction improbable.

Research

Some data from in vitro and animal studies suggest effects of ginseng modulation on CNS neurotransmitters, but the clinical implications of such data are unknown, and extrapolations to in vivo interactions with effects on the monoamine oxidase system are unwarranted at this time. Tsang et al.[78] showed that ginseng extracts dose-dependently inhibited uptake of gamma-aminobutyric acid (GABA), glutamate, dopamine, norepinephrine, and serotonin in rat brain synaptosomes. Ginsenosides compete with agonists for binding to GABA-A and GABA-B receptors.[79] *Panax quinquefolius* extracts are also known to exert GABA-A modulating effects.[80]

Reports

The claimed interaction between phenelzine and ginseng is listed in both conventional sources, such as Stockley,[81] and

in authoritative monographs on *Panax ginseng*, including WHO.[4] This interaction is also reiterated by innumerable secondary and derivative sources, apparently based on two case reports, discussed here in depth.

The first documented report was a brief mention in a 1985 editorial by the then-editors of the *Journal of Clinical Psychopharmacology*, Shader and Greenblatt.[82] The case involved a 64-year-old woman who took an undisclosed dose for an undisclosed period of the combination dietary supplement product "Natrol High" while taking phenelzine, 60 mg/day. She then experienced symptoms of "insomnia, headache, and tremulousness." Unfortunately, the authors failed to include any medical details or to identify the ingredients of the Natrol product, which contains no *Panax ginseng*, but rather some *Eleutherococcus senticosus* (previously known as Siberian ginseng), in combination with several micronutrients (e.g., niacin, vitamin B_6, thiamine) and other herbs, including ginger, mallow, licorice root, and winter berry.[83]

In 1988, Shader and Greenblatt[84] speculated further on the topic, relating to a further episode with the same patient.[84] Now 67 years old and taking 45 mg phenelzine per day, the patient had been prescribed a herbal tea formula and some "ginseng" capsules "for energy." The ingredients of the prescription tea formula and capsules were not identified and the dose not disclosed. She experienced similar symptoms as in the previous episode, but this time associated with increased depression. After cessation of the tea formula and "ginseng" capsules, she "felt better."

The only other report on phenelzine is a letter from Jones and Runikis[85] in 1987 commenting on the case in the original Shader-Greenblatt editorial. They briefly describe a 42-year-old female patient taking 45 mg phenelzine per day, along with 0.5 mg triazolam at night and 1 mg lorazepam four times daily. The patient concurrently consumed an unspecified amount of "ginseng and bee pollen." The species and form of ginseng, the dose, and other constituents of the product were not disclosed. During coadministration of the herbal products and phenelzine, the patient became "extremely active and optimistic," her sleep was decreased, and she did not "feel tired." She also was irritable and had tension headaches and "occasional vague hallucinations," which she attributed to the phenelzine, and she therefore ceased both the drug and the herbs. Her depressive symptoms then began to return, so she restarted the phenelzine at 45 mg/day. This time she experienced no therapeutic benefit from the drug (without the "ginseng and bee pollen"), although she did experience headache with the phenelzine alone.

The persistent citation of these two cases as evidence of a phenelzine-ginseng interaction is remarkable, given that ginseng was not even involved in the first case and not identified as the herb involved in the second. No dose was given, and concurrent multi-ingredient supplements were used, as well as psychiatric comedications in the second case. In addition, the adverse effects described are consistent with well-known adverse effects of phenelzine alone, which in both cases was used at doses higher (60 mg/day, 45 mg/day) than usual for maintenance therapy of 15 mg/day. Also, the Jones and Runikis case report[85] seems to imply that the supplements were responsible for improved therapeutic outcome of the MAO inhibitor therapy, as opposed to the authors' interpretation of an adverse effect, because rechallenge by phenelzine alone without the herbal agents failed to have a beneficial effect on depression.

An unrelated but possibly relevant case report from Italian psychiatrists Gonzales-Seljo and others claimed that ginseng alone is associated with mania. In fact, the patient had been taking lithium carbonate, 1200 mg/day, and amitriptyline, 75 mg/day, for 6 years. She abruptly ceased this regimen, then started taking one "ginseng tablet" (brand, form, dose, and other ingredients unidentified). Ten days after the cessation of lithium and amitriptyline, she became "manic," including being sleepless, irritable, aggressive, and hyperactive. The authors suggested this must have been caused by the "ginseng." Abrupt withdrawal symptoms from both lithium and tricyclics are well known, and relapse into mania after lithium withdrawal has been documented in at least 14 studies.[86]

Clinical Implications and Adaptations

The suggested ginseng-phenelzine interaction is in the "speculative-overstated" category. At least one of the three case reports relates to eleuthero (previously Siberian ginseng); this basic error was documented by Treasure and also by Chen, who notes this is the case in several of the infamous "ginseng abuse syndrome" reports.[87,89] In the other reports the herb is simply unidentified. Neither the reports nor the known pharmacology of the herb lend significant support to the existence of an adverse interaction.

The declining use of phenelzine as a therapeutic intervention for depression (largely because of the lethal nature of interactions of this class of drugs with such common agents as dextromethorphan in OTC cough syrup) suggests that future routine pharmacosurveillance reports are unlikely to be forthcoming or to generate further clarification. The persistent tendency for secondary sources to repeat uncritically the interaction merits the full discussion here, but the clinical significance can be regarded as negligible. However, prudence still suggests great care be exercised when combining classic MAO inhibitors with botanicals or drugs known to interact in any significant way with neurotransmitter function.

Vaccine Immunotherapies

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:	Evidence Base:
2. Probable	○ **Preliminary**

Effect and Mechanism of Action

Ginseng extracts may increase the effectiveness of some vaccine therapies. This synergy has been observed both directly, when vaccines are prepared with the addition of parenteral ginseng saponin ingredients, and indirectly with oral pretreatment with ginseng before vaccination. The mechanism of the increased antibody response may be improved immunogenicity from enhanced antigen-presenting cell (APC) activity. The clinical significance remains to be established.

Research

Scaglione et al.[90] followed 227 patients attending a primary care practice who were scheduled to receive a polyvalent influenza vaccine. They were divided into two groups; one received G115, 100 mg ginseng per day, and the other placebo for 12 weeks. The vaccine was administered on week 4. There was a statistically greater incidence of subsequent influenza in the placebo group. At week 8, antibody titers and NK cell activity were much ($p < 0.0001$) higher in the verum group.

In the veterinary setting, Rivera et al.[91] examined the effects of adding a ginsenoside preparation into a conventional porcine parvovirus (PPV) vaccine in a guinea pig model.

They also injected ginseng and vaccine at separate sites, as well as providing ginseng pretreatment, followed by immunization. An aluminum hydroxide vaccine co-ingredient was also tested with and without ginsenosides. The $Al(OH)_3$ with ginseng mixture vaccine produced a 20-fold increase in immunoglobulin G (IgG) response to the PPV antigen, a synergistic effect greater than adding either $Al(OH)_3$ or ginsenosides alone. Rivera et al.[92] also conducted in vivo investigations with pigs and the commercial PPV vaccine, adjuvated with $Al(OH)_3$, supplemented with ginseng versus vaccine alone. Vaccines with ginseng resulted in higher immunogenicity (higher IgG values by ELISA) than without ginseng. The authors suggest that ginseng may be a useful adjuvant for improving the potency and immunogenicity of commercial vaccine preparations.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Ginseng saponins have well-established immunomodulatory effects. It appears likely that vaccine immunogenicity can be significantly enhanced by ginseng pretreatment and, more interestingly, perhaps by adding ginsenosides as a co-adjuvant to the vaccine mixture itself. The clinical benefits of using immunomodulating herbs for populations at risk of infection, whether alone or combined with conventional therapies, is an established practice among practitioners of botanical and natural medicine. Wider adoption of such integrative strategies may be predicated on currently emerging research data.

The increasing interest in vaccines in oncological settings may provide such a stimulus, and a recent study of relevance to the ginseng-vaccine interaction issue has come from this field. The priming of cell cultures with specific ginseng saponin metabolites (M1and M4 being bacterial hydrolysis products of ginsenosides) has been shown to increase the ability of dendritic cells to induce differentiation of T cells (i.e., to enhance Th1 responses), and ginseng may be a useful adjuvant in the emerging dendritic cell cancer vaccine field.[93] However, future research is needed to clarify the full potential of ginseng in vaccine immunotherapies.

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Evidence: Phenprocoumon (Jarsin, Marcumar), warfarin (Coumadin, Marevan, Warfilone).
Extrapolated, based on similar properties: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability: **5. Improbable**
Evidence Base: **▽ Mixed**

Effect and Mechanism of Action

The mechanism of this suggested interaction, based on a single case report of INR reduction in a patient previously stable on warfarin, is unknown. The proposed interaction seems improbable or idiosyncratic.

Research

Zhu et al.[94] investigated the potential warfarin-ginseng interaction in a rodent model. They examined pharmacokinetic and pharmacodynamic parameters in both single-dose and steady-state warfarin dosing regimens using plasma warfarin AUC and prothrombin time (PT) measurements. No significant effects were found on either single or multiple warfarin doses, either in terms of warfarin AUC or PTs. An open-label human study, using a randomized crossover design in 12 healthy subjects who had 7 days of pretreatment with high-dose ginseng (3.0 g/day, equivalent ~ 45.0 mg ginsenosides/day), found no effect of ginseng coadministration on *S*-warfarin or *R*-warfarin enantiomer clearance and no significant effect on platelet aggregation or INR.[95] By contrast, an in vitro study using human platelet aggregation assay resulted in significant reduction of thrombin- and collagen-induced aggregation in response to a red ginseng extract.[96] The human data contrast with the available animal studies. In rodent models, ginseng administration led to a significant increase in PT and partial thromboplastin time (PTT) of rats treated with various anticoagulants.[96,97]

A recent clinical study used the related species *P. quinquefolius* (American ginseng) to examine potential interactions with warfarin. The study gave 12 healthy volunteers warfarin for 3 days at 5 mg/day, followed by 4 weeks of American ginseng (1.0 g twice daily), with a repeat 3 days of warfarin during the fourth week. Parameters measured were peak warfarin and peak INR, as well as INR AUC and warfarin AUC. Compared to controls, there were modest reductions in INR (except in one patient who showed an INR increase, as well as small but significant reductions in warfarin AUC and peak plasma levels).[98] However, the variability of the results was very high, and there was no pharmacokinetic phenotyping of the healthy volunteers. Cytochrome P450 2C9 polymorphisms are known to be a critical factor associated with warfarin response variability. The ethnic composition of the study group suggested possible CYP450 2C9 phenotype variations as an explanation for the wide variability of the data, which were not controlled for by the investigators.[99-102] The investigators' comment that their study was conducted to clarify the matter of the Janetzky case report[103] (see next) seems curious given the investigators choice of *P. quinquefolius* rather than *P. ginseng*, which was the subject of the warfarin-ginseng case report.

Reports

The case report on which this potential interaction was based concerned a 47-year-old male with a history of hypertension, thrombosis, angina, and osteoarthritis. He was stabilized on warfarin at 5.0 mg/day and an INR of 3.0 to 4.0 for 9 months before commencing a ginseng preparation (Pharmaton 100-mg capsules, unspecified number, three times daily) for 4 weeks. He was comedicated with diltiazem at 30 mg three times daily, nitroglycerin as needed, and salsalate at 500 mg three times daily. After 4 weeks of ginseng coadministration, his INR was found to be 1.5. Two weeks after cessation of the herbal product, the INR returned to 3.3. The patient denied other changes to his dietary regimen, herb intake, or drug protocols. He did not experience a thrombotic episode during the period of reduced INR, but because of his history, a rechallenge was not performed. The authors noted that ginseng appeared to be associated with the INR change, but that the mechanism was not obvious.[103]

A similar report from Rosado[104] involved a prosthetic aortic valve patient who failed to maintain his INR while taking warfarin and was admitted to a hospital with an acute myocardial infarction and diabetic ketoacidosis. The author suggested that self-treatment with an unconfirmed "ginseng" commercial product for an unspecified period was likely the cause of his INR decrease.

Both these reports remain as isolated examples, and given the poor level of documentation, they cannot be taken as reliable support for the interaction.

Clinical Implications and Adaptations

The weight of the currently available research data suggests that the reported ginseng-warfarin interaction is not a clinically significant problem. Further studies of more effective design should be conducted to examine possible differences between American and Asian ginseng species on hemostatic parameters and possible interactions with clinical anticoagulation. Because Coumadin interacts with a wide variety of substances, sometimes unpredictably, it is prudent to measure the INR at least twice weekly in the weeks after starting or stopping any another therapy, including other drugs, nutraceuticals, and botanicals. Only in recent years have the significant interactions of Coumadin with acetaminophen and cranberry juice been recognized, despite both these having been coadministered with Coumadin for many years before recognition of the interaction.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Furosemide and Related Loop Diuretics

Bumetanide (Bumex), ethacrynic acid (Edecrin), furosemide (Lasix), torsemide (Demadex).

A frequently cited letter in *JAMA* suggested that the development of refractory response to diuretic therapy in a 63-year-old man with membranous glomerulonephritis on a regimen that included cyclosporine and furosemide was caused by "germanium" content of a "ginseng" preparation.[105] The ginseng species, dose, and duration of administration were not identified (nor were the other "daily nutritional supplements"). The basis for the authors' supposition that the ginseng product contained germanium is therefore unclear; regardless, the "interaction" was attributed to germanium toxicity, not "ginseng," and therefore describing it a "ginseng interaction" is incorrect by the author's own account. Without any corroboratory data, this interaction report is unevaluable and unsupported.

Oral Hypoglycemic Agents and Insulin

Buformin (Andromaco Gliporal, Buformina), chlorpropamide (Diabinese), glimepiride (Amaryl), glipizide (Glucotrol; Glucotrol XL), glyburide (glibenclamide; Diabeta, Glynase, Glynase Prestab, Micronase, Pres Tab), insulin (animal-source insulin: Iletin; human analog insulin: Humanlog; human insulin: Humulin, Novolin, NovoRapid, Oralin); metformin (Dianben, Glucophage, Glucophage XR); combination drugs: glipizide and metformin (Metaglip), glyburide and metformin (Glucovance); phenformin (Debeone, Fenformin), tolazamide (Tolinase), tolbutamide (Orinase, Tol-Tab).

Several secondary sources claim that there is a potential adverse interaction between ginseng and antidiabetic drugs. This appears to be a typical speculative "reverse extrapolation" based on the established property of American ginseng *(P. quinquefolius)* to induce postprandial glucose level lowering in animal and human studies.[106,107] The use of other ginseng species, including *P. ginseng*, as adjuvants for glycemic control is not currently indicated by the available data, which are confined to parenteral administration in rodent models of polysaccharide compounds, "panaxans," rather than ginsenosides.[108,109]

Clinical application of ginseng-related herbs in diabetes has been well reviewed by Sievenpiper et al.[110-113] Relevant issues concerning commercial product variability, dose, and ginsenoside composition are raised in the context of safety and efficacy of these agents as potential antihyperglycemics. However, speculative assertions of adverse interactions are unwarranted by the data and represent a poorly informed clinical appreciation of the general clinical context of using herbal adjuvants in glycemic control.

The 113 citations in this monograph are located under Ginseng on the CD at the back of the book.

Gotu Kola

Botanical Name: *Centella asiatica* (L.) Urban.
Pharmacopoeial Name: Herba centellae.
Synonym: *Hydrocotyl asiatica* L.
Common Names: Centella, gotu kola, Indian pennywort, Indian water navel wort.

HERB DESCRIPTION

Family

Apiaceae.

Parts Used

Aerial parts (or entire plant).

Common Forms

Dried leaves, by infusion.
Tincture, Fluid extract: 45% alcohol.
Standardized Extracts: Triterpene fraction gotu kola (TFGC); titrated extract *Centella asiatica* (TECA); total triterpene fraction of *Centella asiatica* (TTFCA) based on total triterpenes (typically 40% asiaticosides, 30% madecassic acid, 30% asiatic acid). Manufacturers' preparations may vary.

INTERACTIONS REVIEW

Strategic Considerations

In Ayurvedic medicine, centella (gotu kola) is regarded as a *Rasayana* herb (*rasa*, "essence," and *ayana*, "enters"). Rasayana tonic herbs are believed to rejuvenate and revitalize mind-body-spirit.[1] Centella has been used in traditional South Asian medicine as a topical remedy for leprosy, eczema, psoriasis, and ulcerous skin conditions, as well as a depurative and tonic. Western uses of gotu kola reflect the traditional indications, with primary emphasis on topical effects, including prevention of keloids and hypertrophic scars, treatments of burns, general acceleration of cicatrization and wound healing after surgery or trauma, and treatment for venous insufficiency, leg ulcers, and varicose and postthrombotic issues. The Rasayana aspects of the herb, in Western terms *adaptogenic*, such as its effects on stress and cognitive performance, resulted in increased popularity and widespread adoption of the remedy by Western herbal practitioners, despite only moderate support in the clinical literature for adaptogenic effects.

Despite its recent popularity, gotu kola is underrepresented in modern therapeutic literature. In the 1983 *British Herbal Pharmacopoeia*, gotu kola was mentioned only for its topical dermatological and vulnerary actions.[2] A more recent monograph by the World Health Organization (WHO)[3] restricts supported therapeutic indications to topical use for wounds, burns, and ulcerous skin ailments, as well as internal use for venous disorders and treatment of stress-induced ulcers.

Much of the literature on gotu kola draws on data from earlier studies (1950s through 1970s), primarily from the Indian and other Asian (Thai, Vietnamese, Indonesian) sources, supported by secondary reviews from African ethnobotany and ethnopharmacological sources. The pharmacological and clinical findings extrapolated from this earlier and limited research have not generally been replicated and can be considered problematic. As a result, depending on the variable emphasis placed on these sources by different reviewers, differing portrayals of the herb have appeared in the secondary literature.

The monograph by WHO[3] tends to underemphasize the earlier data and paints a narrow, but evidentially accurate, picture of gotu kola primarily as a dermatological agent. Other, secondary sources accept the earlier data without qualification.[4] Predictably, however, more derivative sources have the extrapolated further from this secondary literature to suggest interactions that are entirely speculative and unrelated to present clinical uses of the herb.[5] In the authoritative botanical literature, however, gotu kola has no known listed interactions with pharmaceuticals.[3] Clinical reports of any interactions with either galenical extracts or triterpene-enriched preparations are unavailable. From an integrative perspective and drawing on more recent research, interactions between gotu kola and pharmaceuticals (and other natural agents) must be considered in the clinical areas of (1) wound healing in relation to trauma and surgery; (2) venous insufficiency and related issues, such as varicosities, ulcers, and diabetic microangiopathy; and (3) cognitive dysfunction, integrative oncology, and toxic metal chelation.

Several experimental and clinical studies support topical use of gotu kola as a wound-healing and cicatrizing agent.[6-8] A tertiary review (Cochrane) examined trials of topical preparations for striae gravidarum and found at least one combination preparation had significant results for this condition.[9] Although the underlying mechanisms for this activity have not been fully elucidated, recent experimental data suggest effects on fibroblast gene expression modulating connective tissue matrix formation and angiogenesis, including by fibroblast growth factor.[10,11] This is consistent with previous animal studies that showed increases in collagen strength and extracellular matrix collagen content in animal wound-healing models, although the involvement of an antioxidant mechanism is also possible.[6,7,12,13] The mechanisms of wound healing suggest that combinations with nutritional and herbal agents directed toward promotion of wound healing are likely to be a fruitful area of interaction research. For example, Cesarone, Belcaro, Incandela, De Sanctis, and others have conducted numerous small clinical trials with oral gotu kola extracts (particularly Centellase, a preparation standardized to 40% asiaticosides, 30% madecassic acid, 30% asiatic acid) for venous insufficiency, varicose veins, and diabetic microangiopathy, with positive results.[14-23] The Cochrane review of trials of topical preparations for treatment of striae gravidarum found that the most effective preparation was a combination product in which the centella extract was combined with α-tocopherol and collagen hydrolysates, suggesting that the combination with vitamin E was more effective than preparations based on the herb alone.[9]

Adaptogenic herbs such as the ginsengs (e.g., *Panax ginseng* C.A. Meyer) have been incorporated in several ways into integrative cancer protocols. Evidence for possible roles for gotu kola interacting with conventional treatments in the integrative oncological environment is limited, however, and its use needs to be approached with caution. Discounting antiproliferative effects on keratinocytes in psoriasis, few

studies show direct cytotoxic effects on cell-lines (Ehrlich ascites and Dalton's lymphoma ascites, MCF-7 and MDA-MB231 breast cancer) and in vivo (mouse lung fibroblast) models.[24,25]

One caveat for use of gotu kola in the oncology setting is that the wound-healing activity of the herb is associated with promotion of angiogenesis.[11] Arguably, in metastatic disease treated with antiangiogenic agents, theoretical antagonism with these agents, such as bevacizumab (Avastin), is possible. Many antiangiogenic drugs are investigational at present but are likely to expand significantly as a drug class in the near future.

Oral extracts of gotu kola appear to have potential for protection against radiation-induced dermatitis in animal models, as well as for reduction of radiation-induced changes in taste-related behavior and protection of healthy cells against damage by radiation.[26-29]

Combinations with cytotoxic chemotherapeutic drugs have recently been investigated in a few experimental studies. In a colon cancer line, asiatic acid dose-dependently synergized with irinotecan (CPT-11).[30] Oral pretreatment with *Centella asiatica* ameliorated doxorubicin-induced cardiomyopathy in a rodent model.[31]

In another study, asiaticoside enhanced the cytotoxicity of vincristine in four cell lines.[32] Such data are preliminary, but taken together with the general antioxidant, neuroprotective, and immunomodulating properties of the herb, suggest promise for its possible incorporation into integrative oncological protocols.

There are few leads to suggest mechanisms of neurocognitive pharmacology of gotu kola, despite its traditional reputation for cognitive enhancement and as a longevity tonic.[33,34] In vitro the herb appears to promote neurite growth and nerve regeneration.[35] Experimental studies suggest some modulation of streptozocin-induced "models" of Alzheimer's disease,[36] and semisynthetic asiaticoside derivatives have been tested positively against beta-amyloid neurotoxicity.[37] Centella extracts may protect against glutamate-induced excitotoxicity in cortical neuron culture systems, an effect considered to be mediated by antioxidant mechanisms.[38] Modulation of the acoustic startle responses in rodents (resembling similar effects induced by anxiolytic drugs) has been demonstrated after oral administration of the extracts and is thought to be mediated by a cholecystokinin (CCK) mechanism.[39,40] Another rodent study examined the effect of oral gotu kola on the course of kindling development, kindling-induced learning deficit, and oxidative stress markers in pentylenetetrazole (PTZ)–induced kindling in rats. The authors suggested a possible interaction role for combining gotu kola with antiepileptic medications to help prevent kindling-promoted learning deficits.[41]

At present the available data, mostly derived from in vitro and animal tests, are not sufficiently coherent for a meaningful analysis of potential interactions with psychiatric or neurological drugs. Nonetheless, research in the role of gotu kola extracts in neurocognitive conditions may lead to their use in psychopharmacological integrative strategies as more data become available.

HERB-DRUG INTERACTIONS

Acetylsalicylic Acid and Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) and Other Ulcerogenic Agents

Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine), ASA, codeine, butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin).

COX-1 inhibitors: Diclofenac (Cataflam, Voltaren), combination drug: diclofenac and misoprostol (Arthrotec); diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), furbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen); combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen); indomethacin (indometacin; Indocin, Indocin-SR), ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Aleve, Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).

COX-2 inhibitor: Celecoxib (Celebrex).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Ulcerogenic agents such as NSAIDs induce or exacerbate gastric mucosal damage. Concomitant administration of gotu kola reduces gastropathic adverse effects by several protective mechanisms, including increased mucosal secretion and angiogenesis.

Research

Experimental rodent models of gastric ulcers induced by both physical methods and pharmacological agents, including aspirin and ethanol, have demonstrated ulceroprotective effects, with increased mucous secretion and proliferation of epithelial cells of the mucosa as well as increased angiogenesis by oral gotu kola extracts, fresh juice, and purified asiaticide peparations.[11,42,43] Treatment of gastric and duodenal ulcers in humans has been supported by three Korean studies (unavailable for review) cited in the WHO monograph.[3] In one of these, an open-label trial, 15 patients with either peptic or duodenal disease received 60 mg gotu kola extract orally per day. Endoscopic and radiological parameters suggested that 73% of ulcers were healed by the treatment, and 93% of patients reported subjective symptom improvement.

Clinical Implications and Adaptations

Given that a variety of well-documented natural agents are protective against aspirin- and NSAID-induced gastropathy, such as deglycyrrhizinated licorice (DGL) and aloe-based preparations (see Licorice and Aloe monographs), in the West this interaction is unlikely to be considered a significant

addition to existing integrative strategies of ulceroprotection by botanicals.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Central Nervous System (CNS) Depressants: Alcohol, Barbiturates, Benzodiazepines, Opioids, and Sedative-Hypnotics

One 1970s rodent study from the Indian literature attributed sedative effects to gotu kola, and a more recent study of stress-induced ulcers in a rodent model concluded that the ulceroprotective effects of gotu kola could be abolished by pretreatment with bicuculline methiodide, a known gamma-aminobutyric acid (GABA) antagonist.[42] Extrapolations from these limited data to suggest additive interactions with CNS sedatives have been made but do not appear justified.

Oral Hypoglycemic, Hypolipidemic, and Hypocholesterolemic Drugs

Two small preclinical studies on gotu kola from the 1960s Indian literature by Appa Rao and co-workers have been cited by various secondary authors.[4,44] These studies found a tendency for oral administration of the extracts to be associated with elevations in blood sugar, serum cholesterol, and red blood cells in normal subjects. The elevations in the first two parameters were not statistically significant. Nonetheless, these findings have been used speculatively to suggest possible interactions between cholesterol-lowering and antidiabetic pharmaceuticals.[45] No recent work on metabolic effects of gotu kola has substantiated these proposed actions.

The 45 citations for this monograph are located under Gotu Kola on the CD at the back of the book.

Green Tea

Botanical Name: *Camellia sinensis* L. Kuntze.
Pharmacopoeial Name: Folium Camellia sinensis (Theae folium).
Synonym: *Thea sinensis* L.
Common Names: Tea, cha. Various prefixes, such as the country name (e.g., Ceylon), district (e.g., Assam), grade or part (e.g., pekoe [buds]), or degree of fermentation (e.g., green, oolong, black), are used to differentiate various commercial tea products by common name.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Corticosteroids, topical ⊕⊕⊕/☼	Tea additively increases anti-inflammatory effects of drug in refractory atopic dermatitis. Coadministration enables lower dose. May apply to tacrolimus/steroid combinations.	Include green tea extract (GTE) in integrative protocols for refractory atopic dermatitis.
Doxorubicin Anthracycline chemotherapy ⊕/☼	Chemosensitization by L-theanine and polyphenols; cardioprotection by polyphenols. Experimentally demonstrated, not clinically established.	Coadminister GTE and L-theanine during anthracycline chemotherapy.
Iron salts, nonheme ◈	Concurrent consumption of tea with iron salts may reduce bioavailability of iron. Only significant in patient groups with, or at high risk of, iron deficiency anemia.	Use heme iron where supplementation necessary, or temporally separate tea and iron salt dosing and use Fe-absorption enhancers.
Methicillin Beta-lactam and other antibiotics ⊕	Coadministration with beta-lactam antibiotics reverses MRSA resistance. May be of more general clinical significance, synergism demonstrated for various antibiotics.	Coadminister GTE with beta-lactam antibiotics to increase efficacy, especially for suspected drug-resistant strains.
SERMs Aromatase inhibitors ⊕	GTE enhances tamoxifen-induced apoptosis in vitro and inhibits aromatase. Interactions not clinically established.	Consider GTE coadministration with adjuvant endocrine therapies in estrogen-dependent malignancy.
Trastuzumab ⊕	Possible additive effects on HER-2/neu inhibition; not clinically established. Tyrosine kinase inhibition may have more general significance.	Consider coadministration in integrative protocols for HER-2/neu–overexpressing cancers.
Warfarin Anticoagulant or antiplatelet agents ?	Possible antiplatelet effects; one unreliable report of warfarin interaction. Clinical significance unknown, probably minor.	Monitor INR; monitor for signs of bleeding. Low levels of GTE unlikely to be problematic.

MSRA, Methicillin-resistant *Staphylococcus aureus*; *SERMs*, selective estrogen response modulators; *INR*, international normalized ratio.

HERB DESCRIPTION

Family

Theaceae (Ternstroemiaceae).

Related Species

At least one subspecies and several cultivars are described.

Habitat and Cultivation

Tea plants are actually evergreen trees maintained as tea bushes by pruning in cultivation to shrub height to enable hand harvesting of the young leaves. Tea *(Cha)* originally was native to the Yunnan province in southwestern China and initially spread to several different areas in China and India, but it has been in cultivation for so long in rain forest zones throughout many Southeast Asian countries that wild-type plants are now rare. China and India are the largest cultivators, and India is the largest exporter. Pu'erh tea *(Pu Erh Cha)* is derived from the leaves of old tea trees on six specific mountains in Yunnan, fermented and aged through specific processes, and is considered a separate beverage with significantly different characteristics and medicinal actions.

Parts Used

Young leaves, tips, and leaf buds.

Common Forms

Dried Leaf.
Powdered Green Tea Leaf.
Dry Extracts: Derived from ethanolic extracts, preparations may vary; some may be decaffeinated, standardized to total catechins of greater than 25%. Concentrates of specific tea polyphenols, up to 97% catechins, and other compounds, such as L-theanine (analog of L-glutamine), are marketed as nutrient preparations and therapeutic agents. L-Theanine is also produced in high yield by microbial fermentation for use in nutriceutical products.

HERB IN CLINICAL PRACTICE

Overview

Tea is the most common beverage in the world (other than water). Tea belongs to the universally popular category of xanthine-containing beverages, such as coffee, cola, maté, and cocoa, the popularity of which is partly related to their caffeine content. Commercially, the principal types are green tea and black tea. Green tea is stabilized and dried immediately

after harvesting, then rolled. This processing method means the crude herb approximates as closely as possible to its natural state at harvesting; thus green tea is designated as the "medicinal" form of the herb, as derived from tea bushes. Black teas are dried after the rolling process, allowing oxidative enzymatic changes to take place, principally polymerization of the flavan-3-ols into the characteristic oligomeric red-brown theaflavins and thearubigins, as well as the polymeric tannins, which are absent from green tea.

Research interest in green tea compounds has accelerated dramatically in the last decade, with epidemiological, experimental, and clinical evidence for chemopreventive, antiproliferative, and cardioprotective benefits of tea polyphenols. These activities are the result of a variety of pharmacological mechanisms, including antioxidant effects, cell cycle effects, and signal transduction effects.[1-4]

Green tea has not traditionally been considered part of the Western herbal materia medica until the rather recent interest in its chemopreventive properties. The usual authoritative sources of botanical medicine have not, to date, produced therapeutic monographs on the plant. In herbal medicine, tea has primarily been regarded as a dietary source of caffeine and astringent tannins and is regarded as a milder stimulant than the caffeine-containing cola and guaraná, which have been preferred when caffeine-containing herbs were indicated. McKenna et al.[5] reviewed the general literature on tea in 2002. Interest in the chemopreventive and cardioprotective properties of tea polyphenols have led to the manufacture of concentrated preparations of these compounds. Tea leaf is regulated as a food beverage ("generally recognized as safe," GRAS) in the United States, whereas isolated and concentrated green tea polyphenols are classified as dietary supplements.

Historical/Ethnomedicine Precedent

Traditional Chinese use of green tea leaf *(Lu Cha)* is primarily for gastrointestinal complaints, for which it is combined with other herbs to treat nausea and vomiting and as an antidiarrheal (astringent). It is also used for headaches and dispelling "damp." In Ayurvedic medicine, green tea is similarly considered a diuretic, astringent, and mild stimulant. As noted, Pu'erh tea *(Pu Erh Cha)* is considered a separate medicinal agent, significantly rarer and highly valued, with distinct qualities and uses. *Pu Erh Cha* is considered "Earth" in nature and *Lu Cha* "Wood" in nature.

Known or Potential Therapeutic Uses

Atherosclerosis; adjunct to some antimicrobial and antineoplastic pharmacotherapies for microbial infections; cardioprotection and reduction of cardiovascular risk factors; chemoprotection; chemoprevention of colon, pancreatic, esophageal, and other cancers; central nervous system (CNS) stimulation; gingival and periodontal infection; headache; hypercholesterolemia; mild diarrhea; thermogenesis (and weight loss); renal insufficiency.

Key Constituents

Methylxanthines, principally caffeine (2%-4%); polyphenols (30%-40%), four principal compounds: (−)-epicatechin (EC), (−)-epigallocatechin (EGC), (−)-epicatechin gallate (ECG), and (−)-epigallocatechin gallate (EGCG).

Other constituents include various flavonols, including proanthocyanidins, amino acids (principally L-theanine), protein, vitamins (ascorbate, B group), minerals, and organic acids.

Note: The abbreviations EC, EGC, ECG, and EGCG are used throughout this monograph to designate the four principal catechin compounds.

Therapeutic Dosing Range

Infusion of Dried Leaf: 1.0 to 3.0 g as required; 1 cup delivers 300 to 400 mg of polyphenols; up to 5 cups per day as a beverage.
Powder: 4 to 12 g by decoction, typical modern Chinese dosing.
Standardized Extract: Polyphenols range from 25% (Exolise, Arktopharma) to 97% (Tegreen, Pharmanex LLC) polyphenols to deliver up to approximately 750 mg of polyphenols per dose.

INTERACTIONS REVIEW

Strategic Considerations

Beverage consumption of tea needs to be delineated from therapeutic administration of polyphenol-rich green tea extracts (GTEs). The popularity of beverage tea consumption, particularly in the form of black tea, is often considered to be based primarily on its caffeine content. Caffeine, an ingredient of hundreds of over-the-counter (OTC) medications, is well known for its CNS-stimulating and adenosine receptor–mediated effects. In beverage use, green tea delivers only 50 to 100 mg caffeine per cup, about half (or less) the quantity of caffeine in a cup of coffee. Some authors, when reviewing green tea interactions, have resorted to listing well-known caffeine-drug interactions without contextualization of beverage versus therapeutic use of tea, or distinction between green tea and black tea forms, and despite the lack of evidence that normal dietary tea consumption induces caffeine-drug interactions.

Caffeine interactions are properly classified in the domain of the drug-drug interaction literature; for example, *Stockley's Drug Interactions*[6] lists more than 70 interactions between caffeine and other drugs. Caffeine, along with related methylxanthines such as theophylline, is cleared oxidatively by cytochrome P450 (CYP450) 1A2, so drugs that strongly inhibit 1A2 (e.g., fluvoxamine, quinolone antibiotics) can accentuate the adverse effects of caffeine consumption in chronic high-level tea consumption. The clinical importance of these effects is not established, however, and case reports are lacking. Caffeine has been shown to contribute to chemopreventive effects of GTEs in the few studies that have made direct comparisons among tea, decaffeinated tea, and caffeine.[7-9]

The principal health benefits of chemoprevention and cardioprotection associated with dietary tea consumption are related to its polyphenol content. The amount of polyphenols in green tea infusions is about 300 to 400 mg per cup, whereas standardized GTEs can contain up to 97% polyphenols, and some may be decaffeinated. Relatively high doses of green tea infusion are required for therapeutic use because of the poor intrinsic oral bioavailability of the polyphenols; 10 cups of green tea per day (not uncommon in Japan) could arguably be considered the transition between beverage and therapeutic dose exposure. Black tea contains considerably less flavan-3-ol catechins, which are transformed by fermentation into oligomeric derivatives, the thearubigins and theaflavins, which are not found in unfermented green tea products.[10]

Typical concerns about potential adverse effects of cardioprotective herbs on hemostasis and possible interactions with anticoagulants are discussed later in relation to tea compounds. The mechanisms underlying the chemopreventive and anticancer effects of green tea are currently subject of much investigation, and emerging data on tea polyphenols' synergistic effects with chemotherapy, modification of drug resistance, and multiple effects on signal transduction are emerging from in vitro and cell-line studies, with potentially valuable implications for integrative cancer therapeutics. These potential interactions are reviewed here, although clinical data are currently anecdotal. However, at least two significant caveats must be considered when in vivo extrapolations are made from the experimental findings. Current epidemiological data on the chemopreventive effects of green tea are positive, at least for breast cancer, although the data are limited and clinical trial evidence is lacking.[11]

First, cell-line studies using concentrations of tea polyphenols in the 100 to 1000 micromolar (μM) range cannot be extrapolated to beverage consumption because of the low oral bioavailability of these compounds. The different polyphenols and their metabolites do have differing bioavailabilities; EGCG is less bioavailable than the other compounds, possibly because it is the only tea polyphenol that is a substrate as well as inhibitor of intestinal P-glycoprotein; P-gp is inhibited by all the tea polyphenols, with EGCG being the most potent inhibitor.[12] A human study of single-oral dose kinetics of EGCG found that higher doses (800 mg) achieved significantly greater area under curve (AUC) and maximum concentration (C_{max}) levels than lower doses (200 and 400 mg), suggesting a saturable first-pass mechanism.[13] Biotransformation of green tea polyphenols is complex and involves glucuronidation, sulfation, and methylation by catechol-*O*-methyltransferase (COMT) as well as intestinal flora-mediated ring fission products that are further metabolized to phenylacetic and phenylpropionic acids. The activities of the different intermediate metabolites remain unclear, although their bioavailability is higher than that of EGCG.[14] Preliminary evidence also suggests that significant differences may exist between rodent and human microsomal metabolism of tea polyphenols.[15]

Second, although derivative literature often ascribes the effects of green tea polyphenols to their antioxidant properties, some of their in vitro activity may result from pro-oxidant actions. EGCG is unstable in cell culture conditions and tends to undergo auto-oxidation, producing superoxide radicals and hydrogen peroxide (H_2O_2).[16] Hou et al.[17] suggested that EGCG-related peroxide formation may underlie cell-line effects such as apoptosis induction and that free radicals may be responsible for the observed EGCG-induced inhibition of growth factor receptors EGFR and PDGR. It is unclear whether such pro-oxidative reactions occur in vivo as a result of the low oxygen partial pressures and high antioxidant capacity found in vivo.

The phenomenon of in vitro pro-oxidant effects is likely an artifact of the in vitro absence of antioxidant networks. Logically, only in vitro systems that include physiological levels of albumin, glucose, uric acid, and glutathione and typical serum levels of diet-derived antioxidants would be reasonable in terms of extrapolating to the in vivo situation. Most in vitro systems do not attempt to replicate in vivo antioxidant networks.

Effects on Drug Metabolism and Bioavailability

Green tea compounds may affect all three phases of drug transport and metabolism and thus potentially participate in pharmacokinetic interactions with drugs. Animal and in vitro evidence suggests that polyphenols inhibit Phase I drug metabolism by CYP450 enzymes 1A1 and 1A2.[18-23] One study using recombinant human CYP450 in a genetically engineered bacterial model found EGCG appears to have nonspecific inhibitory effects on 1A1, 1A2, 2A6, 2C19, 2E1, and 3A4.[24] Different forms of tea exhibit different effects on rat liver enzyme activity in a study of rats fed different teas for 4 weeks; for example, oolong and Earl Grey tea induced increases in 3A4 activity but green tea did not, and 1A2 was unaffected by any tea, but 1A1 was affected by both green and fermented teas.[25] These studies suggest that different tea compounds may exert different effects on various drug-metabolizing enzymes, especially those involved in carcinogen metabolism. At this time, however, the clinical effects in humans remain to be established.

Phase II conjugation reactions are mediated by conjugases and transferases. Tea polyphenols not only are substrates for glucuronidation and sulfation, but also have demonstrated significant induction effects on uridine diphosphate (UDP) glucuronosyltransferase (UGT) and sulfotransferase isoforms (SULTs) as well as glutathione transferase in rodent models and in vitro.[15,26-32] Again, these effects have not been studied in vivo in humans, although it is plausible that they may underlie the chemopreventive effects of green tea against certain carcinogenic and tumorigenic agents.

Phase III, mediated by drug transporters, principally P-gp, is also modulated by all the tea polyphenols, but EGCG appears to be the most potent inhibitor.[12,16,33-38] There is some evidence that additional drug transporter proteins, including the organic anion-transporting polypeptide (OATP), may be inhibited by tea polyphenols.[39-41] No single polyphenol component appears to be responsible for the inhibitory effect of GTE on multidrug resistance-associated protein 2 (MRP-2), found in intestinal cells.[42] The amino acid theanine has specific effects on the glutamate transporter, which is considered to be the mechanism underlying an interaction between theanine (and whole green tea) and anthracycline agents such as doxorubicin.[43-46] At this time, the firmest evidence that tea polyphenols may exhibit significant pharmacokinetic interactions with prescription drugs relates to effects on Phase III drug transporters. Further studies are required to elucidate the details of their effects on Phase I and Phase II enzymes, for which in vivo human data are currently lacking.

Theanine

The amino acid constituent L-theanine (δ-glutamylethylamide) is the primary amino acid constituent of green tea and constitutes 1% to 3% of the dry weight of the dry leaf. L-Theanine has recently become available as a separate nutrient product after research suggested that it underlies the synergistic interactions of GTEs with anthracycline chemotherapeutic drugs, as well as having neuroregenerative and mood-elevating effects that may have applications in Alzheimer's disease and affective disorders. The currently known L-theanine interactions are included in the next section (see Doxorubicin).

HERB-DRUG INTERACTIONS

Corticosteroids, Topical

Alclometasone (Aclovate, Modrasone), amcinonide (Cyclocort), beclomethasone, betamethasone dipropionate/valerate (betamethasone topical; Alphatrex, Beta-Val, Betaderm, Betanate, Betatrex, Diprolene AF, Diprolene,

Diprosone, Luxiq, Maxivate, Teladar, Uticort, Valisone), clobetasol (clobetasol topical; Cormax, Dermoval, Dermotyl, Dermovate, Dermoxin, Eumosone, Lobate, Olux, Temovate, Temovate E, Topifort), clobetasone (Eumovate), clocortolone (clocortolone pivalate topical; Cloderm), desonide (DesOwen, Tridesilon), desoximetasone (Topicort, Topicort LP), desoxymethasone, dexamethasone (Aeroseb-Dex, Decaderm, Decadron, Decaspray), diflorasone (Apexicon, Florone, Maxiflor, Psorcon), diflucortolone (Nerisona, Nerisone), fluocinolone (Derma-Smoothe/FS, Fluonid, Synelar, Synemol), fluocinonide (Fluonex, Lidex, Lidex-E, Lonide, Vanos), fludroxycortide (flurandrenolone), fluocortolone (Ultralan), flurandrenolide (Cordran, Drenison), fluticasone (Cutivate), halobetasol (Ultravate), halcinonide (Halog), hydrocortisone 17-butyrate/acetate/probutate/valerate (hydrocortisone topical; Acticort100, Aeroseb-HC, Ala-Cort, Ala-Scalp HP, Allercort, Alphaderm, Bactine, Beta-HC, Caldecort Anti-Itch, Cetacort, Cort-Dome, Cortaid, Cortef, Cortifair, Cortizone, Cortone, Cortril, Delacort, Dermacort, Dermarest, DriCort, DermiCort, Dermtex HC, Epifoam, Gly-Cort, Hi-Cor, Hydro-Tex, Hytone, LactiCare-HC, Lanacort, Lemoderm, Locoid, MyCort, Nutracort, Pandel, Penecort, Pentacort, Proctocort, Rederm, S-T Cort, Synacort, Texacort, Westcort), mometasone (Elocon, mometasone topical), triamcinolone (Aristocort, Triderm, Kenalog, Flutex, Kenonel, triamcinolone topical); combination drug: triamcinolone and nystatin (Mycolog II).

Interaction Type and Significance

⊕⊕⊕ **Beneficial or Supportive Interaction, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **3. Possible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Coadministration of tea with topical steroids improves dermatological response to these drugs in refractory atopic dermatitis. This may allow reduction of corticosteroid dose and lowered adverse drug effects.

Research

Uehara et al.[47] conducted an open trial of 118 patients with refractory atopic dermatitis, who were instructed to continue with their pharmacological treatments, primarily topical steroids. Some patients (not specified) were taking oral histamines. An infusion of oolong tea was consumed three times a day, the beverage being made from 10 g dried tea infused in 1000 mL water for 5 minutes. After 1 month a significant improvement in skin lesions was recorded in 63% of patients. Benefits appeared after 1 to 2 weeks of treatment, and at 6 months, 54% of patients reported persistent improvement. The authors suggest that oolong tea extracts have antiallergenic properties and improve response to topical steroid pharmacotherapy.[47] The mechanisms of the effect of tea polyphenols on atopic inflammatory responses are not known but may involve antioxidant effects.

Clinical Implications and Adaptations

The small study reporting beneficial effects of coadministration of tea with topical steroids is interesting for the low dose of tea used. Reduction of steroid anti-inflammatory dose is always a desirable goal when these agents are administered chronically. Increasingly, however, the treatment of choice in atopic dermatitis are the topical immunosuppressive agents (e.g., tacrolimus), which are often combined with topical corticosteroids in refractory cases of atopic dermatitis.[48] Effects of tea polyphenols on this combination are unknown.

Doxorubicin and Related Anthrocycline Chemotherapy

Evidence: Doxorubicin (Adriamycin, Rubex).

Extrapolated, based on similar properties: Cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), daunorubicin (Cerubidine, DaunoXome), epirubicin (Ellence, Pharmorubicin), irinotecan (camptothecin-11, CPT-11; Campto, Camptosar), mitoxantrone (Novantrone, Onkotrone).

Related but evidence lacking for extrapolation: Doxorubicin, pegylated liposomal (Caelyx, Doxil, Myocet).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Tea polyphenols appear to reduce doxorubicin-induced cardiotoxicity by modifying lipid peroxidation and cardiomyocyte–fatty acid metabolism patterns. EGCG also increases tumor sensitivity to doxorubicin by inhibiting P-gp, which promotes efflux of the drug from malignant cells. Theanine further enhances the efficacy of doxorubicin through inhibition of glutamate transporters and modulation of the glutathione-*S* conjugate exporter pump (GS-X). Preliminary data suggest that related anthracyclines and possibly unrelated classes of chemotherapy agents such as cisplatin and irinotecan may behave similarly when coadministered with tea polyphenols and theanine.

Research

Sugiyama, Sadzuka, and colleagues have conducted a series of investigations on the effects of theanine and EGCG on the modulation of sensitivity to doxorubicin in different cell lines, including Ehrlich ascites carcinoma cells,[35,49] and in an animal model using M5076 ovarian sarcoma tumor-bearing mice,[44-46,50,51] as well as in P388 leukemia cell–bearing animals.[35] The effect of theanine at 10 mg/kg/day intraperitoneally in the animal model was a significant increase (2.9 times) in intratumor doxorubicin concentration and a significant decrease in hepatic metastasis development. Oral administration of green tea/theanine at 100 mg/kg/day for 4 days also led to a 55% reduction in tumor size compared with doxorubicin-only control animals. Theanine reduced concentrations of doxorubicin in normal tissues (lung, liver, kidney) but was found to increase doxorubicin concentration in hepatic metastases. Theanine also reduced myocardial lipid peroxidation. Theanine, itself a glutamate derivative, inhibits glutamate transporters, and this is now considered to be one mechanism for doxorubicin concentrations to be increased in tumor cells. The experimental findings are reviewed by Sugiyama and Sadzuka.[46]

Tea polyphenols also modulate P-gp by inhibiting the membrane adenosinetriphosphatase (ATPase).[34,38] The well-documented cardioprotective effects of green tea polyphenols have been shown to reduce the toxicity of doxorubicin in cultured cardiomyocytes, as measured by fatty acid composition, conjugated diene concentration, and lactate dehydrogenase

(LDH) release. The primary mechanism is antioxidant prevention of lipid peroxidation by the doxorubicin-induced superoxide and peroxide radicals. However, there is also a direct effect on unsaturated fatty acid metabolism involving the desaturating/elongating enzymes.[52]

Because iron-chelating compounds are also protective against anthracycline-induced cardiac damage, chelation by tea polyphenols may be an additional mechanism, but evidence for this is not available.

Clinical Implications and Adaptations

Experimental data suggest that anthracycline cardiotoxicity can be reduced by green tea polyphenols, and that the green tea component theanine can increase sensitivity to doxorubicin in drug-resistant cell lines. Clinical studies are required to confirm these effects in human patients; however, given the lack of adverse effects of theanine and the green tea polyphenols, employment of these natural compounds as adjuncts to anthracycline chemotherapy should be considered for inclusion in integrative support protocols during anthracycline chemotherapy.

Iron Salts (Nonheme Iron)

Interaction Type and Significance

◈ Impaired Drug Absorption and Bioavailability, Negligible Effect

Probability:
3. Possible

Evidence Base:
● Consensus

Effect and Mechanism of Action

Tea polyphenols have been shown to form chelates with nonheme iron. A pharmacokinetic interaction may occur if green tea is coadministered with food containing nonheme iron, which may reduce the level of iron absorption. The clinical significance of this interaction on iron status is considered minimal.

Research

Samman et al.[53] performed a small open trial using radiolabeled iron added to meals over 4 days in healthy young women. The meals were identical except that green tea polyphenol extract or rosemary extract was added to the baseline test meal. A standard reference dose of an iron salt was also administered to examine variation in iron absorption characteristics. Addition of either natural agent to the meal caused a small decrease in iron absorption, slightly more with green tea than rosemary, a relative absorption decrease of 28% ($p < 0.01$).

A systematic review of available data on the inverse association between tea consumption and iron status examined 16 studies, including subgroups with high and low anemia risk status. Following adjustment for dietary factors there was no association between tea consumption and ferritin and hemoglobin status.[54] Another systematic review of observational studies examining the effects of tea drinking on iron consumption concluded that restrictions on tea drinking were unnecessary in healthy people with no risk of iron deficiency.[55] One often-quoted study suggests that infants age 6 to 12 months consuming 250 mL tea per day (median value) had a higher incidence of microcytic anemia than those who did not drink tea.[56]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Standard medical advice for groups at risk of iron deficiency anemia is to drink tea between meals, waiting at least 1 hour after eating.[57] Iron absorption enhancers such as ascorbic acid can be used in at-risk individuals, and administration of supplementary iron in the form of heme iron will tend to avoid any chelation problems based on the simple salts (e.g., ferrous sulfate, gluconate).

Methicillin and Related Beta-Lactam Antibiotics

Evidence: Methicillin (Staphcillin); beta-lactamase–resistant penicillins: cloxacillin (Cloxapen), dicloxacillin (Dynapen, Dycill), oxacillin (Bactocill); carbapenem antibiotics: meropenem (Merrem I.V.); combination drug: imipenem and cilastatin (Primaxin I.M., Primaxin I.V.).
Extrapolated, based on similar properties: Cephalosporin antibiotics, ciprofloxacin and other fluoroquinolone antibiotics, ketaconazoles, macrolide antibiotics, other penicillin antibiotics; combination drugs: amoxicillin and clavulanic acid (Augmentin, Augmentin XR, Clavulin, Nuclav); clavulanic acid and ticarcillin (Timentin).

Interaction Type and Significance

⊕ Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management

Probability:
1. Certain

Evidence Base:
○ Preliminary

Effect and Mechanism of Action

A synergistic interaction between tea polyphenols when combined with a broad range of beta-lactam antibiotics that appears to reverse beta-lactam resistance by modulating the bacterial phenotype in methicillin-resistant strains of *Staphylococcus aureus* (MRSA). The interaction may be an example of a general interaction between tea polyphenols and antimicrobial drugs.

Research

A number of experimental studies have demonstrated significant reductions in minimum inhibitory concentration (MIC) of methicillin, penicillin, oxacillin, and other beta-lactam antibiotics by two orders of magnitude. This effectively reverses resistance in several isolated MRSA strains by lowering MIC to below the resistance breakpoint.[58-61] Initial studies used either EGCG or ECG, and there were discrepancies regarding the relative potencies of the two catechins, as well as a lack of data on the mechanisms involved and as to whether related polyphenolic compounds might exert similar effects. The mechanism of modulation of resistance may be multifactorial, including efflux pump disabling[62] and penicillinase inhibition,[63] as well as direct binding to peptidoglycan in the bacterial membrane and intercalation in the membrane lipid layer.[64,65]

Stapleton et al.[66] systematically tested ECG, EGCG, and several other gallates and catechins, measuring oxacillin activity against different MRSA isolates, and established that ECG has a greater capacity to modulate beta-lactam resistance than EGCG. They also found that the gallate moiety was essential for activity, and that ECG was also effective with the carbapenem antibiotics imipenem and meropenem. Recent investigations suggest that the synergistic effects with antimicrobials may extend to other drug-microbial combinations, such as macrolides with *Helicobacter pylori*, ketaconazoles with *Candida albicans*, and fluoroquinolones and *Escherichia coli*.[67-71] A rodent model of prostatitis was used to demonstrate a synergistic effect between ciprofloxacin and green tea catechin.[72]

One small, controlled trial examined the effects of inhalation of tea catechins (2 mL containing 7.4 mg polyphenols with 3.7 mg EGCG via nebulizer three times daily for 4 weeks) in 12 elderly patients with confirmed MRSA titer in sputum samples versus 12 similar controls. Classification of MRSA was defined as cultured *S. aureus* showing an oxacillin MIC of more than 4 mg/L. The trial included patients who had been treated with antibiotics, but during the trial period the catechins were administered alone. After 1 week the number of patients in the catechin group with detectable MRSA was significantly less than that of the controls. Hospital stay was also significantly reduced for the catechin group compared with controls.[73] This trial suggests benefits to catechins taken alone in MRSA-positive patients, but did not investigate the effects of coadministration.

To date, clinical trials on combinations are unavailable.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Methicillin-resistant *S. aureus* is a widespread cause of nosocomial infection. Experimental evidence strongly supports the use of tea catechins, particularly EGC, in combination with beta-lactam antibiotics. Although most relevant to the hospital setting, studies have yet to be undertaken. However, integrative practitioners dealing with community-acquired infections in vulnerable populations suspected of demonstrating antibiotic resistance might choose to coadminister tea polyphenol extracts to modulate the antibiotic resistance.

Selective Estrogen Response Modulators (SERMs), Aromatase Inhibitors

Evidence: Tamoxifen (Nolvadex).
Extrapolated, based on similar properties: Anastrozole (Arimidex), exemestane (Aromasin), letrozole (Femara), raloxifene (Evista), toremifene (Fareston).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:
6. Unknown

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

A possible interaction is based on in vitro evidence that tamoxifen-induced apoptosis is increased by EGCG, possibly mediated by inhibitory effects on tumor necrosis factor alpha (TNF-α). Additional evidence suggests that tea polyphenols may also have aromatase inhibitor–like activity. The interaction is not clinically established.

Research

In a series of studies using human lung cancer PC-9 and breast cancer MCF-7 cell lines, Suganuma et al.[74,75] investigated the induction of apoptosis by different tea polyphenols alone and in combination. They found that EC (which lacks the galloyl moiety and has no effect on apoptosis alone) synergistically increased the apoptotic effects of ECGC in a dose-dependent manner. Parallel effects were found on BALB/C-3T3 cells in which EC synergistically increased the effect of EGCG on inhibition of TNF-α (IC_{50} reduced from 60 to 7 μM), leading the investigators to posit a TNF-α–mediated mechanism. Using the same technique, they examined the effects of adding either sulindac (a classic NSAID) or tamoxifen to EGCG in the PC9 cell model and found that cotreatment by EGCG with either agent induced apoptosis more than when EGCG was given alone. The effect was smaller with tamoxifen than with sulindac. They replicated the effects of the combination on TNF-α inhibition in the BALB/C-3T3 cells, as well as in MCF7 cells, although these data were not presented.

Way et al.[76] conducted a series of investigations into the mechanisms of EGCG and three black tea theaflavin compounds effects on HER-2/neu transfected MCF7 breast cells. They demonstrated that both EGCG and theaflavins inhibited tyrosine kinase phosphorylation, and further that EGCG/theaflavins could modulate the resistance of the HER-2/neu transfected cells to tamoxifen. The same study series also found the tea compounds showed significant aromatase inhibitory activity in rat ovarian and human placental microsomes. Aromatase inhibition by tea polyphenols has also been confirmed in a human placenta microsome assay, using a combination polyphenol extract (P-60) (IC_{50} = 28 μM).[77] Because aromatase enzymes, predominantly in fat tissue, synthesize estrogen from adrenal androgens, pharmaceutical aromatase inhibitors are widely used in treatment of estrogen-dependent breast cancer in women without active ovarian function, to reduce estrogen levels further.

As a footnote, a rodent model found that GTE reduced tamoxifen-induced hepatic injury, following 7 days of tamoxifen at 45 mg/kg intraperitoneally, as indexed by transaminase levels as well as increases in glutathione and other antioxidant enzymes.[78]

Integrative Therapeutics, Clinical Concerns, and Adaptations

The current experimental data for possible synergy between tamoxifen and tea polyphenols are preliminary, and extrapolations cannot be reliably made until confirmation of the effects by human and clinical studies. The suggestions that TNF-α pathways may be modulated by estrogen, and that the activity of tamoxifen involves interaction with this and related factors, are supported in the literature, although the mechanisms are not fully understood.[79,80] Given the activities of tea compounds on multiple molecular targets of the cancer process, coadministration of GTEs in hormone-dependent and hormone-independent mammary carcinoma with adjuvant chemotherapeutic agents warrants further study.

Trastuzumab

Trastuzumab (Herceptin).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:
4. Plausible

Evidence Base:
⊕ **Preliminary**

Effect and Mechanism of Action

Potential additive or synergistic interaction occurs between tea polyphenols, especially EGCG, and trastuzumab because of convergent pharmacodynamic HER-2/neu inhibition effects, probably associated with receptor tyrosine kinase activity. The interaction has been experimentally demonstrated, but clinical support is currently not available.

Research

The chemopreventive effects of tea polyphenols have been demonstrated in various animal models as well as by human epidemiological studies. The mechanisms are multifactorial and have been studied in a variety of cell culture models.[1-4,14,17,81-83]

The tea polyphenol EGCG inhibits receptor tyrosine kinase activity (IC_{50} = 1-2 μM).[84] Masuda et al.[85] demonstrated EGCG inhibition of EGFR autophosphorylation in head and neck squamous cell carcinoma and breast carcinoma cell lines. The same investigators later demonstrated significant inhibition of HER-2/neu activation in the same cell lines, although at high concentrations (10 and 30 μg); also, the sensitivity of both cell lines to paclitaxel (Taxol) was significantly increased by much lower doses of (0.1-1.0 μg/mL) of EGCG.[86]

Way et al.[76] conducted a series of investigations into the effects of EGCG and three black tea theaflavin compounds on HER-2/neu transfected MCF7 breast cells. They demonstrated that both EGCG and theaflavins inhibited tyrosine kinase phosphorylation, and further that EGCG/theaflavins could modulate the resistance of the HER-2/neu transfected cells to tamoxifen. The same study series also found the tea compounds showed significant aromatase inhibitory activity in rat ovarian and human placental microsomes.[76] The authors concluded that tea polyphenols could be useful in HER-2/neu–overexpressing cancers. Shimizu et al.[87] used a colon cancer line overexpressing HER-3 and cyclooxygenase-2 (COX-2) and found that very low doses of ECGC inactivated EGFR, HER-2, and HER-3; decreased COX-2 and Bcl-xL proteins; and induced apoptosis.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Concentrated tea polyphenol extracts are typically combined with other chemopreventive compounds in botanical and nutritional components of integrative cancer therapeutic protocols. Despite the preliminary nature of the experimental data, the available studies suggest tyrosine kinase inhibition is one of the pluripotent therapeutic activities of tea polyphenols, and that these may be effective in combination with trastuzumab (Herceptin) in diseases that overexpress the HER-2/neu receptor. Because this receptor is also present on myocardial cells, trastuzumab is associated with cardiotoxicity, which is exacerbated when combined with anthracycline agents, themselves cardiotoxic.[68,88,89] Coadministration of anthracycline chemotherapy agents and trastuzumab is contraindicated because of the high incidence of clinical congestive heart failure that occurred in clinical trials of the combination. Even patients who have received anthracycline chemotherapy many years previously have an increased sensitivity to cardiotoxic effects of trastuzumab. In patients undergoing chemotherapy with trastuzumab, especially in patients who have previously received doxorubicin, coadministration of green tea polyphenol extracts in sufficient doses may ameliorate cardiotoxicity and increase drug effectiveness. Previous reservations about the applicability of cell-line studies with tea compounds are particularly pertinent to these extrapolations (see Strategic Considerations).

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Evidence: Warfarin (Coumadin, Marevan, Warfilone).
Similar properties but evidence indicating no or reduced interaction effects: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar).

Interaction Type and Significance

? Interaction Possible but Uncertain Occurrence and Unclear Implications

Probability:
5. Improbable

Evidence Base:
▽ Mixed

Effect and Mechanism of Action

An interaction was originally suggested by an isolated case report of significant INR reduction after consumption of green tea (beverage) in a patient stable on warfarin. The hypothesized mechanism of vitamin K content of green tea counteracting the effects of warfarin on vitamin K–dependent coagulation factor synthesis is unlikely. Antiplatelet rather than anticoagulant effects are more plausible.

Research

Kang et al.[90] investigated the in vitro effects of tea catechins and EGCG on human platelet aggregation induced by adenosine, epinephrine, collagen, and calcium ionophore A23187 and found a dose-dependent inhibition of platelet aggregation but no change in any coagulation parameters. This confirmed an earlier report by Sagesaka-Mitane et al.[91] that the hot-water extracts of tea and EGCG inhibited collagen-induced aggregation in rabbit platelets. Son et al.[92] performed a series of tests on rabbit and rodent platelets with GTE and concluded that the antiplatelet activity observed in vitro was caused by inhibition of thromboxane A_2 (TXA_2) and prostaglandin D_2 resulting from inhibition of arachidonic acid liberation and of inhibition of TXA_2 synthase in response to collagen-induced aggregation.

Few human studies to date have examined the effects of tea on platelet aggregation. In a randomized crossover study, Duffy et al.[93] examined the effects of acute and chronic black tea beverage consumption versus water placebo on 49 patients with coronary artery disease (CAD). They failed to detect any effects on platelet aggregation induced by adenosine diphosphate (ADP) or thrombin receptor activating peptide by the tea infusions at either acute or chronic doses. However, most patients in this study apparently continued with aspirin antithrombotic therapy, which confounds interpretation of the results. Wolfram et al.[94] found that with 1 month of black tea consumption, healthy volunteers displayed gender differences in effect, with only females showing a slight decrease in ADP-induced platelet aggregation. Hodgson et al.[95] examined a wide range of hemostasis parameters before and after the consumption of black tea (five cups per day for 4 weeks) by 22 volunteers. Platelet aggregation did not differ for collagen or ADP stimulation, and no differences in coagulation or fibrinolytic factor were observed after tea consumption. The same researchers performed a similar study on acute, single-dose tea consumption and similarly found no effects on postprandial platelet aggregation.[96] The available evidence therefore suggests that although in vitro studies show a potential for antiaggregatory activity, these have not been reliably reproduced in vivo. Currently, no evidence exists for any effect on coagulation (as opposed to platelet) parameters of hemostasis.

Reports

Taylor and Wilt[97] reported a case of a 44-year-old man with Marfan's syndrome who was receiving Coumadin (7.5 mg daily) to establish an international normalized ratio (INR) of 2.5 to 3.5 after a mechanical aortic valve replacement procedure. He had been on this regimen for 14 months, although with a history of fluctuation in INR that was countered by anticoagulant dose adjustment. The patient presented for routine primary care and was found to have an INR of 3.79. He was advised to stabilize his intake of vitamin K–containing foods and was retested 22 days later without warfarin dose adjustment. The INR was 1.37. The patient could not be contacted but returned 1 month later for regular INR testing,

when his INR was 1.14. He denied changes in diet, disease, medication, or warfarin dose, but he later admitted that he had commenced drinking green tea, between half and one gallon daily, before the previous INR of 1.37. He was instructed to discontinue the tea, and 1 week later the INR was 2.55. The authors suggested that the only explanation for the INR decrease was antagonism of warfarin by vitamin K in the green tea.[97] This explanation seems improbable, however, because with the lipophilicity of phylloquinone, the vitamin K content of brewed tea is negligible, at 0.05 μg/100 g, versus the 1.43 mg/100 g of green tea leaf (USDA Nutrient Data Research figures).[98] The possibility of tea inhibiting CYP450 1A2, which metabolizes the weaker *R*-enantiomer of warfarin, was not discussed. If the patient were a poor metabolizer at 2C9 (which metabolizes the more active *S*-warfarin enantiomer), this could have been a contributory factor. The report remains difficult to interpret and an isolated case without corroborative data.

Clinical Implications and Adaptations

Given the widespread consumption of tea as a beverage, any impact on hemostasis would be consequential from a public health point of view. The balance of data currently available suggests that the cardioprotective effects of tea polyphenols are unrelated either to vitamin K–dependent coagulation factor modulation or to in vivo antiplatelet effects. Nonetheless, standard practice is for patients using oral anticoagulation and antithrombotic therapies to avoid excessive tea beverage consumption.

Whether concentrated tea polyphenol extracts contain significant amounts of vitamin K is not currently known. In cases of intended coadministration of high doses of such extracts with anticoagulant drugs, standard monitoring of INR should be vigilantly followed, particularly before and immediately after commencement of the extract administration.

The 98 citations in this monograph are located under Green Tea on the CD at the back of the book.

Hawthorn

Botanical Name: *Crataegus laevigata* (Poir) DC, *Crataegus monogyna* Jacq. (Lindm.).
Pharmacopoeial Name: Folium cum Flore Crataegi.
Synonym: *Crataegus oxyacantha* L. (for *C. laevigata*). Also as *Crategus* spp.
Common Names: Hawthorn, English hawthorn, whitethorn, may flower.

SUMMARY

Drug/Class Interaction Type	Mechanism and Significance	Management
Digoxin, digitoxin Cardiac glycosides ⊕/☼	Plausible additive inotropic and antiarrhythmic effects. Interaction not established, possibly overstated. *Crataegus* may enable lower drug levels, reducing digoxin toxicity.	Coadminister with professional management and monitoring.
Doxorubicin Anthracycline chemotherapy ⊕/☼	Theoretical reduction of drug-induced cardiotoxicity.	Adopt, and continue *Crataegus* long-term postchemotherapy.
Hydrochlorothiazide Thiazide diuretics ⊕⊕/☼	Additive beneficial effects on heart failure parameters.	Adopt. Coadminister.

HERB DESCRIPTION

Family

Rosaceae.

Related Species

Crataegus apiifolia Medik. non Michx., *Crataegus piperi* Britton, *Crataegus rivularis* Nutt.
In Chinese herbal medicine, *Crataegus pinnatifida* Bunge.; the fruit has traditionally been used.

Habitat and Cultivation

Thorny shrub or small tree, widespread throughout northern and eastern Europe and northeastern America in temperate zones. Hawthorn species hybridize freely, and in commerce, several related species may be used.

Parts Used

Leaf, flower.

Note: Hawthorn fruits, berries, or haws (Fructus Crataegi) are also traditionally used but lack comprehensive pharmacological and clinical data and are not considered separately here. The fruit is monographed separately in the official *European Pharmacopoeia* and the unofficial *American Herbal Pharmacopoeia*[1] and is "unapproved" by the German Commission E.[2]

Common Forms

Dried leaf and flower.
Tincture: 40% to 60% alcohol
Standardized Extracts: 30 mg 5:1 5% oligomeric proanthocyanidins (OPCs) (Crataegutt, W Schwabe Pharmaceuticals); 80 mg 5:1 18.75% OPCs, ethanol extracted (Crategutt forte WS1442, W Schwabe); 300 mg 4:1 to 7:1 standardized to 2.25% flavonoids (Faros LI 132, Lichtwer Pharma AG).

Note: Oligomeric procyanidins, oligomeric proanthocyanidins, procyanidins, procyanidolic oligomers, and pycnogenols are synonymous terms, with the last also being a trademarked brand name for pine bark extract.

HERB IN CLINICAL PRACTICE

Overview

Hawthorn is currently one of the most popular herbal remedies in Europe and is among the top-20 best-selling botanical products in the United States. In the past 20 years, hawthorn has been studied primarily as an adjuvant therapy for early congestive heart failure (New York Heart Association [NYHA] stage I-II), which is currently one of the principal clinical trial–driven indications for the herb. However, because of the broad spectrum of its pharmacology, resulting in part from the characteristic properties of the flavonoid and oligomeric procyanidin constituents, and its negligible toxicity and favorable adverse effect profile, practitioners of botanical medicine have long regarded hawthorn as a pivotal "all-round cardiovascular wellness remedy," as well as the most significant herb for ischemic heart disease. It has antioxidant, anti-inflammatory, hypocholesterolemic, cardioprotective, angioprotective, hypotensive, antiarrhythmic, and positively inotropic properties, with additional beneficial actions on the digestive system and peripheral circulation, including collagen stabilization.

Hawthorn is suitable for extended duration of consumption, and official sources specify a minimum 4 to 6 weeks of administration to obtain maximum benefits in cardiac insufficiency. The German Commission E,[2] European Scientific Cooperative on Phytotherapy (ESCOP),[3] *American Herbal Pharmacopoeia*,[4] and World Health Organization (WHO)[5] provide monographs on hawthorn leaf and flower.

Historical/Ethnomedicine Precedent

Historically, hawthorn fruits were used for hundreds of years before the incorporation of the leaf and flower into

medicinal usage. The modern use of hawthorn as a cardiac remedy began with the later Eclectics. Both Ellingwood[6] and Felter[7] experimented in the early 1900s with hawthorn fruit, flowers, and bark for functional heart conditions, along with their primary repertoire of cardiac glycoside–containing plants and their favored heart cardiac remedy *Selenicereus grandiflorus*. By the mid-twentieth century, a clinical understanding had developed of the differential indications of various cardiac glycoside–containing plants for congestive heart failure (CHF). German phytotherapist Rudolf Weiss's 1960 review of the cardiac glycoside herbs, including *Digitalis, Strophanthus, Convallaria, Urginea*, and *Adonis*, remains a classic bridging text to the present. For Weiss, as with the Eclectics, hawthorn was a mild remedy essentially indicated for functional heart problems, especially the "senile heart," with the glycoside-containing plants reserved for treatment of organic heart disease.[8]

As purified pharmaceutical digitaloids replaced the routine use of crude herbal drug cardiac glycoside–containing botanicals in heart failure, the German phytopharmaceutical manufacturers repositioned *Crataegus* as a CHF "adjunctive" remedy; backed by a shift in research emphasis based on Schwabe's proprietary (Crataegutt and WS 1442) hawthorn preparations for CHF. In this context, the contemporary emphasis on hawthorn as a CHF treatment is a rather recent and restrictive view of hawthorn, dominated by phytopharmaceutical industry priorities rather than the inherent properties of the remedy.

Known or Potential Therapeutic Uses

Cardiotonic and cardiopreventive for the "senile heart," i.e., mild symptoms, including early angina, nervous heart complaints, myocardial weakness after serious illness, circulatory support, arteriosclerosis, hypertension, low heart rate variability, and peripheral arterial disorders.
Early CHF corresponding to NYHA stages I-II, possibly III.
Feelings of congestion and oppression in the precordium; protection against drug-induced cardiotoxicity.

Key Constituents

Flavonoids, glycosides (e.g., vitexin, vitexin-2-rhamnoside, rutin, quercitin), and related anthocyanidins (cyanidin and others) and oligomeric proanthocyanidins (catechin and epicatechin derivatives).
Triterpenes (crataegolic acid and others), phenylpropanoids, several amino acids, and various monoamines.

Therapeutic Dosing Range

Dried Leaf and Flower: Up to 1.5 g, three to four times daily, by infusion.
Tincture: 3 to 7 mL 1:2 daily.
Standardized Extract: 600 to 900 mg daily.

INTERACTIONS REVIEW

Strategic Considerations

Pharmacopoeial sources, including the 1994 German Commission E monograph, deny any interactions between hawthorn and prescription pharmaceuticals.[2] However, the secondary literature persistently suggests that hawthorn may potentiate digoxin and other cardiac glycoside–containing herbs[4,9] (see later discussion).

Cumulative cardiac drug polypharmacy is a familiar clinical presentation, especially among elder patients, often combined with one or more psychiatric drugs, such as anxiolytics and sedatives. Such patients constitute a "red flag" population for potential interactions of all permutations (i.e., drug-drug, herb-drug, drug-nutrient). It is relevant to consider the possible benefits of hawthorn in such populations. Is hawthorn beneficial and safe in the cardiac polypharmacy environment?

The indirect evidence, especially from clinical trial data, is reassuring. Pittler et al.[10] conducted a meta-analysis of clinical trials of hawthorn extract for treatment of chronic heart failure. Eight of 13 of the qualifying studies specifically allowed concomitant medications for CHF, including diuretics, angiotensin-converting enzyme (ACE) inhibitors, and calcium channel blockers, in their inclusion criteria. The remaining trials did not specify concomitant medications in their eligibility criteria. The majority of studies were therefore actually "interaction" trials between hawthorn and various cardiac medications in a substantial cohort of NYHA stage I-III CHF patients. The meta-analysis concluded there was a better-than-placebo effect on the surrogate endpoints (maximum workload, pressure–heart rate product, left ventricular ejection fraction) for the reviewed studies. Quality of life was tested by subjective questionnaire in only one of the smaller trials (30 patients) and was significantly improved in the verum over the placebo group.[11]

Overall, adverse events were zero in five trials and minimal in the others. Vertigo and dizziness was the most common adverse event, followed by gastrointestinal symptoms. Only two patients (632 total) reported electrocardiologically related symptoms (i.e., palpitations and tachycardia). The implication is that hawthorn is beneficial in the cardiac polypharmacy patient. This is confirmed by the methodological approach of an international multicenter trial examining actual mortality outcomes in NYHA stage II-III CHF patients (n = 2300). The study is investigating Crataegus WS1442 extract versus placebo and various conventional therapies, with cardiac glycosides, beta blockers, diuretics, and ACE inhibitors accepted in the inclusion criteria.[12]

The conclusions from concurrent drug-herb trial data are that addition of hawthorn extracts may be beneficial and may interact positively or at worst may be neutral with a range of cardiac medications in CHF without adverse effects. As Zick et al.[13] indicated in a survey, however, patients in these trials may also be consuming unrelated dietary supplements, some of which may interact with their medications.

Cardiac conduction disturbances are a similar critical area of potential drug interaction. Electrophysiologically, hawthorn corresponds most closely to the Vaughan-Williams class III drugs such as amiodarone (i.e., increase of action potential duration, usually by K^+ channel block).[14-16] Hawthorn extracts have positive inotropic effects, decrease atrioventricular (A-V) conduction time, increase coronary blood flow, and decrease myocardial energy utilization.[17-19] However, intracellular recordings of rodent myocytes demonstrate that the effective refractory period (ERP) is prolonged by hawthorn extracts, not shortened as in class III agents.[20] Confirmation of increased ERP has been shown in the ex vivo Langendorff model (perfused guinea pig heart) by Joseph et al.[15]

Conventional treatment of arrhythmias with pharmacotherapeutic antiarrhythmic agents remains largely empirical and is confounded by several problems, including the proarrhythmic properties of many of the drugs; also, left untreated, arrhythmias may resolve over time.[14] The post–Cardiac Arrhythmia Suppression Trial (CAST) era has seen a reevaluation of the advisability of treating nonlethal disturbances in cardiac rhythm

versus preventing lethal ventricular tachycardia or ventricular fibrillation and sudden cardiac death.[21,22] The antiarrhythmic properties of hawthorn make it a suitable agent for mild arrhythmias before empirical treatment with pharmaceutical antiarrhythmic agents.[23] This is further supported by hawthorn's positive effects on coronary flow and reduction of ischemic reperfusion injury, because transient ischemic events often trigger rhythm disturbances.[24,25] The high morbidity associated with arrhythmias and CHF make hawthorn an outstanding remedy for this patient group.

Further indirect evidence for the pluripotent cardiovascular effects of hawthorn comes from the pharmacology of isolated constituents, particularly the oligomeric cyanidins and flavonoids. In vitro work has demonstrated nitric oxide (NO)–mediated endothelial relaxation by vitexin-rhamnoside. Phosphodiesterase-inhibiting activity, thromboxane A_2 (TXA_2) inhibition of adenosine 5'-diphosphate–induced platelet aggregation, ACE inhibition, and phospholipase A_2 inhibition, as well as antioxidant, hypolipidemic, and antiatherosclerotic properties, have all been shown by in vitro studies.[26–33]

Weiss's summary remains a succinct statement of the strategic framework for hawthorn administration. He contrasts it to digitalis, noting that "the two drugs are at opposite poles of heart therapy; hawthorn's gentle and long lasting action, lacking risks and unpleasant side effects, [means] that patients can on the whole be left to use it without constant supervision." It is "particularly suitable for long-term prophylactic use in middle aged patients, ... and in follow up therapy for myocardial infarction."[8]

HERB-DRUG INTERACTIONS

Digoxin, Digitoxin and Related Cardiac Glycosides

Evidence: Digoxin (Digitek, Lanoxin, Lanoxicaps, purgoxin). Extrapolated, based on similar properties: Deslanoside (cedilanin-D), digitoxin (Cystodigin), ouabain (g-strophanthin).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
3. Possible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Hawthorn extracts have positive inotropic properties and could be used to potentiate digoxin and theoretically may lower the risk of digoxin toxicity by enabling a lower therapeutic dose because of additive inotropic effects.

Research

This interaction has been persistently suggested since animal work in the 1950s by Semm, Bersin, and others that suggested pretreatment of cardiac tissue with hawthorn or cardiac glycoside could act mutually as a sensitizer to the other agent. Extrapolating from this finding, a synergistic effect in vivo was hypothesized that might enable reduced dose of digoxin and a lesser risk of toxicity. This early work has never been repeated and has been criticized as methodologically flawed in design and an inappropriate basis for extrapolating to human use.[34]

The positive inotropic effect of hawthorn extracts has been demonstrated in isolated rodent ventricular myocytes and by guinea pig heart (Langendorff) preparations.[15,20] Trunzler and Schuler[35] used a modified Langendorff model to record contractile amplitude and coronary flow variation with digoxin, digitoxin, g-strophanthinin, and hawthorn extracts (Crataegutt) separately and in combination. The combination of digoxin and Crataegutt showed an increase in both parameters compared with digoxin alone.[35] The mechanism of contractility increase caused by hawthorn extracts is not fully understood, but there is evidence of a similar pharmacodynamic mechanism to the cardiac glycosides with action at the sarcolemmal sodium-potassium adenosinetriphosphatase (Na^+, K^+-ATPase) pump in human cardiac muscle ex vivo.[36] In addition, *Crataegus* does not cause adrenergic blockade at levels that are negatively chronotropic.[37] In summary, the principal cardiac effects of the two agents can be tabulated as follows:

	Digoxin	Hawthorn
Contractility	↑	↑
Spontaneous rate	↑	←→
A-V conduction time	↑	↑
Refractory period	↓	↑
Coronary flow	↑	↑

Modified from references 15 and 19.

Despite widespread suggestions in the secondary literature about the interaction between *Crataegus* extracts and digoxin, case reports are entirely lacking, with negligible pharmacokinetic or pharmacodynamic data. Tankanow et al.[38] examined the possibility of both pharmacokinetic and pharmacodynamic interactions between digoxin and *Crataegus* WS1442 extracts in a preclinical, open-label crossover study of eight healthy subjects, male and female. WS 1442 did not interfere with the digoxin assay, and there was no significant difference in pharmacokinetic parameters (AUC, C_{max}, C_{min}, $t_{1/2}$) between the digoxin and the digoxin plus hawthorn group. However, the trend was for a reduction in digoxin levels in the presence of hawthorn, but the small number of participants rendered the difference statistically insignificant. The authors postulated that this effect resulted from mild induction of P-glycoprotein (P-gp) by quercitin and other flavonoids in the WS 1442 preparation. Electrocardiographic (ECG), heart rate, and blood pressure parameters did not suggest a pharmacodynamic interaction. The principal limitation was the application of a single dose of hawthorn, which is likely inadequate to modify pharmacodynamic parameters.[38]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Digoxin is infamous for its narrow therapeutic index and potential for toxicity. Natural agents, including flavonoid extracts, have been found to modulate P-gp, of which digoxin is a substrate.[39] This is the basis of the pharmacokinetic interaction between St John's wort and digoxin, which can cause a clinically significant decrease in serum digoxin levels.[40] The concurrent administration data from clinical trials of hawthorn extracts and the previous preclinical study[38] suggest that pharmacokinetic interactions between hawthorn extract and digoxin are not clinically significant. Strategic evaluation of the pharmacodynamic interaction between hawthorn and digoxin needs to consider the context of digoxin prescription.

In patients with CHF, digoxin use remains controversial, except in those with atrial flutter or other arrhythmias associated with heart failure.[41–43] In this setting, digoxin is likely to be prescribed additively after first-line measures such as salt restriction, limitation of physical activity, and vasodilation

(ACE inhibitor) have failed to halt progression of symptoms. Diuretics are usually also prescribed in combination. The NYHA functional class for this patient population is typically advanced stage II, or stage III, more progressed than that suggested by clinical trial data for hawthorn use in CHF. However, given the high morbidity associated with dysrhythmias in CHF patients, the lack of adverse effects associated with the digoxin-hawthorn combination, and the potential benefits of the interaction, coadministration would likely be beneficial in this setting.

When digoxin is prescribed for heart rate control in supraventricular arrhythmias outside CHF, the potential benefits of concurrent administration of hawthorn could be greater than for digoxin alone, given the pluripotent cardiac effects of the herb. These multivalent actions suggest that hawthorn may effectively stabilize "cardiac excitability," an arrhythmogenic mechanism added to the basic concept of altered automaticity or impulse propagation by Arnsdorf.[44-46] Another view would be that the multiple effects of hawthorn might maintain or enhance the degree of nonlinearity of cardiac rate and rhythm, which is known to decrease with aging and CHF.[47-50]

The most effective interaction between hawthorn and digoxin may be "prophylactic," in the sense that hawthorn pretreatment or maintenance is the botanical medicine foundation of integrative strategies aimed at prophylaxis of, or intervention and reversal of, early heart failure. In combination with other strategies, such as dietary improvements, smoking cessation, weight loss, stress reduction, exercise, and selective nutritional support, hawthorn may prevent or at least delay the need for digoxin.

Doxorubicin and Related Anthracycline Chemotherapy

Evidence: Doxorubicin (Adriamycin, Rubex).
Extrapolated, based on similar properties: Daunorubicin (Cerubidine), epirubicin (Ellence, Pharmorubicin), idarubicin (Idamycin, Zavedos), mitoxantrone (Novantrone, Onkotrone). Similar properties but evidence lacking for extrapolation: Daunorubicin, liposomal (DaunoXome), doxorubicin, pegylated liposomal (Caelyx, Doxil, Myocet).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **6. Unknown**
Evidence Base: ☐ **Inadequate**

Effect and Mechanism of Action

Doxorubicin is known to induce dose-related cumulative cardiotoxicity (short and long term). This may be reduced by concurrent hawthorn administration.

Research

Doxorubicin is one of the most widely used antineoplastic agents, but its effectiveness is in part limited by well-documented cardiotoxic adverse effects, which can manifest long after cessation of treatment. The pathogenetic mechanisms of anthracycline cardiotoxicity are not fully understood, although the ultimate clinical presentation is indistinguishable from typical CHF. Although an early toxicity may be observed, shortly after initiation of administration (especially in older patients), the symptoms of progressive heart failure can appear months or even years after treatment, and the cardiomyopathy initially may be quite asymptomatic.[51] Several possible cardiac protective agents have been examined, but none found to be effective, including vitamin E and *N*-acetylcysteine. The iron-chelating agent dexrazoxane (Zinecard) reduces cardiotoxicity but has been associated with possible reduction in antitumor effects (doxorubicin toxicity partly may be caused by FeII-dox-complex free-radical formation).[52]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Based on the known pluripotent cardioprotective effects of hawthorn, its efficacy for CHF, benign safety profile, and suitability for long-term administration, cardioprotection protocols for oncology patients using doxorubicin might beneficially incorporate hawthorn extracts, together with related herbal agents (e.g., ginkgo) and nutrients (e.g., coenzyme Q10, acetylcarnitine). Direct studies are required to establish the potential benefits of this strategic interaction with doxorubicin (see also Ginkgo monograph).

Hydrochlorothiazide and Related Thiazide Diuretics, Combined with Triamterene

Evidence: Hydrochlorothiazide (Aquazide, Esidrix, Ezide, Hydrocot, HydroDiuril, Microzide, Oretic); combination drug: hydrochlorothiazide and triamterene (Dyazide, Maxzide). Extrapolated, based on similar properties: Bendroflumethiazide (bendrofluazide; Naturetin), combination drug: bendrofluazide and propranolol (Inderex); benzthiazide (Exna), chlorothiazide (Diuril), chlorthalidone (Hygroton), cyclopenthiazide (Navidrex), combination drug: cyclopenthiazide and oxprenolol hydrochloride (Trasidrex); hydrochlorothiazide combination drugs: hydrochlorothiazide and amiloride (Moduretic); hydrochlorothiazide and captopril (Acezide, Capto-Co, Captozide, Co-Zidocapt); hydrochlorothiazide and enalapril (Vaseretic); hydrochlorothiazide and lisinopril (Prinzide, Zestoretic); hydrochlorothiazide and losartan (Hyzaar); hydrochlorothiazide and metoprolol (Lopressor HCT); hydrochlorothiazide and spironolactone (Aldactazide); hydroflumethiazide (Diucardin), methyclothiazide (Enduron), metolazone (Zaroxolyn, Mykrox), polythiazide (Renese), quinethazone (Hydromox), trichlormethiazide (Naqua).

Interaction Type and Significance

⊕⊕ **Beneficial Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **2. Possible**
Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Addition of hawthorn extract to existing diuretic therapy in CHF patients leads to improved symptom reduction and reduction in adverse effects through a general additive effect compared with diuretic therapy alone.

Research

In a randomized trial by Tauchert[53] of 209 patients with NYHA stage III heart failure, inclusion criteria included only preexisting diuretic or ACE inhibitor therapy. A pretreatment combination of thiazide diuretic and the antikaliuretic triamterene was given for 4 weeks, and patients were then randomized to into two dose groups of hawthorn extract WS 1442 (450 or 900 mg twice daily) versus placebo for 16 weeks while the preexisting combination was also continued. A dose-dependent improvement in exercise capacity and reduction in symptom severity was noted over the placebo (diuretic-only) group. However, the HERB-CHF trial, which involved adding

hawthorn to ACE inhibitor and beta blocker–treated NYHA II-III patients for 6 weeks, found negligible difference between the control drug group and the drug-herb combination group, although in the latter group left ventricular function (LVF) was stable and in the drug-only group the trend was for LVF to decline.[54]

Integrative Therapeutics, Clinical Concerns, and Adaptations

As previously suggested (see Strategic Considerations), inclusion criteria in hawthorn clinical trials suggest that the weight of indirect evidence for the safety of hawthorn in cardiac polypharmacy favors the view of hawthorn as a beneficial interactor. The Tauchert trial[53] comparison with thiazide diuretic therapy supports this view more directly.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Derivative sources have suggested several possible interactions based on overenthusiastic extrapolations from pharmacological data without clinical contextualization. These include suggestions that the vasodilatory effects of hawthorn extracts could interact positively with coronary vasodilators or negatively with topical inhalant vasoconstrictors.[9] Such assertions lack clinical foundation, given the framework of hawthorn administration as a gentle, long-term remedy, as well as any plausible supporting data. The proposal that hawthorn, taken as a beverage tea, may adversely affect the absorption of iron salts lacks evidence and merit.[55]

The 55 citations for this monograph are located under Hawthorn on the CD at the back of the book.

Horse Chestnut

Botanical Name: *Aesculus hippocastanum* L.
Pharmacopoeial Name: Hippocastani semen.
Common Names: Horse chestnut, chestnut.

HERB DESCRIPTION

Family

Sapindaceae (classified in Hippocastanaceae until 1998).

Parts Used

Seeds.
The bark and leaf of the tree are separate remedies, little used today.[1,2]

Common Forms

Tincture: Fresh or dried seed, 65% alcohol.
Standardized Extract: Horse chestnut standardized extract (HCSE)—5:1 to 8:1 standardized to 16% to 20% triterpene glycosides, tablets or capsules (Aesculoforce, Bioforce AG; Venostat, Pharmaton Natural Health Products).
Topical: Ointments, gels containing extracts at 2% aescin.

INTERACTIONS REVIEW

Strategic Considerations

Horse chestnut preparations have been popular in Europe for several decades, used for a variety of conditions of the venous system, both chronic (venous insufficiency, varicosities, hemorrhoids, leg ulcers, and edema) and acute (postoperative and posttraumatic edema, including elevated intracranial pressure, traumatic hematoma, contusions, and soft tissue swelling; sports injuries, especially involving edema). *Aesculus* seed is well described by Weiss[3] under diseases of the venous system and has monographs by the German Commission E[4] (1994, revised from an earlier unapproved monograph of leaf and flower in 1984), World Health Organization (WHO) in 2002, and European Scientific Cooperative on Phytotherapy (ESCOP) in 2003, as well as a recent literature review by McKenna et al.[7] Clinical trials for horse chestnut in chronic venous insufficiency (CVI) have been subjected to meta-analysis for the Cochrane database by Pittler and Ernst,[8] who found positive evidence for short-term efficacy in treating CVI.

Pharmacological attention has focused on the activity of the triterpene saponin fraction, a complex mixture of triterpenoids usually described as escin *(aescin)*, which has venoactive anti-inflammatory and antiedematous properties, with some in vitro antioxidant, antiproliferative, and immunomodulatory activities.[9,10] Available controlled clinical trials (13 total, 8 placebo controlled) of HCSE for venous insufficiency were systematically reviewed by Pittler and Ernst,[11] who concluded HCSE was safe, effective, and superior to placebo for short-term treatment of CVI. European use has also involved parenteral preparations of aescin (sodium escinate) and extensive use of a proprietary topical product Essaven which is a combination of aescin with pharmaceutical ingredients, heparin and phospholipids.

The monographs by German Commission E[4] and ESCOP[6] list no known interactions between horse chestnut seed and pharmaceutical drugs. (See, however, the later precaution regarding gentamicin from WHO.) Interactions reports in the literature are lacking. Positive clinical reports and trials of the topical combination product Essaven since the 1970s suggest a potential benefit of the combination in a wide range of conditions, and this is therefore accorded the status of a beneficial interaction (heparin + phospholipid; see later). Earlier European studies provide some basis for considering a potentially beneficial interaction with corticosteroid therapy; this is also assigned a potential interaction status here despite a lack of recent data. Speculative interactions include warfarin and hypoglycemics. Pharmacokinetic data are not currently available, and effects on drug-metabolizing enzymes, if any, have not been established.

HERB-DRUG INTERACTIONS

Corticosteroids, Oral

Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol) prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:
2. Probable

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

Adrenocortical steroids and analogs combined with HCSE or aescin may provide additive beneficial antiedematous effects, particularly in cerebral edema. This interaction, which has been used in neurosurgical environments, is of unknown significance beyond that specialized clinical context.

Research

Rodent studies in the 1960s on adrenalectomized or hypophysectomized rodents showed that normal corticosteroid levels are required for the antiedematous effects of aescin.[12,13] The combination of sodium aescinate and corticosteroids was more effective than steroids alone in reducing cerebral edema in a study of 142 patients with acute motor vehicle crash–related cerebral trauma.[14] Aescin has been used alone and in combination with steroids in a wide range of neurological situations.[15] A rodent model using cortically injured animals found that aescin dramatically lowered nuclear factor kappa B (NF-κB) activation and tumor necrosis factor alpha (TNF-α) levels and alleviated brain edema after injury.[16]

Integrative Therapeutics, Clinical Concerns, and Adaptations

This interaction is related to use of parenteral horse chestnut saponin preparations in acute surgical situations, and extrapolations are problematic. Single-dose and two-dose pharmacokinetic studies on oral aescin preparations suggest a very low bioavailability, with reduction of absorption by food.[10,17-19] Bowel flora hydrolysis of the glycosides

hypothetically may result in longer-term release of the aglycone or its metabolites, but studies are lacking.[13] Although specific blood-brain barrier data are not available, the established general systemic effects on edema suggest that circulating levels of the saponin aglycones should theoretically be available to cerebral circulatory system. Comparative data on serum levels (AUC) of intravenous (IV) versus oral administration are not available. The possible benefits of the combination using oral HCSE remain to be established.

Heparin Sodium + Phosphatidylcholine + Aescin

Heparin sodium, phosphatidylcholine, and aescin (Essaven, topical).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
1. Certain

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Proprietary combination that synergistically enhances anti-inflammatory, antiedematous, antiexudative effects of the herb.

Research

The antiedematous effects of topical aescin-based HCSE preparations combined with heparin and phospholipids have been well documented since the 1970s. Reports include use for preventing and treating acute injuries from sports injuries, blunt trauma, mastectomy-related lymphedema, thrombophlebitis, hematoma, oral surgery, varicosities, hemorrhoids, and diabetic microangiopathy.[20-45]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Clinically, this interaction inevitably results from an established proprietary phytonutripharmaceutical combination and is as relevant as an example of effective integrative combination as for the inherent importance of interaction.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Gentamicin and Related Aminoglycoside Antibiotics, and Other Potentially Nephrotoxic Agents

Amikacin (Amikin), gentamicin (G-mycin, Garamycin, Jenamicin), kanamycin (Kantrex), neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin), netilmicin (Netromycin), paromomycin (monomycin; Humatin), streptomycin, tobramycin (AKTob, Nebcin, TOBI, TOBI Solution, TobraDex, Tobrex).

WHO[5] suggests a potential interaction based on a report of nephrotoxicity after excessive doses of aescin with gentamicin. The report, dating from 1978, involved a combination of aescin, an IV preparation of purified saponin compounds, with the known nephrotoxic antibiotic gentamicin.[46] McKenna et al.[7] cite an earlier Italian report by Grasso and Corvaglia[47] (text and abstract unavailable for inspection) of two cases of toxic nephropathy associated with high dose of aescin (i.e., intoxication), not interaction. These two cases both involved IV saponin fraction in the clinical context of acute postsurgical edema. Sirtori[10] reports that at the time of these warnings of potential nephrotoxicity, three trials examined the renal function in 83 patients who had preexisting kidney disease and in healthy volunteers who received 10 mg IV aescin per day. No worsening of renal impairment in the renal patients or effect on the healthy individuals was noted.

Oral Hypoglycemic Agents and Insulin

Buformin (Andromaco Gliporal, Buformina), chlorpropamide (Diabinese), glimepiride (Amaryl), glipizide (Glucotrol; Glucotrol XL), glyburide (glibenclamide; Diabeta, Glynase, Glynase Prestab, Micronase, Pres Tab), insulin (animal-source insulin: Iletin; human analog insulin: Humanlog; human insulin: Humulin, Novolin, NovoRapid, Oralin); metformin (Dianben, Glucophage, Glucophage XR); combination drugs: glipizide and metformin (Metaglip); glyburide and metformin (Glucovance); tolazamide (Tolinase), phenformin (Debeone, Fenformin), tolbutamide (Orinase, Tol-Tab).

Based on two rodent studies, claims of interactions with hypoglycemic agents have been speculatively suggested. One study did not use an experimentally induced model of diabetes but compared glucose levels in glucose-loaded normal rats to normal controls.[48] A hypoglycemic effect was observed only in the glucose-loaded rats after administration of purified aescin compounds. A second study found no effect in alloxan-induced diabetic rats.[49] There are no human reports of HCSE disturbing glucose levels in euglycemic or dysglycemic individuals or of interactions with oral hypoglycemics.

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Evidence: Warfarin (Coumadin, Marevan, Warfilone).
Related: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar).

It has been suggested that horse chestnut or HCSE potentiates the anticoagulant effect of warfarin.[50] This is based on two erroneous assumptions: the seeds contain coumarins, and coumarins inevitably interact with warfarin. In fact, esculin and its 6-glycoside esculetin have only been reported in bark of the tree, and this coumarin derivative lacks the 4-OH minimal structural activity for anti–vitamin K activity, although some in vitro evidence suggests it may inhibit platelet lipoxygenases.[51] The suggested interaction has not been clinically reported and lacks foundation in the known pharmacology of HCSE.

The 51 citations for this monograph are located under Horse Chestnut on the CD at the back of the book.

Kava

Botanical Name: *Piper methysticum* G. Forster.
Pharmacopoeial Name: Piperis methystici rhizoma.
Common Names: Kava, kava-kava, kawa, 'awa.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Alprazolam Triazolobenzodiazepines ✗/?	Possible pharmacokinetic and pharmacodynamic interaction resulting in increased central nervous system effects. General significance not established. (May be significant for intravenous midazolam preoperatively.)	Avoid coadministration, except during withdrawal from drug under professional supervision.
Dopamine agonists Dopamine antagonists ?	Herb may have mixed/paradoxical actions on central dopaminergic pathways. Poorly understood and significance unknown, but may be useful in reducing antipsychotic drug-induced tardive dyskinesia.	Avoid coadministration, except under close professional supervision.
Ethanol ?/✗	Potential interaction resulting in increased toxicity of either herb or drug, or both. Mechanism and significance not established.	Avoid.

HERB DESCRIPTION

Family

Piperaceae.

Habitat and Cultivation

Piper methysticum is a vegetatively propagated cultivar, and botanical authorities believe it was derived from wild species (e.g., *Piper wichmanni* C. DC). Historically, kava was widely domesticated throughout the Pacific regions of Polynesia, Micronesia, and Melanesia. Currently, commercial cultivation of the major chemotypic variants occurs principally in Fiji, Vanuatu, and Hawaii.

Parts Used

Rootstock, lateral roots. Notably, the outer root bark/peelings and base stem are not used traditionally, although these have been exported for commercial use.

Common Forms

Fresh or dried peeled rootstock and lateral roots, some lower stem.
Tincture, Fluid Extract: Greater than 60% alcohol.
Standardized Solid Extract: Often acetone extracted, in tablets or encapsulated powder form, usually standardized to 70% total kavalactones. Because chemotypic variants exist, this form of standardization is not necessarily a reliable guide to consistency.
Synthetic Kavain: Racemic D,L-kavain has been incorporated into certain proprietary medications in Germany but is not in common use.

HERB IN CLINICAL PRACTICE

Overview

Medically, kava is currently regarded mainly as a herbal anxiolytic agent. Several positive clinical trials suggest kava root extracts may be a safe and effective alternative to benzodiazepine pharmacotherapy for mild anxiety. Recent systematic reviews, including a Cochrane database review, support the efficacy of kava extracts for anxiety and have emphasized their favorable safety profile.[1-3] The "anxiolytic" indication has overshadowed its wider uses in traditional cultural practice and contemporary herbal medicine. Practitioners of botanical medicine consider the herb useful for urogenital indications, including interstitial and infective cystitis, prostatitis, painful micturition from any cause, nocturnal enuresis, as well as for menopausal symptoms, and value it for its musculorelaxant and sedative effects as much as its anxiolytic indications.[4]

The German Commission E[5] approved the use of kava for anxiety in 1990, listing no known adverse effects, but suggested a limitation to duration of use of 3 months and contraindication in "endogenous depression." The 2002 World Health Organization (WHO) monograph[6] echoes the Commission E. The 2003 therapeutic monograph by the European Scientific Cooperative on Phytotherapy (ESCOP)[7] indicates the use of the herb for anxiety, tension, and restlessness, considering it safe when used as a short-term monotherapy, but contraindicating in cases of preexisting liver disease and alcohol abuse. A 2004 comprehensive overview of the literature from ethnology to pharmacology, edited by kava authority Singh,[8] updates and complements the classic monograph by Lebot.

Commencing in 1998, isolated case reports of possible kava-related hepatoxicity began to emerge.[9-15] On the basis of 28 case reports, the German Bundesinstitut für Arzneimitttel und Medizinprodukte (BfArM; Federal Institute for Drugs and Medical Devices) withdrew product licenses in 2002 from all kava products. Several other countries, including Canada and France took similar action, in 2002 the British Medicines Control Agency (MCA) announced a complete kava product ban, and in 2003 Swissmedic (formerly the Swiss IKS) followed suit. The U.S. Food and Drug Administration (FDA) issued a public advisory in 2001 about concerns of potential kava hepatoxicity, but kava products remain on sale in the United States at this time. A comprehensive review of the controversy is beyond the scope of this monograph; Schmidt[16] reviews each BfArM case (continuously updated on the internet), and in Mills and Bone's comprehensive 2005 survey, Schmidt et al.[17] discuss the 82 cases cited by regulatory authorities, with risk-benefit analysis of kava. The ongoing debate over kava hepatoxicity is discussed later under interactions.

Historical/Ethnomedicine Precedent

Indigenous use of kava, practiced for centuries throughout Polynesia and Micronesia, continues in the South Pacific islands. Kava is consumed regularly, primarily as a diluted fresh (on some islands, dried) root juice extract (succus), both as a relaxing social beverage and as a component of traditional ceremony. Folk healers in these communities use various parts of the plant for treating a wide range of ailments, including urogenital and menstrual problems, headaches, respiratory conditions, sleeping difficulties, and many skin problems.[8] Western therapeutic use began at the end of the nineteenth century, although the crude drug was available on both sides of the Atlantic several decades earlier. In 1892, Cerna[18] described kava's anti-inflammatory and analgesic effects on the male and female urinary tract, also noting its central nervous system (CNS) intoxicant properties. The Eclectics tended to underemphasize the CNS effects but described indications for trigeminal and other neuralgias.[19]

The dual affinities of the herb for the CNS and urogenital tract were retained until the late twentieth century, with Weiss[20] classifying kava both as a tranquilizer and as a treatment for "neurogenic" disorders of the bladder in women and prostatitis in men. The increasing promotion of standardized extracts, especially WS1490 (70% kavalactones; Willmar Schwabe), and the adoption of this extract in clinical studies for anxiety in the 1980s and 1990s coincided with the emergence of the now-dominant psychiatric indications of kava as an anxiolytic and a corresponding deemphasis of its other indications.

Known or Potential Therapeutic Uses

Internal Use: Anxiety; benzodiazepine drug withdrawal; headache; insomnia; irritable bladder; menopausal symptoms; nervous and muscular tension; neuralgia; prostatitis; restlessness of nonpsychotic origin; rheumatism; urinary tract inflammation, infection, and pain.
External Use: Analgesic for joint pain, mouth sores, wounds, and skin conditions.

Key Constituents

Alpha-pyrones known as *kavalactones*: total content varies according to cultivar type, growing conditions, age, and part used, from a typical range of 5.5% to 8%,[21] up to a recorded maximum of 21%.[22] Approximately 18 kavalactones have been described, of which six are considered important: kawain (kavain), dihydrokawian, methysticin, dihydromethysticin, yangonin, and desmethoxyyangonin. Other constituents include the alkaloid pipermethysticine in the leaf and bark, chalcones (flavokavins A-C), and cinammalketone.[23]

Therapeutic Dosing Range

Dried Plant: 6 to 12 g/day by cold maceration, or decoction.
Tincture, Fluid Extract: Based on 1:1, 6 to 12 mL/day.
Standardized Extract: Typically 100 mg, 70% kavalactones, three times daily (i.e., 210 mg total kavalactones daily).

Traditional South Sea beverage use dosage of kavalactones is controversial, given use of local chemotypes and varying preparation methods, but has been estimated as high as 2500 mg of lactones in one "session," or 10 cups at approximately 250 mg of lactones per cup. Most ethnobotanical authorities agree, however, that the traditional dose can be significantly greater than that used in botanical medicine.

INTERACTIONS REVIEW

Strategic Considerations

Before the recent concerns over the potential hepatoxicity of kava extracts, specific interactions of kava with pharmaceutical drugs had not been identified as a significant problem, and the safety of the herb in the preceding decade was considered excellent. The Commission E had pointed out that pharmacodynamic interactions with psychoactive medications, particularly CNS depressants such as barbiturates and alcohol, were theoretically possible.[5] WHO mentioned the alprazolam-kava interaction report (see later) but suggested that it was unconfirmed.[6] Systematic experimental or clinical investigations of pharmacodynamic kava-drug interactions are not available. Extrapolations have been made from limited pharmacological data and the few available case reports, indicating potential interactions issues with CNS depressants and other centrally acting agents, such as alcohol, alprazolam, and levodopa. These data are reviewed later.

Practitioners versed in botanical prescribing view the coadministration of synthetic drugs with herbs that have identical indications as unnecessary and undesirable, if not frankly contraindicated. (This is independent of underlying pharmacological mechanism because there is rarely a simple homology between the effects of herbal extracts and pharmaceuticals.) A good example is St. John's wort (SJW; see monograph) and the serotonin reuptake inhibitors (SRIs) for depression, or kava and benzodiazepine anxiolytics. Exception may be made in particular clinical circumstances, such as elective withdrawal from the drug. Anecdotal clinical experience is available for use of SJW in SRI drug withdrawal, and kava can be used to support benzodiazepine withdrawal.[24]

Hepatotoxicity Controversy and Kava-Drug Interactions

The status of the case reports gathered by Swissmedic, the German BfArM, British MCA, U.S. FDA, and other national bodies to support claims of kava hepatoxicity have been critically reviewed by several authors.[16,17,25-28] Full case details were not initially released for public or expert review, and it subsequently was found that much of the original data were incomplete or defective. Documents from different regulatory authorities contained duplicate cases, errors, and inconsistencies, and in most cases the information provided was significantly below the minimum standards required for rigorous evaluation of potential causality. The emerging expert consensus is that the case for inherent kava hepatoxicity remains unproven, and by implication, the complete banning kava products was precipitous given the clinical trial–demonstrated efficacy and adverse effects profile of the herb for anxiety and its favorable risk-benefit comparison to benzodiazepines.[17,28] Interestingly, the former German Commission E members, generally known for their cautious perspective, unanimously expressed unease at their government's (BfArM) decision to ban kava.[29] A similar statement was made by the Society for Medicinal Plant Research.[30]

Various theories of mechanisms have been proposed to account for the case reports of hepatoxicity, including idiosyncratic drug reactions, immunoallergic responses, pharmacogenetic variation in drug-metabolizing enzymes and metabolic bioactivation to toxic intermediates, glutathione depletion, differences between commercial kava preparations in terms of plant parts used, possible contamination with the alkaloid pipermethysticine present in stem peelings, possible adulteration with known hepatotoxic species such as germander, contamination by extracting solvents such as acetone,

consumption of pure synthetic kavain preparations versus natural kavalactone mixtures, excessive total kavalactone dose, and variance in kavalactone composition of products.[17,26,28,31-33] The overall incidence of verifiable kava-associated hepatotoxic events, estimated on the basis of 3 years' usage data to be 0.1 case per million daily doses, is very low and compares favorably with the relative incidence of suspected hepatotoxic reactions for common benzodiazepines (diazepam: 2.12 cases per million doses).[17] Epidemiologically, this is typical of idiosyncratic hepatotoxic drug responses; the apparently low frequency rate partly results from the multifactorial determinants involved in their causation, with the net probability of a critical adverse event occurrence being the sum of all the discrete probabilities of each determinant factor.[34]

Logically, in the context of potential kava-drug interactions, several of the hepatoxicity cases determined by reviewers as being unable to support claims of inherent kava hepatoxicity because of concurrent comedication are de facto cases of potential kava-drug interactions. Unfortunately, the well-described problems of report quality and reliability also confound reanalysis of these cases as interactions data. Nonetheless, the hypothesis that kavalactones might pharmacokinetically increase the plasma concentrations of drugs associated with idiosyncratic or inherent hepatoxicity requires evaluation, because several of the cases involved comedication with such agents. These drugs included fluoxetine, paroxetine, acetylsalicylic acid, thiazide diuretics, oral contraceptives, nonsteroidal anti-inflammatory drugs (NSAIDs) including celecoxib and diclofenac, antidiabetic agents, and benzodiazepines.[16] Most of these are also known substrates, inducers, or inhibitors of drug-metabolizing enzymes, and most have been associated to varying degrees with hepatic adverse reactions.

As with pharmacodynamic interactions, direct studies on kava-drug pharmacokinetic interactions are not currently available. However, experimental data on the effect of kavalactones on cytochrome P450 (CYP450) mixed oxidases suggest a potential for pharmacokinetic herb-drug interactions.

Effects on Drug Metabolism and Bioavailability

Several in vitro studies have determined that both kava preparations and individual kavalactones can exert inhibitory effects on CYP450 isoforms.[35-39] Zou et al.[37,38] compared activity of both recombinant human CYP450 enzymes and human hepatocytes with standard control compounds and addition of kava. They found that an ethanolic extract of kava containing 28% total kavalactones significantly inhibited (in descending order of effect size) CYP450 2C9, 2C19, 3A4, 2D6, 2E1, and 1E2 at both 100 micromolar (μM) and also at lower concentrations of approximately 10 μM. There was good agreement between the two methods used, and the experiments were repeated with individual kavalactones. Of these, desmethoxyyangonin and methysticin were found to be the most potent inhibitors of 1A2, 2C9, 2C19, 2E1, and 3A4 (median inhibition concentration [IC_{50}] < 10 μM). At higher doses the authors also established toxic effects on hepatocyte viability, although the concentrations were 100 μM and therefore 10 to 20 times that likely attainable in vivo.[38]

Mathews et al.[35] also used a human hepatocyte test system to analyze the in vitro effects of kava extracts (40% lactones) at 100 μM on human P450 enzyme activity compared with positive control substrates. At these high concentrations they found a significant inhibition of 2C9, 2C19, 3A4, 2D6, and 4A9/11. At lower concentrations of 10 μM, individual lactones were tested; 2C9 was significantly inhibited by desmethoxyyangonin, methysticin, and dihydromethysticin; 2C19 by desmethoxyyangonin; 3A4 by desmethoxyyangonin, methysticin, and dihydromethysticin; and 2D6 by meythysticin.

Unger et al.[36] examined the effect of different fractions of a crude ethyl acetate extract of kava root powder for inhibitory activity using a testosterone hydroxylation system to assay 3A4 activity with kava compared to ketoconazole as a positive control.[36] They found a significant inhibition of 3A4 with different solvents used for the kava extract. Using high-performance liquid chromatography (HPLC) fractionation, they established that kavain, dihydrokavain, methysticin, dihydromethysticin, and dihydroyangonin were the most active lactones. However, IC_{50} values were not recorded.

Cote et al.[39] used a standard fluorescence screening assay method to compare traditional water extracts of kava with various commercial solvent extracts against the activity of 1A2, 2C9, 2C19, and 3A4. Kavalactones were present at highest levels in the acetone extracts, which also had the highest CYP450 inhibitory activity. The authors found that 3A4 and 2C19 were inhibited most actively, with IC_{50} values of approximately 1 μg/mL, or about 1 μM. A poster report of a study in six healthy volunteers tested with a probe cocktail for 1A2, 2D6, 2C19, 2E1, and 3A4 found that traditional aqueous extracts only significantly inhibited 1A2.[40]

Raucy[41] used an unrelated approach and screened the mechanisms of 3A4 *induction* by various drugs and natural compounds by examining 3A4 messenger ribonucleic acid (mRNA) values in human hepatocytes incubated with various inducers. Raucy also used a luciferase assay for pregnane X receptor (PXR) activation after transfecting HepG2 cells with plasmids containing hPXR and distal CYP3A4 promoters to assess the possible involvement of PXR in the enzyme induction mechanisms. She found that only kava (of various natural compounds tested) dramatically affected luciferase values consistent with activation of PXR.[41] However, the concentrations of the kava extract were 100 μM, and lower values were not tested.

Gurley et al.[42] performed an in vivo human study with 12 healthy volunteers to investigate the effects of 28 days' administration of several herbal extracts on probe drug cocktail administered before and after supplementation, designed to test the effects of the herb on single-point CYP450 kinetics.[42] In contrast to the in vitro studies, they found no measurable effects with kava on 3A4, 1A2, or 2D6, but pronounced inhibitory effects on 2E1. No elevations of serum hepatic transaminases were noted during the study. 2E1 shares with 1A1 and 1A2 the role of metabolizing aliphatic and aromatic hydrocarbons, but in particular, 2E1 is known to generate carcinogenic intermediates from simple organic compounds (e.g., nitrosamines in cigarette smoke).

Mathews et al.[35] also found evidence for an unidentified metabolic intermediate when methysticin and dihydromethysticin were incubated with human liver microsomes.[35] Zou et al.[43] found the first metabolic intermediate to be identified, dubbed 6-PHO (or 6-phenyl-3-hexen-2-one), demonstrating the reactivity of 6-PHO with reduced glutathione in vitro and also establishing its presence in human urine as a mercapturic (i.e., sulfhydryl) conjugate. The authors speculated that theoretically a nucleophilic compound could conjugate with such metabolic intermediates to form complexes that induce immune-mediated hepatotoxic reactions or direct hepatotoxicity through deoxyribonucleic acid (DNA) alkylation. Tarbah et al.[44] examined the metabolism of D,L-kavain (the synthetic racemate) after oral doses in humans and found that

hydroxylation (probably by CYP2D6) was the initial metabolic transformation step, and that sulfated and glucuronated conjugates were found in serum and urine. Full details of the metabolic degradation of the kavalactones remain to be elucidated.

Russmann et al.[45] reported an interesting analysis on six healthy subjects who were chronic kava consumers. The subjects gave up kava (traditional aqueous extract) for 30 days, undergoing metabolic phenotyping for CYP450 using five probe substrates at days 1 and 31. Kava abstinence led to a "deinhibition" of CYP1A2, suggesting that the extract normally inhibits this enzyme. The authors suggest this may explain the observed inverse association between kava consumption and cancer through prevention of environmental carcinogen activation.[46] However, kava was recently shown to have nuclear factor kappa B (NF-κB) inhibitory properties, and hypothetically this may also confer cancer prevention benefits on the regular traditional kava consumer.[47]

Collectively, the currently available data on kavalactone effects on CYP450 suggest possibly significant inhibitory effects in vivo. This implies the possibility of pharmacokinetic interactions between kava and drug substrates of CYP450.[48] Estimates from existing pharmacokinetic data suggest that the in vitro inhibitory effects at 10-μM concentrations are commensurate with in vivo concentrations after typical kava administration of oral doses at 200 to 250 mg kavalactones.[49] Whether biphasic effects are caused by PXR-mediated induction of 3A4 subsequent to mechanism based inhibition effects is not known, but is a possibility. This would be parallel to the effects of SJW extracts, which initially inhibit then induce 3A4 via PXR-mediated transcription (see St. John's Wort monograph). Since CYP450 2C9, 2C19, 2D6, and 2E1 are inhibited by kavalactones and are also subject to common polymorphisms, a level of pharmacogenetic variability in response to kavalactones is supported by the data. A deficiency in 2D6 was identified in one case of hepatotoxicity associated with kava and alcohol use.[9] Interestingly, the 2D6 polymorphisms that are prevalent at about ten per cent in Caucasians are absent from Polynesian populations.[50]

Formation of potentially reactive intermediates from kavalactones during metabolism under certain circumstances cannot be excluded, although currently the potential reactivity or toxicity is not known. Systematic studies of the effects of kava consumption on plasma levels of various medications are urgently needed to clarify all the in vivo implications of the in vitro data. At present, compelling reasons would be required to coadminister kava extracts with narrow-therapeutic-range drugs that are substrates of CYP450 3A4, 2C9, 2C19, 2D6, and 2E1, particularly in polypharmaceutical combination with other drugs that are noted substrates, inhibitors, or inducers of the same enzymes. (Note that the benzodiazepines are primarily metabolized by 3A4 and 2C19 and the halogenated anesthetics by 2E1.) If such coadministration is required, pharmacokinetic interaction management precautions should be taken, such as plasma drug monitoring with clinical correlation, especially during the periods of addition or withdrawal of any of the agents to a regimen. Ideally, phenotyping of "poor metabolizers" should also be conducted.

The potential for additive pharmacodynamic effects with CNS-active drugs, as well as the possibility of pharmacokinetic interactions mediated by CYP450 modulation and the small but finite risks of idiosyncratic hepatotoxicity, all suggest that adoption of comprehensive history taking, identification of proper clinical indications, monopharmacy prescription, and vigilant monitoring for hepatic signs and symptoms are prudent and appropriate with kava use.

HERB-DRUG INTERACTIONS

Alprazolam and Related Triazolobenzodiazepines

Evidence: Alprazolam (Xanax).
Extrapolated, based on similar properties: Adinazolam (Deracyn), brotizolam (Lendormin), estazolam (ProSom), midazolam (Hypnovel, Versed), triazolam (Halcion).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

? **Interaction Likely but Uncertain Occurrence and Unclear Implications**

Probability: **3. Possible**

Evidence Base: **▽ Mixed**

Effect and Mechanism of Action

A single case report suggests an additive pharmacodynamic interaction between sedative and hypnotic effects of kava with alprazolam, although it may be partly a pharmacokinetic interaction. Clinical significance is not established.

Research

Two lines of evidence have been invoked to support possible pharmacodynamic interactions between kavalactones and CNS depressants. The first is derived from early animal studies showing synergistic enhancement of sleeping times after administration of combination of kavalactones with the barbiturates pentobarbital and hexobarbital. Klohs et al.[51] found extension of pentobarbital-induced sleeping times increased 410% in mice after 60 mg/kg coadministration of oral dihydromethysticin. Other kavalactones had lesser effects at higher doses of 160 mg/kg. Meyer[52] repeated these findings and found that intraperitoneal dihydromethysticin at 20 mg/kg increased sleeping time induced by hexobarbital significantly. Neither study measured blood levels, and thus pharmacokinetic interactions are not ruled out. These results are in conflict with a small, randomized crossover trial with 18 healthy volunteers that investigated the effects of combining 240 mg kavalactones per day with bromazepam (9 mg daily) versus bromazepam alone. This failed to reveal any additive or synergistic effects or any significant effects on performance measures, such as motor coordination, stress tolerance, or vigilance.[53]

The second line of evidence comes from "reverse" extrapolations based on receptor binding and neurotransmitter-mediated studies with kava extracts. However, the available evidence is inconsistent, and kavalactones appear to exhibit inconsistent and weak (if any) binding to gamma-aminobutyric acid (GABA) and benzodiazepine receptors.[54-58] In a multicenter placebo-controlled clinical trial of alprazolam for panic attacks, the safety profile of the drug was revealing: 10 patients of the 263 in the verum group reported serious adverse effects. Of these, three were acute intoxication and two were hepatitis; one hepatitis patient developed jaundice and hepatomegaly, which were reversed on discontinuation of the drug, and the other had elevated transaminase levels, which were reversed by cutting the alprazolam dose by 50%.[59]

Reports

A single case report in a letter from Almeida and Grimsley[60] entitled "Coma from the health food store" in 1996 involved an apparent kava-alprazolam interaction. the report was correctly dismissed as "unevaluable," according to the

Fugh-Berman and Ernst criteria.[61] The form and dose of kava administration were not identified, nor was the dose of alprazolam. The symptoms of the 54-year-old man were not clearly described; a "lethargic and disorientated" state on admission to hospital does not correspond to "coma," according to diagnostic criteria such as the Glasgow scale. Comedications apparently included cimetidine and terazosin, and the authors failed to consider alternative explanations; cimetidine, a potent CYP3A4 inhibitor, may have affected alprazolam levels because the triazolobenzodiazepines are all exclusively substrates of 3A4 (differing from other benzodiazepines, which are metabolized through multiple pathways). The report has no evidential value regarding a possible interaction.[61]

A single case in the hepatoxicity report series (German BfArM reference #93015209, also British MCA case #13) involved a woman who developed cholestatic jaundice symptoms after 3 months' use of kavalactones at 210 mg/day, while also taking diazepam (for 6 months, dose unknown), a combination oral contraceptive, and L-thyroxine.[16] Viral hepatitis was apparently a possible etiological factor. Diazepam is metabolized by 2C19, which is also inhibited in vitro by kavalactones. Schmidt et al.[17] categorized this case as "possible" kava hepatoxicity but conceded that concomitant medications or other etiologies might also be involved.

Clinical Implications and Adaptations

Benzodiazepines are prescribed as hypnotic/anxiolytic agents, which is identical to the principal clinical trial–supported indication for kava. As previously discussed, general prescribing guidelines followed by practitioners versed in use of botanical medicines discourage coadministration of an herbal and pharmaceutical agent taken concurrently for the same indication. It is also well established that kava extracts are comparable in efficacy for mild anxiety states to benzodiazepines, but with a better safety profile; thus "standard of care" botanical practice would be to prescribe kava as a preliminary trial alternative, not an addition, to benzodiazepines.[1,2] Patients should be advised not to self-prescribe kava while using prescription anxiolytics or other CNS-depressant agents.

With appropriately qualified professional management, exceptions to generic cautions are possible under certain circumstances. For example, kava extracts have been used anecdotally by natural health care providers to assist in tapered-withdrawal protocols in patients attempting to break long-term dependencies on benzodiazepines.[24] Combinations with other, mild herbal sedatives such as passionflower (*Passiflora incarnata*) are likely to be synergistic and lack potentially problematic interactions that may occur with pharmaceuticals.[62]

Dopamine Agonists and/or Antagonists

Evidence: Levodopa (L-dopa, Dopar, Larodopa), haloperidol (Haldol).

Extrapolated, based on similar properties: Carbidopa (Lodosyn), levodopa combination drugs: levodopa and benserazide (co-beneldopa; Madopar); levodopa and carbidopa (Atamet, Parcopa, Sinemet, Sinemet CR); levodopa, carbidopa, and entacapone (Stalevo); neuroleptics (i.e., agents inducing extrapyramidal symptoms); dopamine agonists other than levodopa.

Interaction Type and Significance

? Interaction Likely but Uncertain Occurrence and Unclear Implications

Probability:
4. Plausible

Evidence Base:
▽ Mixed

Effect and Mechanism of Action

Kavalactones may have mixed effects on central dopaminergic pathways, but the mechanism and effect of the interaction(s) are not established. This is reflected clinically in apparent kava-induced "parkinsonian" symptoms reversed by anticholinergics, as well as in experimental evidence that tardive dyskinesia induced by the neuroleptic agent haloperidol is reversed by kava.

Research

The multiple effects of kava cannot be attributed to a simple or single neurotransmitter mechanism, and the effect of kavalactones on dopaminergic pathways is not fully understood. Baum et al.[63] used intraperitoneal administration of kava extracts at two doses (20 and 120 mg/kg) as well as separate kavalactones in a rodent model to examine resultant behavioral and changes and their correlation with dopamine concentrations in the nucleus accumbens. Their results indicated both dopamine-agonist and dopamine-antagonistic effects, with yangonin decreasing dopamine concentrations, whereas D,L-kavain and desmethoxyyangonin increased the neurotransmitter levels; dihydrokavain, methysticin, and dihydromethysticin had no effect on dopamine. About half the animals also showed increased 5-hydroxytryptamine (5-HT, serotonin) levels, whereas the others showed no change or decreased 5-HT levels. The authors speculated that yangonin may limit the euphoric or dopaminergic actions of the other lactones.[63]

Noldner and Chatterjee[64] investigated the effect of kava on haloperidol-induced catalepsy in a rodent model, established as a validated test system for detecting compounds with extrapyramidal symptom liability in humans. They found no cataleptogenic effect of kava extract administered alone, and in a second series of experiments they found pretreatment or coadministration of kava (WS1490 at 100 mg/kg orally) completely abolished the cataleptic effects of 0.2 mg/kg haloperidol subcutaneously. They also found that dihydrokavain was the only isolated kavalactone that exerted similar actions, but the effect of the whole extract was greater than that of kavain alone.[64]

Reports

Schelosky et al.[65] described four patients with suspected central dopamine antagonism after kava ingestion. One patient, a 76-year-old woman taking levodopa for Parkinson's disease for more than 8 years, presented at the hospital with an acute attack of involuntary neck extension and forced upward gaze of the eyes, which commenced 90 minutes after ingesting a single dose of 100 mg of standardized kava. The symptoms resolved after 40 minutes without treatment. However, the same patient had a history of acute dystonic symptoms induced by promethazine and fluspirilene for anxiety, which were reversed by treatment with biperiden (anticholinergic). The other cases were not parkinsonian patients, and levodopa was not involved; however, all three had developed various acute-onset dyskinetic symptoms while using kava standardized extracts, and all were successfully treated with 5 mg biperiden intravenously.[65] The authors' suggestion that kava may induce Parkinson-like symptoms led to the Noldner and Chatterjee[64] investigation with kava previously discussed.

Meseguer et al.[66] reported another case of spontaneous tremor, in a 45-year-old woman using kava for anxiety; again the patient improved with anticholinergic treatment. The authors suggested that a genetic susceptibility may explain the apparent induction of parkinsonian symptoms in some individuals using kava.

Clinical Implications and Adaptations

There appears to be a small but finite likelihood that kava extracts spontaneously induce either Parkinson-like or related dystonic symptoms in some patients, reversible by anticholinergics. In one case report a direct interaction seemed to occur with levodopa. Interestingly, the extrapyramidal effects of antipsychotic drugs are known to be related to dopamine antagonism, but there are no reports of worsening of tardive dyskinesia from kava-neuroleptic combinations, and experimental evidence suggests the opposite, that kava may ameliorate such effects. This might also be theoretically predicted from the clinical observations of the muscular relaxant properties of the herb. Parenthetically, in a secondary review of kava, Pepping[67] suggested that the in vitro inhibition of platelet monoamine oxidase (MAO-B) by kavalactones might theoretically display additive effects with selegiline or related MAO-B inhibitors used in the treatment of Parkinson's disease.

At present, evidence is insufficient to determine the predisposing factors for the direction of kava effects in combination with drugs that directly or indirectly affect dopaminergic pathways. Professionally monitored exposure to a trial challenge with the herb might be considered when compelling reasons exist for coadministration with such agents, because the reported apparent dystonic reactions were acute in onset after single doses. Tardive dyskinesia symptoms arising from neuroleptic drug exposure are persistent after cessation of the drug, so kava use for extrapyramidal sequelae to antipsychotic therapy may be appropriate, with professional management. Clinical studies are needed to validate the theoretical benefits of the herb in this context.

Ethanol

Ethanol

Interaction Type and Significance

? **Interaction Likely but Uncertain Occurrence and Unclear Implications**

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability:
4. Plausible

Evidence Base:
▽ **Mixed**

Effect and Mechanism of Action

A suggested interaction, either pharmacodynamic or pharmacokinetic or both, between alcohol and kava theoretically could increase the toxicity of either agent under certain circumstances.

Research

Experiments by Jamieson and Duffield[68] are often cited as support for a possible alcohol-kava interaction. Using a rodent model, these researchers found that alcohol coadministered intraperitoneally with oral lipophilic kava extracts resulted in dose-dependent increase in sleeping times. However, the doses of both alcohol (up to 4 g/kg) and kava extracts (350 or 450 mg/kg) were much higher than those used therapeutically or in indigenous social/ceremonial consumption. The combined doses also proved to have high levels of lethal toxicity in the study animals. Also, the data appear to have little relevance to human clinical or social contexts, although arguably the toxicity of the combination was demonstrated to be greater than the inherent toxicity of either agent alone.

In contrast to the animal findings, Herberg[69] conducted a human study using a typical therapeutic kava dose of 300 mg/day (70% standardized extract). The placebo-controlled, randomized trial with 20 healthy volunteers examined the effects of WS1490 at 100 mg three times daily over 8 days, combined with oral ethanol administered to a blood level of 0.05% concentration, on seven performance parameters (e.g., concentration, vigilance, motor coordination tasks) on days 1, 4, and 8. No multiplicative negative effects of the combination were found. In the concentration test the combination group showed an actual improvement over alcohol alone ($p < 0.01$). On the other hand, Foo and Lemon[70] conducted a series of four trials with 40 healthy subjects, comparing the effects of aqueous kava extract (1 g/kg) alone with alcohol at a "social" dose of 0.75 g/kg alone, alcohol and kava combined, and placebo. In most performance tests, kava alone had little effect, but when combined with ethanol, performance deteriorated, to a greater degree than with ethanol alone.

The available data do not appear to resolve whether there is a pharmacokinetic or pharmacodynamic effect of the kava-alcohol combination, or whether the combination actually has any significant effect on cognitive function at "normal" dose levels. Gurley et al.[42] demonstrated in vivo inhibition of CYP2E1 by kava, but this is not the only pathway for alcohol metabolism. Anke et al.[71] showed that in vitro the four major kavalactones failed to exert detectable inhibition on alcohol dehydrogenase, even at 1 μM; as the authors noted, this suggests lack of pharmacokinetic interaction but does not preclude a pharmacodynamic effect. Further studies are required to clarify the occurrence, effects, and mechanism of the suggested interaction.

Reports

Alcohol was a factor in a detailed adverse event report from Russmann and Lauterburg[9] involving necrotizing hepatitis in a 34-year-old woman who had been consuming 210 mg kavalactones daily for 3 weeks. After consumption of 60 g alcohol, she became icteric, and laboratory values for transaminases and bilirubin were elevated. Biopsy confirmed the histopathological damage. She screened negatively for viral hepatitis but had low titers of Epstein-Barr virus. She recovered 8 weeks after cessation of the kava. She was phenotyped as a 2D6-poor metabolizer by debrisoquine challenge, and a lymphocyte transformation test revealed a strong T-cell reactivity to the kava extract. The authors suggested this was a case of immune-mediated hepatotoxicity, and that 2D6 phenotype may be important in the etiology of such reactions.

Clinical Implications and Adaptations

Evidence for an adverse interaction between alcohol and kava is inconclusive. Hepatoxicity from pharmacokinetic issues may be increased by the combination, particularly when one or both agents are taken at excessive levels. The clinical significance of the potential interaction is arguably less than its possible social implications, given that both kava and alcohol are subject to abuse, and a history of combined abuse of both agents has been recorded in some cases.[72] The interaction appears to be of low significance at therapeutic and socially acceptable doses.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Anticonvulsant Medications

Carbamazepine (Carbatrol, Tegretol), clonazepam (Klonopin), clorazepate (Tranxene), divalproex semisodium, divalproex sodium (Depakote), ethosuximide (Zarontin), ethotoin (Peganone), felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), levetiracetam (Keppra), mephenytoin,

mephobarbital (Mebaral), methsuximide (Celontin), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), phenobarbital (phenobarbitone; Luminal, Solfoton), phenytoin (diphenylhydantoin; Dilantin, Phenytek), piracetam (Nootropyl), primidone (Mysoline), sodium valproate (Depacon), topiramate (Topamax), trimethadione (Tridione), valproate semisodium, valproic acid (Depakene, Depakene Syrup), vigabatrin (Sabril), zonisamide (Zonegran).

Limited experimental studies in rodent models suggest that kava extracts have a potential for antiseizure effects.[73,74] D,L-kavain had only a weak effect against strychnine-induced seizure in mice.[75] Electrophysiological studies show kava induces an increase in slow-wave activity in rodents and humans.[57,76] Human data for antiseizure effects are not available, although Spinella[77] suggested that kava extracts may potentiate anticonvulsants and increase adverse effects, such as lethargy and cognitive impairment. This hypothetical interaction should be avoided and is subsumed under the general contraindication of not coadministering a herb (kava) and drug (anticonvulsant) for the same indication (epilepsy).

Caffeine

Caffeine

Donadio et al.[78] reported a case of acute rhabdomyolysis in a 29-year-old man after ingestion of a single dose of a compound herbal supplement containing 500 mg guaraná, 200 mg ginkgo, and 100 mg kava. The precise dose of the product was not revealed, and neither were comedications and medical history, other than that the patient was a regular weight trainer who had just resumed weight training after 2 years. The patient was hospitalized with myoglobinuria and elevated creatine kinase (CK) and myoglobin levels. He developed no renal complications and recovered fully after 6 weeks. Treatment, if any, was not detailed. The authors speculate that the antidopaminergic and neuromuscular-blocking properties of kava were pathogenetically relevant, along with the methylxanthine effects of caffeine from guaraná. Given the single dose of the supplement and the relatively small amounts of caffeine, equivalent to one or two cups of coffee, the authors' explanation is not readily plausible. The complete lack of additional reports of myoglobinuria in association with caffeine-kava consumption, which is likely a common combination, further detracts from the credibility of this suggested interaction.

Monoamine Oxidase (MAO-B) Inhibitors

Selegiline (deprenyl, L-deprenil, L-deprenyl; Atapryl, Carbex, Eldepryl, Jumex, Movergan, Selpak); pargyline (Eutonyl), rasagiline (Azilect).

Uebelhack et al.[79] conducted in vitro tests for MAO-B inhibitory activity by kava extracts and kavalactones in a human platelet system, both with intact and homogenized platelets. They found an IC_{50} of 24 μM for intact platelets, with substantially lower values for platelet homogenate.[79] MAO inhibitor activity has not been reported for kavalactones in neurotransmitter studies, and the in vivo effects of the herb are not commensurate with selective MAO-B inhibition. Suggestions have been made of theoretical interactions with MAO inhibitors[67]; these are speculative.

Proton Pump Inhibitors

Evidence: Omeprazole (Losec, Prilosec).
Extrapolated, based on similar properties: Esomeprazole (Nexium), lansoprazole (Prevacid, Zoton), pantoprazole (Protium, Protonix, Somac), rabeprazole (AcipHex, Pariet).

Of the cases of hepatoxicity reported by BfArM, 21 included comedications with several prescription or over-the-counter (OTC) pharmaceuticals. Notably, the proton pump inhibitor (PPI) omeprazole (or rabeprazole) was involved in chronic use in four cases, two of which involved liver failure and transplant; one of these patients died after transplantation.[16] None of the cases was well documented, and all involved additional polypharmacy (see hepatotoxicity and interactions section earlier). Omeprazole (and all other PPIs) are metabolized by CYP450 3A4 and 2C19, both of which are inhibited by kava, with 2C19 subject to a poor-metabolizer polymorphism. Omeprazole alone is known to be associated with reports of acute hepatitis, transaminitis, and hepatic failure.[80-83]

Reliable data on the kava-omeprazole interaction are not available. However, given that omeprazole is often used for periods considerably longer than the manufacturer's recommended 4-week limit, pharmacokinetic interactions with kava are possible, resulting in elevated plasma levels of the drug. Therefore, increased risk of hepatic side effects may be of more than theoretical concern.

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Warfarin (Coumadin, Marevan, Warfilone).
Related: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar).

A human platelet aggregometry study by Gleitz et al.[84] established that isolated kavain could suppress arachidonic acid–induced aggregation at IC_{50} of 78 μM/L. This figure is an order of magnitude in excess of in vivo–attained concentrations after oral administration of kavalactones. Reports of interactions with drugs affecting hemostasis are unavailable. The *S*-enantiomer of warfarin is metabolized by CYP2C9 and the less active *R*-enantiomer by CYP1A2; both are inhibited by kavalactones at therapeutic dose levels (see pharmacokinetics discussion earlier).[35-40] Pharmacokinetic interactions with warfarin are therefore theoretically possible, although no interactions with anticoagulants have been reported, and no bleeding adverse effects have been attributed to kava.[85]

The 85 citations for this monograph are located under Kava on the CD at the back of the book.

Licorice

Botanical Name: *Glycyrrhiza glabra* L.
Pharmacopoeial Names: Liquiritae radix, Radix glycyrrhizae
Synonym: *Glycyrrhiza glandulifera* Waldst. and Kit.
Common Names: Licorice, licorice root; U.K. spelling = liquorice; literally, "sweet root."

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Acetaminophen UGT1A substrates ⊕⊕/☼	Licorice induces UGT1A and increases clearance of acetaminophen. Minor significance for acetaminophen due to multiple pathways of the drug's metabolism.	None relevant; vigilance with drugs exclusively conjugated by UGT.
Acetylsalicylic acid gastrointestinal and ulcerogenic agents ⊕⊕	Licorice helps reduce gastrointestinal adverse effects of aspirin. Clinically significant; anecdotally applicable to other drugs, such as NSAIDs, mucosa-inducing chemotherapy agents, and ethanol.	Coadministration preferred. Deglycyrrhizinated licorice (DGL) is effective.
Antibiotics ◈	Activation by hydrolysis of licorice glycoside (GL) to aglycone (GA) depends on bowel flora. Antibiotics reduce bowel flora number and function and may reduce herb bioavailability.	If coadministration necessary, use probiotics or DGL, if appropriate.
Beta-lactam antibiotics ⊕	Licorice constituents reduce or reverse drug resistance in MRSA when combined with beta-lactam antibiotics.	Coadminister licorice with drug in diagnosed MRSA.
Cimetidine Histamine (H_2) receptor antagonists ⊕	Synergistic increase in ulceroprotective and ulcer-healing properties suggested by combination of drug with DGL.	Coadminister.
Cortisol Prednisolone Corticosteroids, oral ⊕⊕/☼	Licorice spares steroid by inhibiting metabolic degradation, potentiates anti-inflammatory effects; reduced adverse effects because lower drug doses permitted by combination.	Combination used to minimize steroid doses; assist in tapered steroid drug withdrawal.
Digoxin Cardiac glycosides ✗✗	Supratherapeutic doses of licorice may induce hypokalemia, which has been associated with potential digitalis toxicity. Clinical significance low if drug and herb correctly prescribed and monitored, with electrolyte monitoring.	Avoid excessive doses and herb administration. Monitor electrolytes, and supplement with K^+/Mg^{++} if coadministration indicated.
Furosemide Potassium-depleting diuretics ✗✗/◈	Additive hypokalemic toxicity possible. In practice, reported cases all caused by unwitting or inappropriate self-administration of licorice-containing products.	Avoid. Caution patients to monitor labels of candy, laxatives, and other possible licorice-containing products.
Spironolactone Aldosterone antagonists ?	Complex interaction involving opposition of hypokalemia by drug at mineralocorticoid receptor, and possible reduction in licorice adverse effect of hypertension. Significance not established.	Avoid until further data available.
Nitrofurantoin Nitrofuran urinary antiseptics ☼	Reduction of gastrointestinal side effects of drug. Clinically less relevant due to replacement of nitrofurans with ciprofloxacin, etc. Arguably same interaction as with aspirin, i.e., generic gastroprotective effect of herb.	Coadminister DGL with gastrointestinal drugs known to cause adverse effects.

UGT1A, Uridine diphosphate (UDP) glucuronosyltransferase; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *MRSA*, methicillin-resistant *Staphylococcus aureus*.

HERB DESCRIPTION

Family

Fabaceae.

Related Species

Glycyrrhiza uralensis Fisch ex DC (*Gan cao*). The favored Chinese species, *Gan cao* is pharmacologically similar to *Glycyrrhiza glabra*.[1]

Habitat and Cultivation

A perennial shrub in the pea family, *G. glabra* is a Mediterranean native, but more than 20 related species are distributed throughout Europe, Asia, the Americas, and Australia. *Glycyrrhiza uralensis* and *G. glabra* are both widely cultivated in warmer zones throughout Eurasia.

Parts Used

Root, stolons.

Common Forms

Dried Root: Whole dried root, and powdered dried root without bark.
Tincture, Fluid Extract: 15% to 20% alcohol.
Standardized Extracts: Up to 20% glycyrrhizin.
Deglycyrrhizinated Licorice (DGL): 0.5% to 2.0% flavonoids as liquiritigenin.

HERB IN CLINICAL PRACTICE

Overview

Licorice is one of the most ubiquitous herbs in Asian medicine and has been an important remedy in Western herbalism since

Greco-Roman times. Licorice is a complex and clinically valuable herb that, without substantial justification, has acquired an uneven reputation in conventional medicine. In part, confusion arises from the many different forms of the herb, its constituents, concentrates, and derivatives, such as the antiulcer drug carbenoxolone sodium, deglycyrrhizinated licorice (DGL), or parenteral products such as SNMC (no longer available) from Japan. These preparations were developed after the emergence of scientific interest in the pharmacology of the herb because of its unusually broad range of effects, including multiple actions on steroid metabolism and inflammatory pathways; hepatoprotective, chemopreventive, and antitumorigenic properties; and pronounced antiviral activities (e.g., glycyrrhizin is the most potent SARS antiviral agent currently known).[2,3]

A significant proportion of "bad press" associated with licorice root is attributable to the use of concentrated glycyrrhizin in the processed food and tobacco industries as a flavoring agent because of its characteristic intense sweetness. "Licorice" is also used to describe a range of widely available popular confectionery products; notably, in the United States, these are more often flavored with anise rather than real licorice or glycyrrhizin. Reports in the medical literature of licorice-related adverse events are invariably associated with the use/abuse of such products, rather than therapeutic doses of the crude herb or its extracts in a clinical setting.

Therapeutic monographs on licorice root are available by the European Scientific Cooperative on Phytotherapy (ESCOP),[4] British Herbal Medical Association (BHMA),[5] World Health Organization (WHO),[6] and German Commission E.[7] The herb is official in the 2003 *United States Pharmacopoeia–National Formulary*, the *European Pharmacopoeia*, and the 1997 *Pharmacopoeia of the People's Republic of China*.

Historical/Ethnomedicine Precedent

Licorice has been used for food and medicine around the world since ancient Egyptian and Assyrian records were first written on papyri and clay tablets. It was one of the riches stored in King Tutankhamen's tomb. Scythians near the Sea of Azov knew the sweet root to be a successful treatment for people with asthma and dry cough. Documented in the third century BCE by the Greek Theophrastus, this use is still common with many herbalists today. Medicinal uses of licorice are recorded from every dynasty of Chinese history. The herb is one of the most frequently used in Chinese formulae, often included as an adjuvant in prescriptions to harmonize other herbs, and thus esteemed as the "Great Harmonizer"; it is primarily considered to tonify spleen (*Pi*) and stomach (*Wei*) *qi* deficiencies, moisten the lungs (*Fei*), relieve pain, clear "Heat" and "Toxins."[8] The herb is also used widely in other Asian traditions, including Kampo and Ayurvedic medicine.

In Western use, licorice attracted medical interest when the Dutch physician Revers discovered at the end of World War II that some of his patients were using licorice as a home remedy to treat their ulcers successfully. This led to the development of semisynthetic antiulcer medication called *carbenoxolone*, long since replaced by newer classes of drug, such as histamine (H_2) blockers and proton pump inhibitors. Deglycyrrhizinated licorice was a byproduct of carbenoxolone manufacture, and DGL is currently used to deliver high levels of anti-inflammatory licorice flavonoid compounds with significantly lower levels of glycyrrhetinic acid (GA), reducing the risk of GA-induced pseudoaldosteronism. The effects of the herb on glucosteroid metabolism simultaneously led to medical interest in its use for Addison's disease.[9,10] This is reflected in the incorporation of licorice into prescriptions for (functional) "adrenal insufficiency" and chronic fatigue conditions by modern herbalists and naturopathic physicians. In botanical medicine the herb continues to be valued for its general tonic properties as well as for its more specific indications (e.g., peptic ulcers).

Known or Potential Therapeutic Uses

Addison's disease, adrenal insufficiency, asthma, bronchitis, cancer chemoprevention, chronic fatigue, constipation, cough, hepatoprotection against toxicity, herpes simplex infection (topically), human immunodeficiency virus (HIV) infection, inflammations of the gastric and urinary tracts, joint inflammation, mouth ulcers, peptic ulcers, polycystic ovarian syndrome, sudden acute respiratory syndrome (SARS), sore throat, stress, viral hepatitis.

Key Constituents

Triterpene saponins, principally glycyrrhizin 2% to 6% (aglycone = glycyrrhetin or glycyrrhetinic acid).
Polysaccharides, flavonoids (approximately 1.0%) including liquiritin, chalcones including isoliquiritin, isoflavonoids, sterols.

Note: Nomenclature for the glycyrrhizin and its aglycone varies. This monograph adopts the abbreviation "GL" for the *glycoside* (glycyrrhizin, glycyrrhizic acid, glycyrrhizinic acid) and "GA" for the *aglycone* (glycyrrhetinic acid).

Therapeutic Dosing Range

Dried Root: By decoction, 3 to 10 g/day; typical maximum Chinese dose: 15 to 30 g/day.
Tincture/Fluid Extract: Based on 1:1, 2 to 5 mL three times daily.
Standardized Extract: Up to 20% glycyrrhizin, equivalent to 5 to 15 g/day DGL—0.5% to 2.0% flavonoids, chewable tablets approximately 380 mg three times daily.

INTERACTIONS REVIEW

Strategic Considerations

The major therapeutic monographs for licorice root vary slightly in their accounts of potential interactions between licorice root preparations and prescription drugs, but the general theme is consistent. The German Commission E maintains that "potassium loss due to other drugs may be increased," and suggests that "with potassium loss, sensitivity to digitalis glycosides may be increased."[7] The same warning is repeated by ESCOP,[4] who include other "antiarrhythmic drugs or drugs which induce reversion to sinus rhythm such as quinidine" in their precautions about hypokalemia, as well as repeating the warnings of Commission E about combining licorice with potassium depleters, including stimulant laxatives and loop or thiazide diuretics. ESCOP also notes a possible alteration of prednisolone pharmacokinetics (i.e., glucocorticoid-sparing effect) with licorice. The WHO monograph[6] includes a further precaution about combining aldosterone antagonists such as spironolactone or amiloride with licorice.

These warnings are representative of most discussions on licorice's interactions with prescription drugs. Strictly speaking, these are better classified as drug "contraindications" based on the known pharmacological property of GL to induce a syndrome known as *pseudoaldosteronism* or "apparent

mineralocorticoid excess." The first report of licorice-induced hypokalemia was unwittingly made by London physician de Cayley in 1950, who recorded the three cases of hypokalemic arrhythmia associated with *p*-aminosalicylic acid (PAS) therapy for tuberculosis.[11] De Cayley did not detect the connection to licorice, but the following year, Strong[12] realized that PAS was in fact flavored with licorice root extract. In 1979, Ulick et al.[13] used "apparent mineralocorticoid excess" (AME) to describe the congenital pediatric syndrome of hypertension, hypokalemia, suppressed renin-angiotensin-aldosterone axis, and increased urinary ratio of 11β-hydroxy to 11-oxo metabolites of cortisol (suggesting a failure of conversion of cortisol to cortisone).[14,15]

Subsequently, the ability of licorice extracts to inhibit the enzyme 11β-hydroxysteroid dehyhydrogenase (11β-HSD) became established through in vitro, animal, and human experiments, and the resultant effects are usually termed licorice-induced "pseudoaldosteronism" to distinguish it from congenital AME.[16-19] Renal 11β-HSD-2 normally serves to "protect" local mineralocorticoid receptors from activation by cortisol by metabolizing the endogenous glucocorticoid locally to its inactive form. That is, the enzyme confers aldosterone specificity on intrinsically nonspecific renal mineralocorticoid receptors. When this enzyme is inhibited, the resulting excess cortisol stimulates both the glucocorticoid and the "unprotected" renal mineralocorticoid receptors, promoting potassium loss. If unchecked, this can lead to sodium retention and hypokalemia, with possible sequelae of hypertension, myopathy, rhabdomyolysis with potential renal failure from myoglobinemia, and cardiac rhythm disturbances.[17-27] The corollary impression that licorice is thus associated with potentially life-threatening toxicities pervades secondary accounts of the herb and reports of its interactions.

In practice, the situation is less clear-cut. First, the theoretical potential of licorice and its derivatives (except DGL) to induce pseudoaldosteronism is well known to practitioners of natural medicine who regularly use the herb and has been documented in conventional medical literature for over half a century. Coadministration of licorice with potassium-depleting drugs such as thiazide or loop diuretics, especially in patients vulnerable to electrolyte disturbance or using narrow-therapeutic-index antiarrhythmics, is a contraindication and clear departure from the standard of care. If two separate agents possessing similar toxicities are coadministered, there is risk of additive toxicity. This is not strictly speaking an interaction, unless there is evidence for unexpected "synergistic" or nonlinear increases in toxicity resulting from the combination. In botanical medicine settings, high doses of licorice are never prescribed for prolonged periods, and when used at normal therapeutic doses for 6 to 8 weeks, the adverse sequelae of pseudoaldosteronism are rarely observed. Blood pressure is usually monitored during higher-dose licorice prescription. There are no published reports of licorice-induced pseudoaldosteronism arising from practitioner-administered use of licorice; all published reports relate to either unwitting or deliberate consumption of products such as licorice candy, chewing tobacco, or flavored and sweetened beverages and laxatives. The risks of adverse events from self-administration are small but finite, given the public availability of these products, but it is appropriate to distinguish these concerns from clinical practice.[28]

Second, inhibition of renal 11β-HSD-2 by licorice and resulting mineralocorticoid receptor–mediated effects do not appear to account fully for the known features of the pseudoaldosteronism syndrome, particularly the varying individual expressions of both hypertension and edema. There is evidence of central nervous system (CNS) involvement unrelated to the renin-angiotensin axis, as well as local renovascular nitric oxide (NO)–mediated endothelial effects in addition to direct mineralocorticoid effects.[29,30]

The impact of licorice on steroid metabolism is complex and not fully understood. Inactivation of cortisol by 11β-HSD-2 is reversible because the enzyme is a bidirectional oxidoreductase. There are at least two isoforms of the enzyme; 11β-HSD-1 is widely distributed in peripheral tissues and the brain and acts predominantly as a reductase (i.e., reactivating glucocorticoids); 11β-HSD-2 is also bidirectional, but a higher-affinity enzyme that predominantly inactivates glucocorticoids, and it is co-localized with mineralocorticoid receptors (e.g., in the kidney).[31] Evidence for a third isoform, found in choriocarcinoma cells, has also been presented.[32] Glucocorticoid receptors are also subject to polymorphisms that contribute to individual variability in responses. There appears to be pronounced sexual dimorphism in humans between the relative contributions to cortisol inactivation by the A-ring reductases and 11β-HSD-1.[33,34] Licorice and GA also inhibits the A-ring reductases (5α- and 5β-reductase); both these enzymes irreversibly inactivate glucocorticoids.[35,36] The relationship between relative activities of the irreversible A-ring reductases and bidirectional oxidoreductases appears to vary widely and independently, depending on metabolic conditions.[37,38]

Data from animal studies used to explore the steroid biology must be extrapolated with caution to humans because definite species differences exist in the enzymatic determinants of steroid metabolism, which have diverged throughout mammalian evolution.[36,39-42] Pharmacokinetic variation in the bioavailability of GA has been demonstrated, and given the dependence of GL hydrolysis and release of GA on intestinal flora, this factor may be highly significant.[43-46] (See later discussion on the interaction between licorice and antibiotics.) Other compounds in food or herbal medicines may also inhibit 11β-HSD-1, notably grapefruit juice.[47,48]

In the final analysis, the inhibition of 11β-HSD isoenzymes by licorice arguably underlies only one clinically significant drug interaction, which is the consequent ability of licorice to "spare" prescription glucocorticoids (see licorice-prednisone/corticosteroid interaction). This interaction is not emphasized by secondary sources or the general literature. Licorice dosage required to effect a sustained inhibition of 11β-HSD have been estimated in a human pharmacokinetic study by Krahenbul et al.[49] to be 1000 to 1500 mg GA per day, whereas dose levels of less than 500 mg GA/day did not appear to be able to sustain levels of inhibition. Similar results were established by Bernardi et al.,[50] who found mild adverse effects only at the highest dose (814 mg GL/day) in a trial of healthy volunteers taking different daily doses for 2 weeks, although measurable renin depression occurred at lower-dose groups of 217 and 380 mg GL daily.[50]

The modulation by licorice of multiple steroid-metabolizing enzymes has some impact on sex hormones as well as glucocorticoids. Reports have suggested mild antitestosterone effects and weak estrogen receptor (ER) binding by licorice, and pronounced biphasic phytoestrogenic activity for the flavonoid compounds isoliquiritigen and glabidrin.[51-63] Speculations about interactions between licorice and prescription steroid sex hormones have inevitably been made but are currently unsupported by clinical data. The only available trial was a small, open-label study with 15 women and 21 men that examined the effects of 4 weeks' daily consumption of 9 g licorice (150 mg GA) on steroidal hormone levels. Negligible effects

were found in the androgens, but in men a slight decrease in dehydroepiandrosterone sulfate (DHEAS) was observed[64] (see Theoretical, Speculative, and Preliminary Interactions Research).

Effects on Drug Metabolism and Bioavailability

Effects of licorice on the major drug-metabolizing and xenobiotic-metabolizing enzymes and effects of its compounds have not been fully characterized. Kent et al.[65] tested recombinant human cytochrome P450 (CYP450) enzymes in vitro for inhibition by whole-licorice-root extract and the licorice flavonoid glabidrin and found significant inhibition of 3A4 and 2B6 by both licorice extract and glabidrin. The effects were mechanism based and dose dependent but were demonstrated at plausible concentrations of licorice extract, with 6.9 micromolar (μM) achieving more than 50% inhibition of 3A4. CYP 2C9 was competitively inhibited by the licorice flavonoid glabidrin, whereas 2D6 and 2E1 did not appear to be affected by either licorice extract or isolated glabidrin.[65] Using a live rodent model, however, Jeong et al.[66] demonstrated that CYP450 2E1 inhibition was a component part of the mechanism underlying carbon tetrachloride hepatotoxicity prevention by oral pretreatment with GA.[66]

Paolini et al.[67,68] found that single doses of licorice extract or GL had no effect on mixed oxidases in a murine model. However, prolonged administration of 240 or 480 mg/kg GA resulted in significant increases of CYP450 3A4 activity, also shown to result from changes in messenger ribonucleic acid (mRNA), denoting increased induction of the enzyme. Smaller increases in 2A1, 2B1, 1A2, and 2B9 were also noted. A much-quoted in vitro fluorometric screening assay by Budzinski et al.[69] of several commercial herbal extracts and compounds on human 3A4 suggests that licorice extract was a moderate inhibitor of 3A4. However, the concentrations used were effectively in the 5-millimolar range, far in excess of attainable in vivo levels. Also, the relationship between in vitro fluorometric data and in vivo activity has not been demonstrated to have any consistent correlation.

The current picture of licorice effects on phase I drug metabolism remains incomplete. Clinical studies are required to establish how the preliminary and inconclusive experimental data may translate into significant drug-herb interactions. One rodent study suggests a possible enhancement effect of licorice on the phase II conjugase enzyme uridine diphosphate (UDP) glucuronosyltransferase (UGT1A), which did not appear to be an induction (mRNA) effect.[70] Additional evidence suggests possible effects of licorice on drug transporters of the organic anion peptide subfamily.[71] Finally, some animal data suggest that steroid drug distribution may be affected by licorice modulating steroid-binding globulins; however, the clinical significance of these data is not known.[72,73]

In conclusion, preliminary evidence exists that licorice may exert pharmacokinetic interaction effects on phases I, II, and III of drug metabolism, as well as some aspects of drug distribution. A preliminary report based on Chinese licorice *(Gan cao)* suggests the possibility that *Glycyrrhiza uralensis* compounds may bind to the pregnane X receptor (PXR).[74] If corroborated for licorice root, such effects might indicate a more significant potential for pharmacokinetic interactions than has been established to date. At present, however, clinical reports suggestive of pronounced pharmacokinetic interactions between licorice and pharmaceutical drugs are absent, and the complex effects on steroid-metabolizing enzymes dominate the considerations of the herb from an interactions perspective.

HERB-DRUG INTERACTIONS

Acetaminophen

Evidence: Acetaminophen (APAP, paracetamol; Tylenol); combination drugs: acetaminophen and codeine (Capital with Codeine; Phenaphen with Codeine; Tylenol with Codeine); acetaminophen and hydrocodone (Anexsia, Anodynos-DHC, Co-Gesic, Dolacet, DuoCet, Hydrocet, Hydrogesic, Hy-Phen, Lorcet 10/650, Lorcet-HD, Lorcet Plus, Lortab, Margesic H, Medipain 5, Norco, Stagesic, T-Gesic, Vicodin, Vicodin ES, Vicodin HP, Zydone); acetaminophen and oxycodone (Endocet, Percocet 2.5/325, Percocet 5/325, Percocet 7.5/500, Percocet 10/650, Roxicet 5/500, Roxilox, Tylox); acetaminophen and pentazocine (Talacen); acetaminophen and propoxyphene (Darvocet-N, Darvocet-N 100, Pronap-100, Propacet 100, Propoxacet-N, Wygesic). Extrapolated, based on similar properties: Substrates of glucuronosyltransferase (UGT1A).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

In this pharmacokinetic interaction, acetaminophen clearance is increased by the induction of glucuronosyltransferase activity by licorice.

Research

Moon and Kim[70] used a rodent model to investigate the effects of licorice root on acetaminophen pharmacokinetics. Pretreatment with glycyrrhizin (1 g/kg) for 6 days increased biliary and urinary excretion of glucuronic conjugates, but not of sulfate or thioether conjugates. Acetaminophen is also conjugated by sulfurotransferases and oxidized by CYP450 3A4.

Clinical Implications and Adaptations

Because acetaminophen is metabolized by multiple pathways, the significance of this interaction is low. Notably, the critical factors in acetaminophen toxicity are the extent of the hepatotoxic metabolite NAPQI formation by CYP 2E1 and the availability of glutathione for its conjugation.

Acetylsalicylic Acid and Other Gastroirritant and Ulcerogenic Agents

Evidence: Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine,

butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin).
Extrapolated, based on similar properties: Ulcerogenic/gastropathic drugs of several unrelated classes, including NSAIDs, ethanol, and antineoplastic chemotherapy agents.

Interaction Type and Significance

◉ **Emerging**

Effect and Mechanism of Action
The antiulcer and gastroprotective effects of licorice and DGL reduce the incidence of aspirin-induced gastric irritation and bleeding. The mechanism is multifactorial, including increase of mucin secretion to restore the gastric mucosal barrier, together with probable inhibition of gastric acid secretion; anti-inflammatory and cell proliferation effects may also be involved.

Research
A rodent study demonstrated that ulcer lesion scores and bleeding severity after gastric tube administration of ASA at 64 mg/kg were reduced significantly by coadministration of DGL at 2000 mg/kg. However, pretreatment with DGL did not have the same protective effect.[75] Other rodent studies found a protective reduction in bile acid and aspirin-induced ulceration in rats with DGL coadministration and a reduction in ulcer index using oral aspirin with a licorice coating.[76,77] The mechanism appears to be primarily related to increased mucin production.[78] Only one human study has examined the effects of coadministering aspirin with DGL. Rees et al.[79] performed a placebo-controlled, double-blind crossover study with patients who received either aspirin alone (325 mg three times daily) or aspirin (325 mg) plus DGL (175 mg three times daily). Fecal blood loss was significantly lower in the combination group, and the authors believed the result would have been more marked with higher doses of DGL.

Clinical Implications and Integrative Therapeutics
Aspirin-induced (and NSAID-induced) gastropathy is a well-documented and widespread problem and the cause of a significant number of serious drug-related adverse events, even at cardioprotective doses of 80 mg ASA/day.[80,81] Coadministration with proton pump inhibitors (PPIs) is considered a pharmaceutical management approach. An alternative is cotreatment with DGL, which appears to provide substantial protection while avoiding the adverse effects of long-term PPI use. Anecdotal clinical uses of the gastroprotective effects of licorice and DGL include prophylaxis and treatment of antineoplastic chemotherapy–induced mucositis.

Antibiotics and Antimicrobial Agents (Systemic)

Aminoglycoside Antibiotics: Amikacin (Amikin), gentamicin (G-mycin, Garamycin, Jenamicin), kanamycin (Kantrex), neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin), netilmicin (Netromycin), paromomycin (monomycin; Humatin), streptomycin, tobramycin (AKTob, Nebcin, TOBI, TOBI Solution, TobraDex, Tobrex).
Beta-Lactam Antibiotics: Methicillin (Staphcillin); aztreonam (Azactam injection); carbapenem antibiotics: meropenem (Merrem I.V.); combination drug: imipenem and cilastatin (Primaxin I.M., Primaxin I.V.); penicillin antibiotics: amoxicillin (Amoxicot, Amoxil, Moxilin, Trimox, Wymox); combination drug: amoxicillin and clavulanic acid (Augmentin, Augmentin XR, Clavulin); ampicillin (Amficot, Omnipen, Principen, Totacillin); combination drug: ampicillin and sulbactam (Unisyn); bacampicillin (Spectrobid), carbenicillin (Geocillin), cloxacillin (Cloxapen), dicloxacillin (Dynapen, Dycill), mezlocillin (Mezlin), nafcillin (Unipen), oxacillin (Bactocill), penicillin G (Bicillin C-R, Bicillin L-A, Pfizerpen, Truxcillin), penicillin V (Beepen-VK, Betapen-VK, Ledercillin VK, Pen-Vee K, Robicillin VK, Suspen, Truxcillin VK, V-Cillin K, Veetids), piperacillin (Pipracil); combination drug: piperacillin and tazobactam (Zosyn); ticarcillin (Ticar); combination drug: ticarcillin and clavulanate (Timentin).
Cephalosporin Antibiotics: Cefaclor (Ceclor), cefadroxil (Duricef), cefamandole (Mandol), cefazolin (Ancef, Kefzol), cefdinir (Omnicef), cefepime (Maxipime), cefixime (Suprax), cefoperazone (Cefobid), cefotaxime (Claforan), cefotetan (Cefotan), cefoxitin (Mefoxin), cefpodoxime (Vantin), cefprozil (Cefzil), ceftazidime (Ceptaz, Fortaz, Tazicef, Tazidime), ceftibuten (Cedax), ceftizoxime (Cefizox), ceftriaxone (Rocephin), cefuroxime (Ceftin, Kefurox, Zinacef), cephalexin (Keflex, Keftab), cephapirin (Cefadyl), cephradine (Anspor, Velocef), imipenem combination drug: imipenem and cilastatin (Primaxin I.M., Primaxin I.V.); loracarbef (Lorabid), meropenem (Merrem I.V.).
Fluoroquinolone (4-Quinolone) Antibiotics: Cinoxacin (Cinobac, Pulvules), ciprofloxacin (Ciloxan, Cipro), enoxacin (Penetrex), gatifloxacin (Tequin), levofloxacin (Levaquin), lomefloxacin (Maxaquin), moxifloxacin (Avelox), nalidixic acid (Neggram), norfloxacin (Noroxin), ofloxacin (Floxin, Ocuflox), sparfloxacin (Zagam), trovafloxacin (alatrofloxacin; Trovan).
Macrolide Antibiotics: Azithromycin (Zithromax), clarithromycin (Biaxin), dirithromycin (Dynabac), erythromycin oral (EES, EryPed, Ery-Tab, PCE Dispertab, Pediazole), troleandomycin (Tao).
Sulfonamide Antibiotics: Sodium sulfacetamide (AK-Sulf, Bleph-10, Sodium Sulamyd), sulfamethoxazole (Gantanol), sulfanilamide (AVC), sulfasalazine (salazosulfapyridine, salicylazosulfapyridine, suphasalazine; Apo-Sulfasalazine, Azulfidine, Azulfidine EN-Tabs, PMS-Sulfasalazine, Salazopyrin, Salazopyrin EN-Tabs, SAS), sulfisoxazole (Gantrisin); combination drug: sulfamethoxazole and trimethoprim (cotrimoxazole, cotrimoxazole, SXT, TMP-SMX, TMP-sulfa; Bactrim, Bactrim DS, Cotrim, Septra, Septra DS, Sulfatrim, Uroplus); triple sulfa (Sultrin Triple Sulfa).
Chemotherapy, Cytotoxic Antibiotics: Bleomycin (Blenoxane), dactinomycin (Actinomycin D, Cosmegen, Cosmegen Lyovac), mitomycin (Mutamycin), plicamycin (Mithracin).
Miscellaneous Antibiotics: Bacitracin (Caci-IM), chloramphenicol (Chloromycetin), chlorhexidine (Peridex), colistimethate (Coly-Mycin M), dapsone (DDS, diaminodiphenylsulphone; Aczone Gel, Avlosulfon), furazolidone (Furoxone), lincomycin (Lincocin), linezolid (Zyvox), nitrofurantoin (Macrobid, Macrodantin), oral clindamycin (Cleocin), trimethoprim (Proloprim, Trimpex), vancomycin (Vancocin).

Interaction Type and Significance
◇ **Adverse Drug Effect on Herbal Therapeutics, Strategic Concern**

Probability:
2. Probable

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

Bioavailability of licorice root metabolites is partially dependent on bacterial flora which hydrolyze glycyrrhizic acid (GL) to its aglycone form. Oral antibiotic therapy suppresses normal bowel commensal flora and may reduce bioavailability of glycyrrhetinic acid (GA).

Research

The involvement of bowel flora in hydrolysis of GL to GA was first demonstrated in humans by Hattori et al.[44,45] Animal studies suggest significant species differences in stomach and bowel formation of licorice metabolites.[46] A rodent study showed that coadministration of a licorice-containing Chinese formula to rats with triple anti–*Helicobacter pylori* drug combination (omeprazole, amoxicillin, and metronidazole) significantly reduced the AUC of GA compared with administration of the formula alone. The authors attribute the effect to loss of GL-hydrolysis activity through reduction of bowel flora caused by the antimicrobials.[82]

Human data are equivocal. Cantelli-Forti et al.[43] showed little difference between the bioavailability of GL and GA up to 36 hours after single dosing.[43] A human pharmacokinetic study by Krahenbuhl et al.[83] demonstrated that GL and GA both undergo biliary elimination; GL is recycled enterohepatically, whereas GA is conjugated as a glucuronide before removal in the bile. Almost all orally administered GL reaches systemic circulation as GA after bowel flora hydrolysis.

Integrative Therapeutics, Clinical Concerns, and Adaptations

No studies are available demonstrating decreased bioavailability of GA in patients with reduced bowel flora after antibiotic therapy. Based on current information, however, antibiotics may reduce GA plasma levels if coadministered. This would not affect DGL preparations.

Beta-Lactam Antibiotics

Evidence: Oxacillin (Bactocill).
Extrapolated, based on similar properties: Methicillin (Staphcillin); beta-lactamase–resistant penicillins: cloxacillin (Cloxapen), dicloxacillin (Dynapen, Dycill); carbapenem antibiotics: meropenem (Merrem I.V.); combination drug: imipenem and cilastatin (Primaxin I.M., Primaxin I.V.); cephalosporin antibiotics, ciprofloxacin and other fluoroquinolone antibiotics, ketaconazoles, macrolide antibiotics, other penicillin antibiotics; combination drugs: amoxicillin and clavulanic acid (Augmentin, Augmentin XR, Clavulin, Nuclav); clavulanic acid and ticarcillin (Timentin).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:	Evidence Base:
4. Plausible	○ **Preliminary**

Effect and Mechanism of Action

Licorice constituents may reduce or reverse drug resistance of methicillin-resistant *Staphylococcus aureus* (MRSA) to beta-lactam antibiotics.

Research

Experimental data are accumulating that a variety of natural compounds can effectively reverse drug resistance in various phenotypes of resistant *S. aureus*.

Licorice compounds have shown this potential with oxacillin against MRSA in vitro.[84] Mechanisms are not fully understood, but direct binding to bacterial wall peptidoglycans by the flavonoids is considered likely, and the effect is synergistic, not additive.[85]

Clinical Implications and Integrative Therapeutics

Clinical implementation of this potential interaction by combining licorice extracts with antibiotic therapy in MRSA has not been institutionally implemented. Substantial in vitro evidence also exists for green tea polyphenols and other natural compounds that exhibit similar resistance-reversing potential (see Green Tea monograph). Despite current lack of clinical support in the literature, integrative practitioners encountering MRSA infection, whether hospital or community acquired, should consider empirical trials of potentially synergistic herb-drug combinations given the serious nature of these infections.

Cimetidine and Related Histamine (H_2) Receptor Antagonists

Evidence: Cimetidine (Tagamet; Tagamet HB).
Extrapolated, based on similar properties: Famotidine (Pepcid RPD, Pepcid, Pepcid AC), nizatidine (Axid, Axid AR), ranitidine (Zantac); ranitidine, bismuth, and citrate (Tritec).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:	Evidence Base:
4. Plausible	○ **Preliminary**

Effect and Mechanism of Action

Cimetidine and DGL combined are reported experimentally to exert synergistic antiulcer effects greater than either agent used alone.

Research

The efficacy of licorice derivatives in the form of DGL (Caved-S) has been compared to cimetidine in several clinical trials.[86-88] On balance, the evidence suggests that the botanical and the pharmaceutical are comparable in their ulcer-healing effects, possibly with slightly more rapid results achieved by cimetidine. Relapse rates are also no different between the two agents. A single study by Bennet et al.[89] suggested that in a rat model of aspirin-induced mucosal damage, coadministration of DGL and cimetidine resulted in greater gastroprotection than either agent given alone.

Clinical Implications and Integrative Therapeutics

The clinical significance of this possible synergy is not established, although it presents an "integrative" treatment choice that may be superior to the use of either herb or drug alternative alone.

Cortisol, Prednisolone, and Related Corticosteroids (Oral and Topical)

Evidence: Hydrocortisone oral (Cortef), methylprednisolone oral (Medrol), prednisolone oral (Delta-Cortef, Orapred, Pediapred, Prelone); topical hydrocortisone 17-butyrate/acetate/probutate/valerate (Acticort100, Aeroseb-HC, Ala-Cort, Ala-Scalp HP, Allercort, Alphaderm, Bactine, Beta-HC, Caldecort Anti-Itch, Cetacort, Cort-Dome, Cortaid, Cortef, Cortifair, Cortizone, Cortone, Cortril, Delacort, Dermacort, Dermarest, DriCort, DermiCort, Dermtex HC, Epifoam, Gly-Cort, Hi-Cor, Hydro-Tex, Hytone, LactiCare-HC, Lanacort, Lemoderm, Locoid, MyCort, Nutracort, Pandel,

Penecort, Pentacort, Proctocort, Rederm, S-T Cort, Synacort, Texacort, Westcort).

Similar properties but evidence indicating no or reduced interaction effects: Cortisone and prednisone (semisynthetic steroids with an 11-keto substitution), including prednisone oral (Deltasone, Liquid Pred, Meticorten, Orasone); triamcinolone oral (Aristocort).

Extrapolated, based on similar properties: Topical corticosteroids: Alclometasone (Aclovate, Modrasone), amcinonide (Cyclocort), beclomethasone, betamethasone dipropionate/valerate (betamethasone topical; Alphatrex, Beta-Val, Betaderm, Betanate, Betatrex, Diprolene AF, Diprolene, Diprosone, Luxiq, Maxivate, Teladar, Uticort, Valisone), clobetasol (clobetasol topical; Cormax, Dermoval, Dermotyl, Dermovate, Dermoxin, Eumosone, Lobate, Olux, Temovate, Temovate E, Topifort), clobetasone (Eumovate), clocortolone (clocortolone pivalate topical; Cloderm), desonide (DesOwen, Tridesilon), desoximetasone (Topicort, Topicort LP), desoxymethasone, dexamethasone (Aeroseb-Dex, Decaderm, Decadron, Decaspray), diflorasone (Apexicon, Florone, Maxiflor, Psorcon), diflucortolone (Nerisona, Nerisone), fluocinolone (Derma-Smoothe/FS, Fluonid, Synelar, Synemol), fluocinonide (Fluonex, Lidex, Lidex-E, Lonide, Vanos), fludroxycortide (flurandrenolone), fluocortolone (Ultralan), flurandrenolide (Cordran, Drenison), fluticasone (Cutivate), halcinonide (Halog), halobetasol (Ultravate), mometasone (Elocon, mometasone topical), triamcinolone (Aristocort, Triderm, Kenalog, Flutex, Kenonel, triamcinolone topical); combination drug: triamcinolone and nystatin (Mycolog II).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
1. Certain

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Licorice pharmacokinetically potentiates prednisone and cortisol and spares endogenous cortisol through inhibition of the enzymatic degradation by A-ring reductase and oxidoreductase enzymes. Steroid side effects may be reduced indirectly through sparing of the drug, allowing lower doses, and directly through pharmacodynamic mechanisms, including increased anti-inflammatory effects.

Research

The inhibitory effects of GL and GA on 11β-SDH isoforms, A-ring reductases, and other steroid-metabolizing enzymes are well documented (see Strategic Considerations). An interesting rodent study by Whorwood et al.[90] found that the inhibition of 11β-HSD by licorice derivatives combined with exogenous cortisol resulted in large changes in mRNA of the enzyme, indicating pretranslational inhibition significantly greater than that observed with either cortisol or GA alone. Inhibition of endogenous cortisol breakdown by GA in humans has been confirmed by Mackenzie et al.[23] in a small (n = 10) open-label study. Another small (n = 6) crossover human study examined the effect of oral pretreatment with GL (50 mg four times daily) on the pharmacokinetics of a single-dose infusion of prednisolone. The AUC of free plasma prednisolone was significantly increased and clearance significantly decreased by the GL pretretament.[91] In a skin vasoconstrictor assay, topical GA potentiated the action of hydrocortisone on human skin.[92] An unrelated study examined the effects of GA on the antiproliferative activity of glucocorticoids against breast cancer cell lines MCF-7 and ZR-75-1; GA significantly increased the degree of antiproliferative activity by the steroids.[93]

Clinical Implications and Integrative Therapeutics

The sparing effect of GL and GA on glucocorticoids is well established and follows from the same enzyme inhibition mechanisms that underlie licorice-induced pseudoaldosteronism. Unlike the latter, this potentially beneficial interaction is not generally recognized in the conventional literature. A primary area of application of the sparing effect of licorice on corticosteroids has been in the context of tapered steroid drug withdrawal.[94] Anecdotally, this is an important clinical use of the herb in botanical medicine, along with the related ability to minimize steroid daily-dose levels required for maintenance of chronic inflammatory conditions such as temporal arteritis. The inhibitory effects of GA and GL persist after cessation of administration, at least 2 to 4 weeks.[95] This partly results from a transcriptional component in the lowering of the enzyme activity, evidenced in rodent studies by reduced mRNA levels for the enzyme after GA administration.[90] A possibly relevant point in consideration of this interaction is that the semisynthetic steroids with an 11-keto substitution (e.g., cortisone, prednisone) require initial activation by reduction, which is effected through hepatic 11β-HSD (i.e., the enzyme inhibited by GL). Therefore, if coadministration is proposed, it would be preferable to use steroids that do not require enzymatic activation, such as cortisol and prednisolone.

Digoxin and Related Cardiac Glycosides

Evidence: Digoxin (Digitek, Lanoxin, Lanoxicaps, purgoxin). Extrapolated, based on similar properties: Cardiac glycosides and antiarrhythmics including deslanoside (cedilanin-D), digitoxin (Cystodigin), ouabain (g-strophanthin)

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Licorice extracts in supratherapeutic doses may induce hypokalemia, which theoretically may increase toxicity of antiarrhythmic drugs such as digitalis. Arguably, this is more an avoidable toxicity than an interaction. A single case report is available, but this fails to establish the interaction because of confounding factors.

Research

Potential hypokalemic effects consequent to licorice inhibition of renal 11β-HSD-2 are described in Strategic Considerations. A recent experimental study may have bearing on the kinetics of the licorice and digoxin combination. Ismair et al.[71] demonstrated that GL is both a substrate and inhibitor of several organic anion-transporting polypeptides (OATPs) localized in human hepatocytes, including OATP-8. Digoxin is known to be transported by OATP-8.[96] Whether and how this may affect the bioavailability of digoxin coadministered with licorice remains to be clarified.

Report

A single, well-documented report is available.[97] An 84-year-old man with a history of mitral regurgitation and atrial fibrillation was prescribed furosemide (80 mg/day) and digoxin (0.125 mg/day; plasma digoxin level of 1.0 ng/mL). The patient took a Chinese herbal laxative formula containing licorice root (400 mg) and rhubarb root (1600 mg) three times daily for 7 days. By day 7 he complained of fatigue, appetite loss, and dependent edema. On examination he had a heart rate of 30 beats per minute, blood pressure of 120/60, enlarged heart and lung congestion on radiograph, digoxin level of 2.9 ng/mL, and potassium of 2.9 mEq/L. Renin activity and aldosterone were low normal. Both the digoxin and the laxative were discontinued; 18 days later his pulse was 60 beats per minute, potassium 4.3 mEq/L, and renin and aldosterone levels midrange. Digoxin was restarted, and the plasma level was 0.6 ng/mL.

This report cannot be used to infer any direct causal support for a licorice-digoxin interaction. Furosemide, a potassium depleter, was already coadministered with digoxin in this patient. However, the case illustrates the possible risks of drug toxicity in at-risk patient populations when narrow-therapeutic-index drugs are combined with inappropriate herbal formulae added to polypharmacy. Rhubarb root (*Rheum palmatum*) is an anthraquinone-containing stimulant laxative, typically regarded as having the potential to induce electrolyte imbalance and volume depletion (both demonstrated in this case report). In this case, *three* potassium-depleting agents are involved: the furosemide, the rhubarb root, and the licorice. Finally, regarding the digoxin-licorice interaction, this patient, although bradycardic, was only mildly hypokalemic and did not display signs of more extreme digitalis intoxication, such as bigeminy, or require treatment with digoxin Fab.

Clinical Implications and Adaptations

The effects of potassium depletion on digitalis toxicity are not established. Stockley[98] reviewed data from several retrospective studies for evidence of a connection between potassium-depleting diuretics and digitalis toxicity and concluded that a link is not established beyond reasonable doubt, with several studies failing to demonstrate any connection. Nonetheless, the apparent consensus is that concurrent use of potassium-depleting diuretics with cardiac glycosides may result in digitalis intoxication. One management solution is the use of potassium-sparing diuretics, such as spironolactone or triamterene.[99] However, spironolactone interacts with licorice, as discussed later.

Complications of drug therapy in elderly patients with heart failure are common, particularly with the cardiac glycosides.[100,101] Digoxin itself causes increased renal magnesium excretion, and magnesium depletion also increases digitalis toxicity.[102] Elderly cardiac patients, especially those on polypharmacy regimens, should have their drugs regularly reviewed. Use of cardiac glycosides with potassium-depleting agents should ideally be accompanied by monitoring of drug and electrolyte levels, and where appropriate, patients should be supplemented with both potassium and magnesium.

Cases of licorice root–induced hypokalemia have been described only after self-administration of licorice-containing products by consumers. No reports support an interaction between licorice and digitalis. Hypokalemia resulting from therapeutic-dose levels of licorice is unlikely in clinical practice. The licorice–cardiac glycoside combination is better regarded as a contraindication because of additive adverse effects, and unless compelling reasons exist for coadministration, it should be avoided. Notably, this warning would not apply to the use of DGL.

Potassium-Depleting Diuretics: Loop and Thiazide Diuretics

Evidence: Furosemide (Lasix).

Extrapolated, based on similar properties:

Loop diuretics: Bumetanide (Bumex), ethacrynic acid (Edecrin), torsemide (Demadex).

Thiazide diuretics: Bendroflumethiazide (bendrofluazide; Naturetin), benzthiazide (Exna), chlorothiazide (Diuril), chlorthalidone (Hygroton), cyclopenthiazide (Navidrex), hydrochlorothiazide (Aquazide, Esidrix, Ezide, Hydrocot, HydroDiuril, Microzide, Oretic); hydroflumethiazide (Diucardin), methyclothiazide (Enduron), metolazone (Zaroxolyn, Mykrox), polythiazide (Renese), quinethazone (Hydromox), trichlormethiazide (Naqua).

Related but evidence lacking for extrapolation: Combination drugs: bendrofluazide and propranolol (Inderex); cyclopenthiazide and oxprenolol (Trasidrex); hydrochlorothiazide and amiloride (Moduretic); hydrochlorothiazide and captopril (Acezide, Capto-Co, Captozide, Co-Zidocapt); hydrochlorothiazide and enalapril (Vaseretic); hydrochlorothiazide and lisinopril (Prinzide, Zestoretic); hydrochlorothiazide and losartan (Hyzaar); hydrochlorothiazide and metoprolol (Lopressor HCT); hydrochlorothiazide and amiloride (Moduretic); hydrochlorothiazide and enalapril (Vaseretic); hydrochlorothiazide and lisinopril (Prinzide, Zestoretic); hydrochlorothiazide and spironolactone (Aldactazide); hydrochlorothiazide and triamterene (Dyazide, Maxzide).

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

◈ **Adverse Drug Effect on Herbal Therapeutics, Strategic Concern**

Probability:
2. Probable

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Inhibition of renal 11β-HSD-2 by licorice may induce hypokalemia, especially at excessive doses administered for chronic periods. In combination with potassium-depleting diuretics such as furosemide, additive hypokalemic toxicity results. Myopathy and acute renal failure resulting from rhabdomyolysis and myoglobinuria have been recorded in settings of consumer self-administration of licorice.

Research

The pseudoaldosterone effects of licorice have been documented for more than 50 years in the medical literature (see Strategic Considerations). Potential adverse renal and muscular sequelae have been reviewed.[95] Importantly, furosemide, as with GL and GA, inhibits renal 11β-HSD-2 directly, thus sharing (at least in part) the same mechanism of potassium depletion.[47]

Reports

Shintani et al.[103] reviewed 57 published case reports of glycyrrhizin-induced hypokalemic myopathy in the literature from the 1960s to 1980s. Two salient features emerged from their review.

First, the reports appeared linked to different historical "fashions" of licorice consumption by the public. Initially, cases in the 1950s were from England and Australia related to PAS in the treatment of tuberculosis. In the 1960s, case reports predominantly originated from France and were associated with excessive consumption of a licorice-flavored alcoholic beverage, "Boisson de Coco." From the 1970s on, the emphasis shifted to Chinese herbal medicines and various commercial products for gastrointestinal complaints, including antiulcer medications and laxatives; more recently, a variety of licorice-flavored products (e.g., chewing tobacco) as well as licorice confectionary (e.g., "pontefract cakes") have been implicated. Notably, the cases reviewed were associated with self-administration of licorice compounds, often at supratherapeutic doses, and often for extended periods.

Second, the overwhelming associated factor in the reports of licorice-induced hypokalemia was the concurrent use of potassium-depleting diuretics. Also, the majority of patients belonged to the older-age demographic of 60 to 89 years.[103]

Another effect of prolonged hypokalemia is rhabdomyolysis. Chandler[95] analyzed three available case reports linking glomerulopathy, tubulopathy, and acute renal failure to myoglobinemia resulting from rhabdomyolysis induced by licorice consumption. In all three cases, furosemide was in concurrent use and regarded as a contributing factor in the renal reactions. Recent reports of hypokalemic myopathy or renal complications are extremely rare. Chubachi et al.[104] reported a case of renal failure associated with both furosemide and licorice ingestion. Elinav and Chajek-Shaul[105] reported an unusual case of licorice-induced myopathy related to use of licorice as a sweetener and not associated with furosemide.

Clinical Implications and Adaptations

No therapeutic rationale exists for coadministration of licorice root extracts with potassium-depleting diuretics. The potential additive hypokalemic effects amount to a contraindication for the combination, particularly in vulnerable demographics such as older cardiac patients. The availability of the potassium-sparing diuretics, together with the licorice derivative DGL, which lacks the mineralocorticoid effects of the parent herb for use in peptic ulcer treatment, provides alternative management strategies. Patients prescribed potassium-depleting agents should be warned of the possible risks of unwitting consumption of licorice as an ingredient of commercial products.

Spironolactone

Evidence: Spironolactone (Aldactone).
Extrapolated, based on similar properties: combination drug: spironolactone and hydrochlorothiazide (Aldactazide).

Interaction Type and Significance

? Interaction Likely but Uncertain Occurrence and Unclear Implications

Probability: **2. Probable**

Evidence Base: **○ Preliminary**

Effect and Mechanism of Action

Spironolactone is classified as a potassium-sparing diuretic but is a competitive inhibitor of aldosterone at the mineralocorticoid receptor, used clinically to oppose hypokalemia. Experimental evidence suggests spironolactone appears to normalize licorice-induced hypertension by restoring endothelial-dependent vascular relaxation function. The clinical significance of this is not established.

Research

Quaschning et al.[106,107] investigated renovascular hemodynamics in a rodent model of hypertension. Rats were fed GA for 21 days to induce hypertension through 11β-HSD-2 inhibition by the licorice derivative. The resulting hypertension was causally related to the renovascular nitric oxide (NO) system as well as mineralocorticoid receptor–mediated effects. The GA administration reduced endothelial NO synthase (eNOS) and endothelin-1 levels, which were restored by spironolactone. There is emerging evidence that 11β-HSD activity may be depressed in essential hypertension.[108]

Clinical Implications and Adaptations

The reversal of GA-induced hypertension by spironolactone suggests a therapeutic potential for treatment of 11β-HSD deficiency–related cardiac disease. However, the implications of the interaction are unclear, given that coadministration of licorice and spironolactone would generally be avoided because of their opposing effects on kaliuresis.

Nitrofurantoin and Related Nitrofuran Antibiotics

Evidence: Nitrofurantoin (Furadantin, Macrobid, Macrodantin).
Extrapolated, based on similar properties: Nitrofuran antibiotics: Furazolidone (Furasian, Furoxone), furaltadone, nitrofurazone (Actin-N, Furacin).

Interaction Type and Significance

○ Prevention or Reduction of Drug Adverse Effect

Probability: **4. Plausible**

Evidence Base: **○ Preliminary**

Effect and Mechanism of Action

The urinary antibiotic nitrofurantoin is associated with pronounced adverse effects. It has been suggested that coadministration with DGL reduces nausea and vomiting. The mechanism is not established but is probably related to the established gastroprotective effects of DGL.

Research

The nitrofurans were important urinary antiseptics, particularly for treatment of infection by *Escherichia coli* and other enterococci in the 1970s and 1980s. Despite concentration by the renal tubules and localization in the bladder, nitrofurantoin is associated with pronounced systemic adverse effects, including nausea and vomiting, and possible serious pulmonary fibrosis. Two studies performed more than 25 years ago suggested that coadministration with DGL led to increased clearance and a reduction in nausea and vomiting, together with improved effects on pyelonephritis.[109,110]

Clinical Implications and Adaptations

Nitrofuran treatment of urinary tract infection is less common now, partly because of the resistance of many strains of bacteria to the drug and its poor adverse effects profile. Fluoroquinolones (e.g., ciprofloxacin) have a superior oral bioavailability and fewer adverse effects and are now the preferred agents. The apparently beneficial DGL-nitrofurantoin interaction was established at the time of widespread prescription of the drug and is likely to receive minimal further investigation. However, a number of drugs

with pronounced gastroirritant properties may be better tolerated with coadministration by DGL.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Cyclophosphamide

Cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox).

A single animal study examined the effects of several herbal preparations, including licorice, coadministered with cyclophosphamide on mice inoculated with Lewis lung carcinoma and found reduction in tumorigenesis and metastasis compared with cyclophosphamide alone, although quantitative and statistical details were not available.[111] Suggestions of a synergistic interaction with cyclophosphamide or related antineoplastic chemotherapy have not been made to date and would be premature.

Insulin

Animal-source insulin (Iletin); human analog insulin (Humanlog); human insulin (Humulin, Novolin, Novo-Rapid, Oralin).

A human study suggested that carbenoxolone may improve insulin sensitivity in healthy individuals.[112] Another study, however, indicated coadministration of parenteral (SNMC) licorice with insulin in diabetic patients led to hypokalemia, sodium retention, and suppression of the renin-angiotensin axis, which the authors claimed was not caused by the pseudoaldosterone effects of SNMC because of normal urinary potassium levels.[113] The implications of these two studies are unclear but insufficient to support the claim of an insulin-licorice interaction.

Interferon and Related Antiviral Immunotherapy

Interferon alpha (Alferon N, Intron A, Roferon-A); combination drug: interferon alpha-2b and ribavirin (Rebetron).

Licorice is an established component of botanical medical treatment of viral hepatitis B and C, and GA has demonstrated potent antiviral activity against SARS.[2,3] In vitro evidence suggests that GL and GA can increase endogenous interferon production by lymphocytes and macrophages in response to concanavalin A.[114] A human study with hepatitis patients using SNMC (parenteral GA) in combination with interferon demonstrated a significant effect on normalization of alanine transaminase (ALT) compared with interferon alone.[115] Related experimental data support a possible role for licorice in stimulation of interferon production and efficacy against viral hepatitis.[116-118] Although the data suggest a possible interaction between licorice and recombinant interferon immunotherapies, this remains speculative pending further studies, particularly with oral rather than parenteral preparations.

Laxatives

Two reports indicated hypokalemia after use of licorice-containing laxatives.[97,119] Both preparations included anthraquinone-containing laxative herbs, which are also associated with potential electrolyte disturbances, especially when abused. Harada et al.[97] reported concurrent administration with a potassium-depleting diuretic (see licorice-furosemide interaction under Digoxin). Generic cautions about laxative use interactions with licorice are overstated.

Monoamine Oxidase (MAO) Inhibitors

MAO-A inhibitors: Isocarboxazid (Marplan), moclobemide (Aurorix, Manerix), phenelzine (Nardil), procarbazine (Matulane), tranylcypromine (Parnate).

MAO-B inhibitors: Selegiline (deprenyl, L-deprenil, L-deprenyl; Atapryl, Carbex, Eldepryl, Jumex, Movergan, Selpak); pargyline (Eutonyl), rasagiline (Azilect).

An in vitro study demonstrated that the licorice isoflavone isoliquiritigenin from *G. uralensis* exhibited MAO-inhibition activity (IC_{50} = 17.3 millimolar).[120] Hatano recorded moderate in vitro MAO-inhibiting activity by a number of licorice compounds, including coumarins such as licocoumarone. The in vivo significance of these studies is unclear, and suggestions of potential interactions between licorice root and MAO inhibitors or biogenic amines is unsupported by clinical reports or pharmacological data. Recently, however, licorice isoflavonoids were shown to inhibit serotonin reuptake in vitro.[121]

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCep 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).

Suggestions of potential interactions between licorice and oral contraceptives (OCs) have been made speculatively. Pharmaceutical drug induction of UGT1A and CYP3A4 (e.g., by griseofulvin, rifampin) has been documented to lead to increased clearance of ethinyl estriol and progestins, with potential breakthrough bleeding and loss of clinical efficacy. Evidence for UGT and CYP3A4 induction by licorice is confined to murine and in vitro models at this time. Healthy volunteers consuming 9 g licorice/day for 4 weeks exhibited no changes in androgens or DHEAS.[64] Additionally, biphasic dose-related phytoestrogenic effects have been observed with licorice isoflavones, and GL inhibition of 17β-hydroxylase and modulation of sex steroid–binding globulin contribute to the difficulty of extrapolating from the complex pharmacological data to an in vivo interaction. Until clinical reports are available, the potential interaction with OCs should be classified as speculative.

Oral Vitamin K Antagonist Anticoagulants

Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar), warfarin (Coumadin, Marevan, Warfilone).

A licorice coumarin derivative was demonstrated in vitro to have antiplatelet activity, mediated through cyclic adenosine monophosphate, and GL has been shown to have in vitro antithrombin properties.[122,123] Currently, no support exists for interactions between licorice and anticoagulant drugs, and clinical reports are unavailable.

The 123 citations for this monograph are located under Licorice on the CD at the back of the book.

Milk Thistle

Botanical Name: *Silybum marianum* (L.) Gaertner.
Pharmacopoeial Name: Fructus silybi mariae.
Synonyms: *Carduus marianus* L., *Cnicus marianus* L., *Cnicus benedictus* L.
Common Names: Milk thistle, St. Mary's thistle, holy thistle, wild artichoke.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Cisplatin Platinum chemotherapy Alkylating agents ⊕⊕/☼	Silymarin reduces drug-induced nephrotoxicity by countering lipid peroxidation and cell membrane destabilization. Silymarin may additively increase anticancer effects of platinum compounds.	Coadminister during and after platinum chemotherapy. May be restorative retroactively.
Doxorubicin Anthracycline chemotherapy ⊕⊕/☼	Drug cardiotoxicity reduced by silymarin. Possible chemosensitization of resistant cells to anthracyclines. Drug transporter inhibition may be involved.	Coadminister silymarin as adjunctive to support protocols during and after anthracycline chemotherapy.
Hepatotoxic substances; various agents and classes ⊕⊕⊕/☼	General drug-induced hepatotoxicity countered by silymarin coadministration through multiple mechanisms, including free-radical scavenging, reduced lipid peroxidation, membrane stabilization, and cirrhosis/fibrosis inhibition. Demonstrated for numerous drugs and xenobiotic toxins. Wide clinical significance probable.	Coadminister especially in hepatically compromised patients requiring drugs that stress liver function.
Insulin ⊕	Silymarin normalizes glycemic control, maintains islet integrity, reduces insulin requirement. May protect against diabetic sequelae, especially in cirrhotic patients.	Coadminister, long term.
Metronidazole Nitroimidazole antiprotozoals ◈◈/⊕✗/☼	Coadministration of herb with drug may reduce drug availability by induction of drug-metabolizing enzymes.	Avoid coadministration. Preexisting herb use may require higher drug dose for therapeutic efficacy.

HERB DESCRIPTION

Family

Asteraceae.

Related species

Silybum eburneum Coss and Dur.

Habitat and Cultivation

Originally a Mediterranean native, milk thistle is now naturalized in many parts of Europe and North America, in drier sunny soils. Considered an invasive weed in some areas, it is widely cultivated for commercial use.

Parts Used

Fruit, typically described as milk thistle seed.

Common Forms

Powdered or whole dried hulled seed.
Tincture, Fluid Extract: 50% ethanol.
Standardized Extract: Solid concentrate 70:1, standardized to 70% to 80% silymarin (as silibinin).

HERB IN CLINICAL PRACTICE

Overview

Long known as a liver remedy in European and American botanical medicine, milk thistle is now well documented as a hepatoprotective herb and is used as an antidote to liver intoxication with chemical and biological toxins, including alcohol and a range of hepatotoxic drugs. After German researchers identified the flavolignan complex "silymarin" as the active component of the ripe seeds in the late 1960s, silymarin became available as a purified concentrate, and pharmacological research focused on the effects of silymarin on the liver. Silymarin was found to have antioxidant properties and was able to reverse glutathione depletion; it stabilized cell membranes and modulated efflux pumps such as P-glycoprotein (P-gp); it promoted hepatic ribosomal ribonucleic acid (rRNA) synthesis and liver regeneration; and it exerted anticirrhotic effects through inhibition of the transformation of stellate hepatocytes into fibroblasts. Several controlled clinical trials have found silymarin increases survival in alcohol-induced cirrhosis. It is widely prescribed for these indications, particularly in Germany.

The herb is well tolerated, with negligible toxicity and an excellent safety record. In the United States the herb typically ranks just under the "top 10" in retail sales. The German Commission E approved the whole herb for dyspeptic complaints and separately approved silymarin isolates for toxic liver damage and supportively for chronic inflammatory liver disease and hepatic cirrhosis.[1] The World Health Organization (WHO) monograph approves the herb for supportive treatment of acute and chronic hepatitis and cirrhosis induced by alcohol, drugs, or toxins.[2] A survey in 1998 showed that milk thistle was the most common hepatoprotectant used by outpatients in gastroenterological clinics.[3] A recent Cochrane systematic review of 13 trials of milk thistle extracts for alcoholic or hepatitis B/C virus–related liver disease found that liver-related mortality across all trials was significantly reduced. However, the methodological quality of the trials was poor,

and the highest-quality data did not support the efficacy of the herb by criteria of overall mortality, liver histology, or liver-related complications.[4] Recent research has focused more on the anticancer effects of silymarin, but at present, despite promising basic science results with silymarin, clinical trial evidence in the oncological setting is lacking.[5]

It is important to distinguish among milk thistle seed extracts (whole herb), the flavolignan complex or "silymarin" present in small quantities in the whole herb but available as a concentrated solid extract, and *silybin* (also called silibinin), the predominant component among the flavolignan constituents, used as a reference for standardization. Most preclinical and clinical trials have used silymarin concentrate (see Key Constituents).

Historical/Ethnomedicine Precedent

Dioscorides mentions milk thistle use for snakebite, and the herb and seeds were used in Europe in the Middle Ages for liver conditions. The leaves have been used as a food, according to Culpeper, especially as a cleansing spring vegetable when well cooked, and were also considered to enhance milk production in nursing mothers. The ethanolic seed extract, which included the husks, was first promoted in the United States by Rademacher in 1841. The homeopathic physicians in the U.S. were enthusiastic about the remedy, which was included in the U.S. *Homeopathic Pharmacopeia* in 1878, where it is indicated for melancholy as well as varicose ulcers, among other uses. The Eclectic physician Ellingwood used the extract for hepatic indications closer to contemporary use, although other Eclectics viewed the seeds extracts as an "alterative." Brinker[6] provides a comprehensive historical review of the migration of the herb into American botanical medicine.

Known or Potential Therapeutic Uses

Amanita mushroom poisoning, amenorrhea, chemotherapy adjunctive, cholestasis, cirrhosis, constipation, diabetic complications, dyspepsia, fatty liver, gallstones, hepatitis (drug, alcohol, or chemical induced), hepatoprotection, protective against skin cancer (phototherapy, ultraviolet B, or radiation induced), right-upper-quadrant pain (associated with jaundice, hepatomegaly, or gallstones), uterine hemorrhage, varicose veins, venous congestion/stasis.

Key Constituents

1.5% to 3.0% silymarin, a flavolignan complex of silybin and isosilybin (its stereoisomer), silychristin, and silydianin. Silybin is also called silibinin. Other flavolignans are present, but silibinin is the primary compound.
Flavonoids: Quercetin, taxifolin, and dehydrokaempferol.
Lipids: 20% to 30% of the fruit is a lipid fraction, including linoleic acid and beta-sitosterol. Silymarin concentrates do not incorporate the broad spectrum of ingredient compounds, including the lipid fraction.

Therapeutic Dosing Range

Dried seed by infusion or decoction: Up to 15 g per day.
Tincture/Fluid Extract: Up to 8.5 mL 1:1 per day.
Standardized Extract: Concentrated 200 to 800 mg 70% to 80% silymarin per day. Clinical trial doses have typically been 420 mg/day in divided dose. The most common proprietary form is a 140 mg per dose 36:1 to 44:1 extract (from an ethyl acetate extraction), known as Thisilyn in the United States or Legalon in Europe, standardized to approximately 80% silymarin as silibinin. Bioavailability of oral silymarin is very low, and preparations complexed with lipids such as phosphatidylcholine have been developed.

INTERACTIONS REVIEW

Strategic Considerations

Therapeutic monographs for milk thistle are notable for an absence of established interactions with drugs. Herbalists regard the seeds as among the more benign, neutral, nontoxic foodlike botanicals in the materia medica; this is supported by the clinical trial data, which report negligible adverse effects, other than minimal incidence of mild gastric discomfort.[4] Toxicity studies corroborate this, with median lethal dose (LD_{50}) tests failing to produce mortality at oral doses of 20 g/kg in rodents.

In practice, the herb is used to ameliorate the adverse effects of xenobiotics, including pharmaceuticals, particularly on the liver. These beneficial effects of milk thistle were first discovered through its ability to antidote to *Amanita* mushroom intoxication.[7] Subsequently, similar hepatoprotective effects were established for a wide range of industrial chemicals and poisons, including carbon tetrachloride (CCl_4), tyramine beta-hydroxylase (TBH), and heavy metals.[8-15] The mechanisms underlying these effects are multifactorial; they include antioxidant activity through free-radical scavenging, prevention of glutathione depletion and enhancement of superoxide dismutase (SOD) activity, prevention of lipid peroxidation, stabilization of hepatocyte cell membranes, stimulation of liver regeneration, promotion of hepatocyte protein and glycoprotein synthesis, and antifibrotic effects from prevention of collagen formation by stellate hepatocytes. Silymarin also chelates metals such as lead and thallium, exhibits anti-inflammatory effects (by lipoxygenase inhibition and other mechanisms), and has chemopreventive influences through its inhibition of intestinal beta-glucuronidase, modulation of carcinogen-metabolizing enzymes, and signal transduction effects (notably epidermal growth factor receptor [EGFR] inhibition) and kinase inhibition. Recent research on the pharmacology of silymarin has been reviewed.[16-22]

The multiple mechanisms underlying the hepatoprotective properties of milk thistle seed connect a number of documented beneficial interactions between silymarin and hepatotoxic drugs. These are considered here as thematically related and are described later.

Effects on Drug Metabolism and Bioavailability

In vitro, silymarin has been shown to have some modulating effects on phase I and phase II drug-metabolizing enzymes, but the relevance of the limited available data is unclear. The few in vivo studies that have been performed suggest that clinically significant modulation of drug availability by silymarin on cytochrome P450 (CYP450) is *unlikely*. For example, the disposition of indinavir (a well-known substrate of both CYP3A4 and P-gp) is unaffected by milk thistle coadministration in healthy volunteers despite in vitro evidence of CYP3A4 and P-gp inhibition by silymarin.[23,24] Effects on phase II drug conjugation through induction of glutathione-*S*-transferase and inhibition of beta-glucuronidase (affecting conjugated drug–glucuronides subject to enterohepatic recycling) are also possible.[25,26] Effects on phase III (transporter proteins) may be significant, although at present this is extrapolated from in vitro data.

A universal problem, discussed throughout this text, is the issue of validity of such extrapolations, especially from nonphysiological concentrations used in vitro to in vivo clinical practice. This is particularly acute with silymarin, which has very low bioavailability and may only attain nanogram levels in the plasma after oral administration.[27] Weyhenmeyer et al.[28] found that at high oral doses (1270 mg silymarin per day, or approximately two to three times the normal therapeutic dose), peak plasma concentration of silibinin isomers in healthy volunteers was only 2.0 μg/mL. Preparations that complex silymarin with phosphatidylcholine (or lecithin) have superior bioavailability.[29–31]

In vitro CYP450 modulation data can be summarized as follows: Beckmann-Knopp et al.[32] found no significant effect on 2E1, 2C19, 1A2, or 2A6 but significant inhibition of 3A4 and 2C9 (at IC_{50} of 29–45 micromolar [μM]) with human liver microsomes and silibinin. Budzinski et al.[33] used dilutions of milk thistle whole-seed extract and found no significant effect on 3A4 using fluorometric assays with recombinant human enzymes. Venkataramanan et al.[34] used human hepatocytes and determined that 0.25 millimolar (a very high concentration) silymarin effected 100% inhibition of 3A4 and uridine glucuronosyltransferase (UGT1A). Zuber et al.[35] found that all three flavolignan components of silymarin exhibited dose-dependent competitive inhibition of 2D6, 2E1, and 3A4; however, doses were in excess of physiological levels in vivo, and interactions caused by enzyme inhibition were unlikely. Raucy[36] found that silymarin caused no significant changes in CYP3A4 messenger ribonucleic acid (mRNA) levels of human hepatocytes, suggesting that silymarin did not induce 3A4. Patel et al.[37] found a similar lack of effect on CYP3A4 mRNA and MDR1 mRNA in a CaCo-2 cell-line model. Sridar et al.[38] used recombinant enzymes and established that purified silibinin could effect a dose-dependent inhibition in vitro of 3A4 and 2C9. The potassium iodide (KI) values for 3A4 (166 μM) were not comparable to in vivo levels, although the lower value of 5.0 μM for 2C9 may be more clinically significant. Another rodent model was used to examine the effects of silymarin on drug-induced increases in 2E1 following chronic exposure to three 2E1 inducers. When the drugs were coadministered (for 12 weeks) with 50 mg/kg silymarin orally, 2E1 levels were not elevated.[39]

Extrapolation from data that employ different milk thistle preparations or compounds (silibinin, silymarin, whole-seed extract) in a range of experimental models at widely varying concentrations is problematic. The significance of the lack of effect on in vivo indinavir pharmacokinetics has already been noted.[23,24] This suggests that CYP3A4 is not inhibited in vivo despite the in vitro inhibition data. In fact, a small clinical trial by Rajnarayana et al.[40] suggested that silymarin pretreatment for 9 days at 140 mg/day significantly *increased* the clearance of 3A4/2C9 cosubstrate metronidazole, suggesting an in vivo *induction* effect. In a clinical study, Gurley et al.[41] examined the effects of herbal compounds on CYP450 in healthy volunteers by means of probe cocktails administered after 28 days of pretreatment with each botanical. Milk thistle was administered at 175 mg, standardized to 80% silymarin, twice daily. No significant changes were found in 1A2, 2D6, 2E1, or 3A4. The authors concluded that pharmacokinetic interactions with prescription pharmaceuticals were unlikely. Van Erp et al.[42] examined the effects milk thistle on the pharmacokinetics of irinotecan in six cancer patients. Irinotecan is a known substrate of CYP3A4 and UGT1A1. The administration of milk thistle (for 4 or 12 days) did not produce any significant change in irinotecan disposition.

The principal drug-metabolizing enzymes of phase II drug transformation are the uridine-5′-diphosphate glucuronosyltransferases (UGTs). This family of enzymes is primarily hepatic but is also distributed intestinally; it plays a key part in first-pass metabolism of drugs. Glucuronide conjugates are eliminated in the bile and, when hydrolyzed by beta-glucuronidase, undergo enterohepatic recirculation while the glucuronic acid recycles for use in further conjugation. There is in vitro evidence for silymarin-induced inhibition of UGT enzyme inhibition in a recombinant human enzyme model.[34,38] However, a study with rodent hepatocyte model and in vivo liver models showed that UGT inhibition induced by galactosamine might be reversed by silymarin.[43] Some inhibitory effects have also been found on the glutathione-*S*-transferases (GSTs), also involved with phase II metabolism, in the rodent hepatocyte model.[44] These GST inhibition effects have not been identified in vivo, where the main action of silymarin is on the prevention of thiol depletion and promotion of thiol replenishment, particularly in conjunction with cysteine donors.[45] On balance, induction of GST seems probable, and enzyme increase has been demonstrated in rodent liver, lung, stomach, skin, and small bowel after systemic administration of silibinin at 50 mg/kg orally.[26] These authors suggest that phase II enzyme induction may underlie the chemopreventive properties of silymarin, as demonstrated especially with skin cancers.[18,46,47]

Several herbal agents are now known to modulate drug transporters (phase III) at transcriptional and posttranscriptional levels.[48] Experimental data suggest that milk thistle flavolignans inhibit P-gp. This has been shown using the standard Caco-2 model in vitro, with drugs that are substrates of P-gp, such as digoxin, doxorubicin, vinblastine, and ritonavir.[37,49,50] Nguyen et al.[51] used a pancreatic cell-line (Panc-1) that overexpresses the MRP-1 transporter protein to examine the effects of flavonoids on the accumulation of transporter substrates daunorubicin and vinblastine. Silymarin significantly inhibited transport of these drugs. Because of the interest in potential modulators of drug resistance in cancer therapy, structure/function studies have examined the effects of different compounds on transporter proteins. Semisynthetic derivatives of silibinin have been tested to be even more effective P-gp inhibitors than the natural parent compound.[52–54] Combinations of flavonoid molecules in a "cocktail" from different botanicals, including silymarin sources, appear to have additive effects on inhibition of resistance to mitoxantrone in an MCF-7 in vitro model.[55] Once again, in vitro and in vivo data appear to be in conflict. For example, Gurley et al.[56] found that milk thistle supplementation for 2 weeks in healthy volunteers had no significant effect on any pharmacokinetic parameters of digoxin compared with rifampin and clarithromycin, used as positive controls for P-gp induction and inhibition, respectively.

In summary, in vivo pharmacokinetic interactions caused by milk thistle seem improbable, despite suggestions from in vitro studies. The case of metronidazole is a possible exception, as discussed later.

HERB-DRUG INTERACTIONS

Cisplatin and Related Platinum-Based Chemotherapy

Evidence: Carboplatin (Paraplatin), cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ).
Extrapolated, based on similar properties: Oxaliplatin (Eloxatin).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Silymarin (pretreatment or coadministration) reduces the nephrotoxicity of cisplatin and carboplatin without reducing and possibly increasing the antitumor effects of these agents in certain malignancies.

Research

Rodent studies using parenteral silibinin pretreatment have demonstrated protective effects against a nephrotoxic dose of cisplatin. Bokemeyer et al.[57] established that pretreatment with pure silibinin by infusion before cisplatin treatment significantly reduced nephrotoxicity, as measured by excretion of brush border enzymes and magnesium. Silibinin alone had no effect on renal function. The authors then used a human testicular cancer cell line to establish that silibinin did not lower the cytotoxicity of either cisplatin or ifosfamide. A similar model was used by Gaedeke et al.,[58] who employed a single-dose pretreatment of silibinin (200 mg/kg intravenously) 1 hour before a single dose of cisplatin. The silibinin pretreatment completely prevented any decrease in creatine clearance or proteinuria, and enzymuria and magnesium wasting were significantly reduced. The nephroprotective effect was correlated with histological findings of decreased tubular morphology changes.

Karimi et al.[59] found that both silymarin and a methanoic extract of milk thistle seeds could provide protection against tubular damage induced by cisplatin. Pretreatment was more effective than administering the milk thistle or silymarin 2 hours after cisplatin. Doses of silymarin were lower in this study (50 mg/kg).

In addition to protection against platinum-induced renal damage, a synergistic effect between silibinin and platinum compounds has been reported in which drug cytotoxicity was increased or potentiated by the flavolignan compound. Apoptosis in MCF-7 cells was increased by a combination of carboplatin and silibinin (but not by cisplatin and silibinin).[60] Silibinin and cisplatin exerted dose-dependent synergistic effects on platinum-resistant ovarian cancer cell lines at low concentrations of 0.1 to 20 μM.[61] Giacomelli et al.[62] performed in vitro experiments that showed silibinin alone had no activity against a human ovarian cancer line, A2780, but that it produced a dose-dependent increase in the cytotoxicity of cisplatin against these cells at 1-μM and 10-μM levels. In vivo, tumors induced in rodents by xenografts of the same cell line were treated by cisplatin alone and in combination with silibinin (450 mg/kg orally) in the form of a phosphatidylcholine-complexed preparation, IdB 1016; the combination therapy produced a statistically significant increase in treatment efficacy, as measured by tumor size. Interestingly, the combination-treatment groups recovered more rapidly from cisplatin treatment, as measured by body weight, than the cisplatin-only group. Finally, the researchers found a statistically significant in vivo antiangiogenic effect of the combination on the xenografted animals. Silibinin doses used in this experiment were considerably higher than therapeutic equivalents in humans.[62]

Dhanalakshmi et al.[63] used a prostate cancer cell-line model to examine the effects of silibinin combined with carboplatin or cisplatin on cell growth and apoptosis. At 50- to 100-μg additions of silibinin in combination with the platinum drugs, significant increases in cell growth inhibition were found. The mechanisms included increased apoptosis for both platinum agents, increased G2–cell cycle arrest for cisplatin, and complete S-phase arrest for carboplatin.[63]

Integrative Therapeutics, Clinical Concerns, and Adaptations

The purely experimental data are supportive of nephroprotective effects of silymarin or silibinin when coadministered with platinum compounds. Because tubular damage can be a dose-limiting toxicity of platinum chemotherapy, this is a potentially valuable beneficial interaction, although it remains to be clinically demonstrated. The data also suggest that silibinin may sensitize certain malignancies to platinum treatment; this may have importance in ovarian cancer, for which platinum is a common treatment. The observed sensitization effects of silibinin and platinum on prostate cell lines may simply be additive, not synergistic, because independent activity of silymarin against prostate lines has been demonstrated by several studies.[17,64-69]

Pharmacokinetic and pharmacodynamic studies are needed to determine the clinical significance of all these effects, particularly because the dose levels of silymarin/silibinin used experimentally are relatively high, and the preparation typically employed was pure silibinin. There may also be important differences among malignancies in terms of chemosensitization effects induced by silibinin.

Doxorubicin and Related Anthracycline Chemotherapy

Evidence: Doxorubicin (Adriamycin, Rubex).
Extrapolated, based on similar properties: Daunorubicin (Cerubidine), epirubicin (Ellence, Pharmorubicin), idarubicin (Idamycin, Zavedos), mitoxantrone (Novantrone, Onkotrone).
Similar properties but evidence lacking for extrapolation: Daunorubicin, liposomal (DaunoXome); Doxorubicin, pegylated liposomal (Caelyx, Doxil, Myocet).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Milk thistle or silymarin may reduce adverse effects of anthracyclines through reduction of lipid peroxidation and membrane stabilization. The herb may also sensitize drug-resistant cells by inhibition of P-gp to increase drug cytotoxicity.

Research

In a rat cardiomyocyte model, co-incubation of silymarin (and component flavolignans) with doxorubicin resulted in dose-dependent reductions in cardiotoxicity, with silydianin exerting the most significant effects.[70] Psotova et al.[71] demonstrated that the protective effects of silymarin flavolignans against doxorubicin-induced rat cardiomyocyte mitochondrial and microsomal damage were related to free-radical scavenging rather than iron chelation. Tyagi et al.[60,72] have demonstrated additive cytotoxic effects against a prostate cancer cell

line when doxorubicin and silibinin are coadministered. P-glycoprotein inhibition may play a part in the sensitization of anthracycline-resistant cells because silymarin has been demonstrated to be an inhibitor of the efflux pump. This is supported by the work of Zhang and Morris,[49] who used MCF-7 cells to demonstrate the effects of silymarin co-incubation on increasing intracellular daunorubicin and doxorubicin accumulation. In a pancreatic cancer model, intracellular daunorubicin accumulation was also significantly increased by silymarin.[51]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Direct support for the cardioprotective effects of silymarin is limited. However, given the general protective effects of the herb against parenchymal damage to hepatic, renal, and pancreatic tissue, there would seem to be circumstantial support for including silymarin in protective protocols during and after anthracycline chemotherapy administration. Currently, evidence for possible modulation of resistance to anthracycline chemotherapeutic drugs is preliminary, but the underlying mechanics have been established as inhibition of P-gp. Clinical studies are required to establish the significance of this potentially useful interaction.

Hepatotoxic Substances, Including Acetaminophen, Acetylsalicylic Acid, Antitubercular Agents, Butyrophenone and Phenothiazine Neuroleptics, Ethyl Alcohol, Halothane, Methandienone, Methotrexate, Nortriptyline, and Phenytoin

Evidence: Acetaminophen (APAP, paracetamol; Tylenol); acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); amitriptyline (Elavil).

Antitubercular agents: Isoniazid (isonicotinic acid hydrazide; INH, Laniazid, Nydrazid), pyrazinamide (PZA; Tebrazid), rifampicin (Rifadin, Rifadin IV); combination drugs: isoniazid and rifampicin (Rifamate, Rimactane); isoniazid, pyrazinamide, and rifampicin (Rifater); chlorpromazine (Largactil, Thorazine); ethyl alcohol; halothane (Fluothane); methandienone, methandrostenolone (Dianabol); methotrexate (Folex, Maxtrex, Rheumatrex); nortriptyline (Aventyl, Pamelor); phenytoin (diphenylhydantoin; Dilantin, Phenytek).

Extrapolated, based on similar properties: See table for classes.

Acetaminophen combination drugs: Acetaminophen and codeine (Capital with Codeine; Phenaphen with Codeine; Tylenol with Codeine); acetaminophen and hydrocodone (Anexsia, Anodynos-DHC, Co-Gesic, Dolacet, DuoCet, Hydrocet, Hydrogesic, Hy-Phen, Lorcet 10/650, Lorcet-HD, Lorcet Plus, Lortab, Margesic H, Medipain 5, Norco, Stagesic, T-Gesic, Vicodin, Vicodin ES, Vicodin HP, Zydone); acetaminophen and oxycodone (Endocet, Percocet 2.5/325, Percocet 5/325, Percocet 7.5/500, Percocet 10/650, Roxicet 5/500, Roxilox, Tylox); acetaminophen and pentazocine (Talacen); acetaminophen and propoxyphene (Darvocet-N, Darvocet-N 100, Pronap-100, Propacet 100, Propoxacet-N, Wygesic).

Acetylsalicylic acid/aspirin combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Anticonvulsant medications: Carbamazepine (Carbatrol, Tegretol), clonazepam (Klonopin), clorazepate (Tranxene), divalproex semisodium, divalproex sodium (Depakote), ethosuximide (Zarontin), ethotoin (Peganone), felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), levetiracetam (Keppra), mephenytoin, methsuximide (Celontin), oxcarbazepine (Trileptal), phenobarbital (Luminal, Phenobarbitone, Solfoton), piracetam (Nootropyl), primidone (Mysoline), sodium valproate (Depacon), topiramate (Topamax), trimethadione (Tridione), valproate semisodium, valproic acid (Depakene, Depakene Syrup), vigabatrin (Sabril), zonisamide (Zonegran).

Butyrophenone neuroleptics: Benperidol (Anquil, Benperidol-neuraxpharm, Frenactil, Glianimon), droperidol (Dridol, Inapsine), haloperidol (Haldol), melperon (Buronil), triperidol (Trifluperidol).

Halogenated inhalational anesthetic agents: Desflurane (Suprane), enflurane (Ethrane), isoflurane (Forane), sevoflurane (Sevorane, Ultane).

Phenothiazines: Acetophenazine (combination drug: Tindal, with hydrocodone), fluphenazine (Permitil, Prolixin, Prolixin Decanoate, Prolixin Enanthate), mesoridazine (Serentil), methotrimeprazine (levomepromazine; Nozinan), perphenazine (Trilafon); combination drugs: Etrafon, Triavil, Triptazin), prochlorperazine (Stemetil), promazine (Sparine), promethazine (Phenergan), propiomazine (Largon), thiethylperazine (Torecan), thioridazine (Mellaril), trifluoperazine (Stelazine), trifluprom azine (Vesprin).

Tricyclic antidepressants: Amoxapine (Asendin), clomipramine (Anafranil), desipramine (Norpramin, Pertofrane), doxepin (Adapin, Sinequan), imipramine (Janimine, Tofranil), protriptyline (Vivactil), trimipramine (Surmontil).

Effect and Mechanism of Action

Coadministration of milk thistle extracts or silymarin with hepatotoxic drugs reduces biochemical and histopathological markers of drug-induced hepatocellular toxicity. The mechanism is multifactorial, including antioxidant free-radical scavenging, prevention of lipid peroxidation, stabilization of cell membranes, prevention of fibrosis, increase in bepatocellular regeneration, prevention of thiol depletion, induction of GST, and possibly inhibition of CYP2E1 activation of procarcinogens.

Research

Most data, except for ethanol-induced damage, are derived form preclinical evidence using a wide range of experimental models. (See table.)

Drug	Model (Citation)	Mechanism (or Finding)
Acetaminophen	Rodents, acute intoxication[73,74] Rat hepatocytes[9] Human hepatocytes[75] Human cell lines A431 and Hep G2[76]	Prevention of glutathione (GSH) depletion and lipid peroxidation. Prevention of GSH depletion. Downregulation TNF-α. Increase in GSH, mitochondrial membrane stabilization.
Acetylsalicylic acid, aspirin	Rodent CCl_4-induced cirrhosis, + ASA[77] Rodent portal vein ligation (PVL)—induced portal hypertension[78]	ASA pharmacokinetics normalized by silymarin coadministration. ASA pharmacokinetics normalized in PVL by silymarin coadministration.
Anabolic steroids	Rodents, coadministration of methandienone and silymarin[79]	Improved hepatocyte histochemical parameters.
Anticonvulsants (phenytoin)	Human case report[80] Observational study, psychiatric patients[81]	Decrease serum cholinesterase. Reduction of elevated transaminases, normalized bromsulphalein levels.
Antitubercular agents (isoniazid, rifampicin, and pyrazinamide)	Rodents, chronic intoxication[29,82]	Reversal of lipid peroxidation and GSH depletion, CYP2E1 activation, and transaminase normalization.
Ethanol	Rodents, acute intoxication[83-85] Rat behavioral model to assess effects of ethanol fetotoxicity[86] Rodents, acute intoxication[74] Placebo-controlled double-blind clinical trials of alcohol-induced liver disease treated with silymarin (420 mg/day)[87-90]	Antioxidant activity on alcohol metabolism and inhibition of lipid peroxidation. Reduction of ethanolic natal induced learning deficits by coadministration silymarin. Prevention of GSH depletion and lipid peroxidation. Various improvements, including reduction of transaminase elevation, decreased bilirubin, increased GSH levels, general symptom improvement, increase in survival rates.
Halothane	Rodents, acute intoxication[91] Hypoxic rodents, acute intoxication[92]	Prevention microsomal activity suppression by silibinin. Transaminase reduction.
Methotrexate, 6-MP	Case report, AML patient during chemotherapy[93]	Silymarin coadministration reduced transaminase elevation.
Narcotics (unspecified)	Clinical trial, cholecystectomy patients[94]	Serum cholinesterase reductions with silymarin before and after surgery.
Neuroleptics (butyrophenones and phenothiazines)	Double-blind clinical trial in long-term patients[95] Comparative study, long-term chlorpromazine patients[96]	Decreased serum malondialdehyde levels, decreased transaminases. Silymarin decreased or normalized drug-induced transaminase elevations.
Tricyclics (amitriptyline, nortriptyline)	Neonatal rodent hepatocytes[12]	Reduction of histopathological changes, lower transaminase alterations.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Most evidence for hepatoprotective effects of milk thistle with specific pharmaceuticals has been derived from experimental models. However, the clinical use of milk thistle in alcohol and *Amanita* intoxication has clinical support, and in well-established experimental models of hepatocellular damage such as CCl_4 intoxication, silymarin has shown pronounced hepatoprotective effects. Several of the contributing mechanisms may apply to the parenchyma of other organs besides the liver, including pancreas and kidney, in relation to various drug-induced toxicities.[97-100]

Hepatoprotection may be conferred by "concurrent" or "retroactive" administration, depending on whether silymarin is coadministered with drugs known to be hepatotoxic or administered in response to an unanticipated hepatotoxic reaction or an "idiosyncratic" hepatotoxic reaction. Anecdotally, in clinical practice, milk thistle is widely used in various situations of compromised liver function, and the primary markers or endpoints of efficacy are usually transaminase levels, because the establishment of precise differentials in apparent hepatotoxicity cases often remains unknown.

Insulin

Animal-source insulin (Iletin), human analog insulin (Humanlog), human insulin (Humulin, Novolin, NovoRapid, Oralin).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:
3. Possible

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Exogenous insulin requirements in insulin-dependent diabetes may be reduced by silymarin coadministration. Clinical trial evidence is available for type 2 diabetic patients with liver cirrhosis. Therefore, extension to other diabetic groups (e.g., type 1 without liver disease, otherwise-normal type 2) is not possible, although experimental evidence supports a hypoglycemic and islet-protective activity by silymarin.

Research

Soto et al.[99,101,102] conducted a series of experiments in the rodent model of alloxan-induced diabetes and found that islet damage can be reversed by silymarin. Three antioxidative enzymes—SOD, glutathione peroxidase, and catalase—were all increased as a result of silymarin administration, and when alloxan was followed by prolonged silymarin treatment (200 mg/kg/day orally for 9 weeks), the animals became normoglycemic, with insulin and glucagon levels comparable to untreated controls, and showed normal islet histology.

A controlled but open clinical trial was conducted over 12 months with insulin-dependent (type 1) diabetic patients who also had biopsy-confirmed liver cirrhosis. After 4 months' administration of silymarin (600 mg/day), glycemic control significantly improved, and exogenous insulin requirements and fasting insulin levels were reduced. All other parameters (HbA_{1c}, C-peptide, malondialdehyde, transaminases, bilirubin, total and HDL cholesterol, triglycerides, creatinine,

microalbuminuria) continued to improve throughout the 12 months.[103] Unfortunately, lack of placebo control, together with progressive improvement of hepatic function in the cirrhotic patient population, confounds a generalization of the results to noncirrhotic patients. Further studies with different patient groups would help establish the significance and mechanisms of the observed results.

Integrative Therapeutics, Clinical Concerns, and Adaptations

Lipid peroxidation and cell membrane damage are associated with ineffective antioxidant defense in type 1 and type 2 diabetic patients and also with sequelae such as microangiopathy. Therefore the potential of silymarin in preserving pancreatic function and glycemic control in these populations is important. Adjunctive use of silymarin at relatively high doses (600 mg/day) in combination protocols may be a useful option in integrative strategies targeting normalization of glycemic and oxidative stress parameters.

Metronidazole and Related Nitroimidazole Antiprotozoals

Evidence: Metronidazole (Flagyl).

Interaction Type and Significance

◈◈ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**
⊕/✗ **Bimodal or Variable Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **3. Possible**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

In this combination interaction, milk thistle may reduce the bioavailability of the drug, as well as reduce drug-induced adverse effects.

Research

Metronidazole is a cosubstrate of CYP450 3A4 and 2C9. In a study discussed earlier under Effects on Drug Metabolism and Bioavailability, Rajnarayana et al.[40] administered 140 mg silymarin to 12 healthy volunteers for 9 days. The silymarin pretreatment increased the clearance of the drug by 30%. The time scale suggests an induction of the metabolizing enzymes. Unfortunately, the subjects of this small trial were not phenotyped by 2C9 polymorphism. A canine study found that coadministration of silymarin with metronidazole increased the efficacy of drug treatment (measured by fecal cyst count) and improved a number of metabolic parameters compared with metronidazole alone.[104]

Integrative Therapeutics, Clinical Concerns, and Adaptations

Efficacy of metronidazole therapy is determined by clearance of parasite. The drug is generally considered to be poorly tolerated, but addition of milk thistle to ameliorate hepatic side effects during therapy should be avoided because decreased plasma levels are possible, based on the limited available data. The use of silymarin posttherapeutically to normalize liver function can be considered. Addition of metronidazole to patients who are chronic milk thistle users may require increased drug dose levels, although as in all such cases, the pharmacokinetics of the drug will be subject to individual variability, which is often not considered in prescribing.

Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCep 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).
Hormone replacement therapy (HRT), estrogens: Chlorotrianisene (Tace); conjugated equine estrogens (Premarin); conjugated synthetic estrogens (Cenestin); dienestrol (Ortho Dienestrol); esterified estrogens (Estratab, Menest, Neo-Estrone); estradiol: topical, transdermal, ring (Alora Transdermal, Climara Transdermal, Estrace, Estradot, Estring FemPatch, Vivelle-Dot, Vivelle Transdermal); estradiol cypionate (Dep-Gynogen, Depo-Estradiol, Depogen, Dura-Estrin, Estra-D, Estro-Cyp, Estroject-LA, Estronol-LA); estradiol hemihydrate (Estreva, Vagifem); estradiol valerate (Delestrogen, Estra-L 40, Gynogen L.A. 20, Progynova, Valergen 20); estrone (Aquest, Estragyn 5, Estro-A, Estrone '5', Kestrone-5); estropipate (Ogen, Ortho-Est); ethinyl estradiol (Estinyl, Gynodiol, Lynoral).
HRT, estrogen/progestin combinations: Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); conjugated equine estrogens and norgestrel (Prempak-C); estradiol and dydrogesterone (Femoston); estradiol and norethindrone, patch (CombiPatch); estradiol and norethindrone/norethisterone, oral (Activella, Climagest, Climesse, FemHRT, Trisequens); estradiol valerate and cyproterone acetate (Climens); estradiol valerate and norgestrel (Progyluton); estradiol and norgestimate (Ortho-Prefest).
HRT, estrogen/testosterone combinations: Esterified estrogens and methyltestosterone (Estratest, Estratest HS).
It has been speculated that silymarin may interfere with oral contraceptive therapy, with the theoretical consequence of possible contraceptive failure. This proposed interaction is presumably based on an extrapolation from an assumption of increased clearance of estrogenic compounds caused by altered hepatic metabolism, or beta-glucuronidase–mediated effect on enterohepatic recirculation of estrogen conjugates. One study reported silymarin inhibition of human beta-glucuronidase, but evidence for pharmacokinetic effects on reproductive steroid metabolism is not available.[25]

A recent study with recombinant estrogen receptors (ERs) has demonstrated that silymarin appears to exert a selective estrogen response modulator (SERM)–like effect by acting as

a selective ligand for ER-beta receptors while lacking an effect on ER-alpha receptors; however, the in vivo consequences of these activities remain to be demonstrated.[105] A single adverse event report in Australia involved a reaction in a 57-year-old woman taking ethinylestradiol as HRT, co-prescribed with amitriptyline. On taking a supplement that included silymarin, among other ingredients, she had acute gastrointestinal (GI) symptoms, including nausea and vomiting, colicky cramping, and diarrhea. The GI symptoms were repeated on rechallenge with the supplement. Although recording this as an adverse reaction to milk thistle, the report concedes that causality was not established.[106]

Tacrine

Tacrine (Tetrahydroaminoacridine, THA; Cognex).

A small clinical trial was conducted with Alzheimer's patients using tacrine to determine if silymarin might reduce the hepatic transaminase elevation typically associated with long-term administration of the drug. The study failed to reveal a significant effect of milk thistle on hepatic parameters, but the authors maintained that nonhepatic drug adverse effects (e.g., GI symptoms) were lower in the verum group than the control group.[107] The significance of this is unclear because milk thistle itself has been associated with mild GI adverse effects.

The 107 citations for this monograph are located under Milk Thistle on the CD at the back of the book.

Red Clover

Botanical Name: *Trifolium pratense* L.
Pharmacopoeial Name: Trifolii flos.
Common Names: Red clover, purple clover, trefoil.

HERB DESCRIPTION

Family

Fabaceae.

Parts Used

Flowers (traditional); "leaf" (standardized isoflavone preparations).

Common Forms

Dried flowering tops.
Tincture, Fluid Extract: Flowers, ethanol 25% to 35%, typically 1:2 to 1:5.
Standardized Extract: Standardized to 40 mg total isoflavones (Promensil, Trinovin); note: these are not red clover flowers (see following discussion).

INTERACTIONS REVIEW

Strategic Considerations

Current mainstream perceptions of red clover are dominated by the view of the herb as a source of phytoestrogenic isoflavones. This contrasts with traditional medicine's view of red clover flowers as having "alterative" (i.e., normalizing and "blood cleansing") properties. Historically, red clover flowers have been used internally as an alterative, antiscrofulous, antispasmodic, expectorant, and topically as a poultice for acne, ulcers, and cancerous growths.

Red clover flowers were a key ingredient of a famous Eclectic medical formulation "Trifolium Compound." Other ingredients included compound fresh extracts of *Stillingia sylvatica, Lappa minor, Phytolacca decandra, Cascara amarga, Berberis aquifolium, Podophyllum peltatum, Xanthoxylum carolinianum,* and potassium iodide. It was intended for administration "in syphilis, scrofula, chronic rheumatism, glandular and various skin affections."[1] The popularization of red clover as a cancer treatment in the first half of the twentieth century derived from various sources, including Jethro Kloss and the controversial Harry Hoxsey, whose anticancer "Hoxsey Formula" incorporated most of the herbs of the original Trifolium Compound, including red clover flowers.[2] Hoxsey formula–type products persist in the retail marketplace today. Red clover flowers remain in widespread use by modern herbalists, particularly in women's health care, despite the rise of interest in standardized leaf extracts, based on isoflavones.[3]

Interactions reports for red clover flower are not available. Extrapolations from the available pharmacological literature encounter difficulties. First, there is the difference between traditional red clover flower preparations and isoflavone standardized extracts. Bone[4] suggests that the traditional 25% alcohol extracts of red clover flowers have a very different constituent profile than the leaf-based standardized extracts. Analytical data suggest that the isoflavone content of clover flowers is 25% that of the leaves. Thus the flower heads have relatively small quantities of isoflavones, and only formononetin has been positively demonstrated.[5] In addition, the traditional pharmacopoeial remedy Trifollii flos is based on *Trifolium pratense* inflorescence (flowers). The literature on red clover flowers itself is not extensive. The herb is monographed in the *British Herbal Compendium*[5] and *British Herbal Pharmacopoeia*[6] but has received scant attention from other pharmacopoeial sources.

Second, much of the related research and literature focuses on the two soy-derived isoflavones, genistein and daidzein. These occur naturally as free compounds and as glycosides, genistin and daidzin. Red clover primarily contains biochanin A and formononetin, which are not present in soy. For example, a recent patent registered by Novogen Research Pty., the manufacturers of Promensil, for "therapy of estrogen associated disorders," cites the use of "clovers" (*Trifolium* spp.) and "chick peas" (*Cicer arietinum* L., Fabaceae) as sources of isoflavones. The clover species in the patent include *Trifolium repens* and *T. subterranean*, as well as "any clover related species or chick pea variety." The use of multiple leguminous sources for the isoflavone content of standardized extracts is controversial from a traditional pharmacopeial perspective, and such extracts are likely to include high concentrations of materials not present in red clover flowers. However, significant differences in effect are likely with the different proportions of different isoflavone ingredients.

Booth et al.[7] analyzed the estrogenicity and estrogen receptor (ER)–binding properties of different isoflavone compounds in a "preformulated red clover clinical extract." All the isoflavones, except formononetin, showed binding activity to one or other recombinant ER type. Analytical methods have been developed that allow accurate characterization of the isoflavone content of clover products.[8,9] Given the use of semipurified extracts containing isoflavones from multiple sources in commercial preparations used in controlled trials on "red clover" and available commercially for menopausal symptom relief, the interactions relating to these products are closer to those relating to soy isoflavones, isolates that are not a food, nutrient, or herb in any commonly accepted sense, than to red clover.

Pharmacokinetics and Effects on Drug Metabolism

Setchell et al.[10] reviewed the complex metabolism of these compounds and analyzed 33 commercial isoflavone-containing supplements. They concluded that the ingredients showed considerable variation and demonstrated that pharmacokinetics of different preparations were not at all equivalent. The naturally occurring form of the isoflavones is glycosidic, as genistin and daidzin. In vivo, the glycosides undergo bacterial hydrolysis in the large bowel to release the aglycones genistein and daidzein. Availability of appropriate bacterial enzymes for hydrolysis of glycosidic isoflavones may also vary widely based on varying endogenous bacterial ecologies, which may lead to large variations in biovailability of the aglycone forms.

The red clover isoflavones include biochanin A and formononetin, which are not present in soy; these are partially metabolized in vivo to the estrogenic metabolite equol. Polymorphisms between "fast" and "slow" equol producers have been described, and equol also undergoes enterohepatic recirculation.[11] Biochanin A and formononetin may also be metabolized in hepatocytes to genistein and daidzein.[12] The modulation of cytochrome P450 (CYP450) enzymes by isoflavones has been a topic of research interest; the inhibition of CYP450 1A2 partly explains the chemopreventive properties of the compounds.[13] Biochanin A and formononetin may also modulate P-glycoprotein.[14] Budzinski et al.[15] showed that an unidentified commercial ethanolic red clover extract was a potential inhibitor of CYP3A4 in a high-throughput in vitro screening assay of various compounds and commercial extracts. However, no reports of interactions with CYP3A4-metabolized pharmaceuticals have been made to date. Meanwhile, Kroyer[16] established that the total polyphenolic content and antioxidant activity of ethanolic extracts of red clover leaf were significantly higher than those of comparable soybean-based extracts.

A double caveat must therefore be applied in evaluating the literature pertaining to red clover. Not only are red clover flower extracts significantly different from standardized red clover preparations, but data derived from isolated soy isoflavones such as genistein and daidzein are not directly applicable to red clover isoflavone extracts.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar), warfarin (Coumadin, Marevan, Warfilone).

Diverse secondary sources repeat the persistent claim that the presence of coumarin compounds in *Trifolium* spp. may cause interaction with anticoagulant drugs such as warfarin. Not only are reports of this interaction entirely lacking, but this assertion is based on incorrect pharmacological assumptions. The coumarin content of red clover is in the form of coumestrol, a molecule lacking the 4-hydroxylation structure required for anticoagulant effects of dicoumarol and never associated with clinically significant modification of coagulation parameters. Fermentation (decomposition) is the only natural method whereby coumarin can become transformed into a congener of dicoumarol, and red clover extracts are not made from composted crude herb.

Simple coumarins are widespread constituents of numerous vegetable roots, such as carrots, parsnips, and celery.[17]

The 17 citations for this monograph are located under Red Clover on the CD at the back of the book.

Reishi

Botanical Name: *Ganoderma lucidum* (W. Curtis.: Fr.) P. Karst.
Pharmacopoeial Name: Fructus ganodermi.
Synonym: *Boletus lucidus* Fr.
Common Names: Reishi, reishi mushroom, red reishi; Ling Zhi. (*Ganoderma japonicum* = black reishi; *Ganoderma applanatum* = artist's conk).

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Acyclovir, cefazolin Antimicrobials Antivirals ⊕	Synergistic effects (greater than additive) have been observed with antimicrobial and antiviral combinations. Significance not established generally.	Consider coadministration, especially for immunocompromised patients with chronic viral and microbial infection.
Immunosuppressive, myelosuppressive chemotherapy ⊕/☼	Multifactorial interaction between reishi and chemotherapy; combination may improve therapeutic outcomes. Clinical significance anecdotally established. Related mushroom polysaccharides also effective.	Consider pretreatment, coadministration, and posttreatment with chemotherapy.

HERB DESCRIPTION

Family

Ganodermataceae (Polyporaceae).

Related Species

Ganoderma japonicum (Fr.) Lloyd. (synonym, *G. sinense* Zhao, Xu et Zhang.), *Ganoderma applanatum* (Pers.) Pat, *Ganoderma tsugae* Murrill.

Habitat and Cultivation

A woody shelf-fungus that grows on rotting tree stumps and fallen logs in temperate forests throughout much of North America, most of Europe, South America and Asia, typically affecting oak trees. Reishi is now rare in the wild in China and rarer in Japan but has been under widespread industrial-scale cultivation in China for several years, which constitutes the bulk of commercial reishi supply internationally.

Parts Used

Fruiting body. Spore and mycelium preparations exist but have limited commercial availability; they are not identical to the fruiting body in composition or activity.

Common Forms

Dried whole fruiting body, by decoction (or very finely powdered).
Tincture: Traditionally, rice wine extract.
Standardized Solid Extract: Concentrates available greater than 20:1.

INTERACTIONS REVIEW

Strategic Considerations

Traditional Chinese use of reishi includes stand-alone herb for various conditions (Chinese syndrome-patterns), including heart *(Xin) qi* and lung *(Fei) qi* deficiencies.[1] In modern Western usage, reishi is primarily considered as a safe and virtually nontoxic immunomodulatory agent. It is primarily used in the clinical context of immunocompromise, such as chronic fatigue immune dysfunction syndrome (CFIDS), or as an adjunct in integrative cancer protocols to support patients undergoing myelosuppressive conventional therapies. Pharmacological data suggest four primary areas of activity for reishi extracts: immune enhancing and antitumorigenic, cardiovascular regulatory, hypoglycemic, and hepatoprotective.[2] Of these, interactions with pharmaceuticals are suggested primarily by the immunomodulatory data.

Support for use of reishi in oncological settings is largely derived from experimental studies on the biological activities of its polysaccharide and triterpene compounds. These have direct antitumor activity mediated by several pathways, notably the inhibition of the key transcription factors nuclear factor-kappa B (NF-κB) and activating protein 1 (AP-1). The indirect anticancer effects are mediated by promotion of mixed-lymphocyte responses, including enhancement of cytotoxic activity of monocyte-macrophages, natural killer (NK) cells, and lymphokine-activated killer (LAK) cells and increased secretion of cytokines such as interleukin-1 (IL-1), IL-6, and interferon gamma (IFN-γ).[3-5] Protection against myelosuppression from chemotherapeutic agents and radiation therapy has moderate experimental and anecdotal clinical support; however, clinical trials are required to establish the efficacy of reishi for this purpose. Although some sources have cited Chinese-language clinical studies in support of these uses, full translations are unavailable, and evaluation of these trials by these secondary sources is typically schematic.[6]

More substantial clinical data are available for related mushrooms, such as *Coriolus, Polyporus,* and *Lentinus,* and medicinal mushroom polysaccharides, particularly the branched (1→3)-beta-D glucans, are thought to be broadly similar in their general immunomodulatory and anticancer effects.[7,8] Additive interactions with antimicrobial pharmaceutical agents have been reported (see later), but these probably are also indirect results from a general enhancement of cell-mediated immunity and antiviral activity by reishi compounds, rather than specific herb-drug interactions. The long-term use of immunomodulating herbs in patient populations dependent

on immunosuppressive therapies (e.g., to prevent graft rejection) is de facto contraindicated, and reishi extracts have been shown to reverse immunosuppressive effects of morphine.[9]

Cardiovascular drug interactions seem unlikely given the mild cardiotonic effects of reishi despite suggestions in secondary literature of possible potentiating interactions with cholesterol-lowering and anticoagulant drugs. These interactions have not been demonstrated or reported, and claims of their likelihood are classified as "speculative" here, along with equally hypothetical suggestion of interactions with hypoglycemic drugs, as discussed later.

Effects on Drug Metabolism and Bioavailability

Pharmacokinetic interactions between reishi and pharmaceutical drugs have not been reported, and studies on the effects of the herb on drug-metabolizing systems have not been conducted to date. Induction of human hepatic glutathione-*S*-transferase in vitro by reishi polysaccharide has been recorded in one in vitro study.[10] Inhibition of beta-glucuronidase in vitro by the triterpene constituent ganoderenic acid A was demonstrated in vitro, and the same constituent had a potent inhibitory effect against carbon tetrachloride (CCl_4)–induced hepatotoxicity in a rodent model.[11]

The hepatoprotective effects of the herb may counter solvent and other chemical or solvent-induced hepatotoxicity.[12,13] These effects on drug-metabolizing enzymes may contribute, along with the antioxidant effects of the herb, to the established hepatoprotective properties of reishi observed in some studies. From these limited data, the potential theoretically exists for some modulation of clearance of glucuronide prodrugs, as well as accelerated clearance of glutathione and glucuronated drug conjugates. The effects of variation in activity of beta-glucuronidase on drug metabolism have not been systematically studied to date, but it may be a clinically significant determinant of variability of individual response to pharmaceuticals.[14]

HERB-DRUG INTERACTIONS

Antimicrobial and Antiviral Therapies

Evidence: Acyclovir (Zovirax), cefazolin (Ancef, Kefzol).
Extrapolated, based on similar properties: Cephalosporin antibiotics: Aztreonam (Azactam injection), cefaclor (Ceclor), cefadroxil (Duricef), cefamandole (Mandol), cefdinir (Omnicef), cefepime (Maxipime), cefixime (Suprax), cefoperazone (Cefobid), cefotaxime (Claforan), cefotetan (Cefotan), cefoxitin (Mefoxin), cefpodoxime (Vantin), cefprozil (Cefzil), ceftazidime (Ceptaz, Fortaz, Tazicef, Tazidime), ceftibuten (Cedax), ceftizoxime (Cefizox), ceftriaxone (Rocephin), cefuroxime (Ceftin, Kefurox, Zinacef), cephalexin (Keflex, Keftab), cephapirin (Cefadyl), cephradine (Anspor, Velocef), imipenem combination drug: imipenem and cilastatin (Primaxin I.M., Primaxin I.V.); loracarbef (Lorabid), meropenem (Merrem I.V.); possibly many other antimicrobial and antiviral agents.
Similar properties but evidence lacking for extrapolation: Nucleoside (analog) reverse-transcriptase inhibitors (NRTIs or NNRTIs): Abacavir (Ziagen), didanosine (ddI, dideoxyinosine; Videx); dideoxycytidine (ddC, zalcitabine; Hivid), lamivudine (3TC, Epivir), stavudine (D4T; Zerit), tenofovir (Viread), zidovudine (azidothymidine, AZT, ZDV, zidothymidine; Retrovir); combination drugs: zidovudine and lamivudine (Combivir); abacavir, lamivudine and zidovudine (Trizivir).
Similar properties but evidence indicating no or reduced interaction effects: Vidarabine (Ara-A, arabinoside; Vira-A).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability:	Evidence Base:
4. Plausible	○ **Preliminary**

Effect and Mechanism of Action

Synergy between reishi extracts or polysaccharides with acyclovir and cefazolin have been demonstrated in vitro. These effects are greater than linear additive effects but may be augmented in vivo by general enhancement of T helper cell type 1 (Th1) immune responses by reishi. The clinical significance of the interaction or general applicability to other antimicrobial or antiviral agents has not been established.

Research

An in vitro study measured the minimum inhibitory concentration (MIC) of an aqueous extract of Ganoderma alone and in combination with several antibiotics (ampicillin, cefazolin, oxytetracycline, chloramphenicol) against a variety of gram-negative and gram-positive bacteria. In combination with cefazolin against *Klebsiella oxytoca* and *Bacillus subtilis*, synergistic versus linear additive reductions in MIC were observed.[15] Oh et al.[16] used an in vitro model of human herpes simplex virus type 1 (HSV-1) and type 2 (HSV-2) in culture and examined the effects of acyclovir and vidarabine nucleoside agents, alone and in combination, on viral plaque size with an acidic protein-bound polysaccharide extract of reishi. They found a synergistic antiviral effect with acyclovir and reishi extract against both types. With vidarabine, however, there was an antagonistic effect against HSV-2 but a synergistic effect against HSV-1, suggesting that results may not generally be applicable to other nucleoside antivirals or specific viruses. Several reishi triterpene compounds have also been found to exhibit anti–human immunodeficiency virus (HIV) activity in one in vitro study.[17]

Clinical Implications and Integrative Therapeutics

Reishi extracts alone have in vitro antiviral effects against both HSV-1 and HSV-2.[18,19] The antiviral effects mechanism is not thought to directly involve cytokine such as IFN, but rather an interaction between reishi polysaccharides and the HSV glycoproteins involved in binding to host cell membranes.[19] In addition, reishi polysaccharides enhance Th1 immunity, including the promotion of Th1 cytokines such as IFN-γ and IL-12, as well as NK cell activity.[20-22] Clinically, the experimental data suggest that herpetic viral conditions may benefit from reishi coadministered with acyclovir, but extrapolations to other antivirals or other viral infections cannot reliably be made. However, reishi polysaccharides enhance cell-mediated immunity, tending to induce increased antimicrobial and antiviral aspects of immune responses, and can be administered to maintain immunocompetence before or after drug administration. Also, reishi extracts are effective in controlling postherpetic pain.[23]

Antineoplastic Therapies, Including Anthracyclines, Radiotherapy, and Surgery

Evidence: Cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox), doxorubicin (Adriamycin, Rubex).
Extrapolated, based on similar properties: Daunorubicin (Cerubidine, DaunoXome), epirubicin (Ellence, Pharmorubicin), idarubicin (Idamycin, Zavedos), mitoxantrone (Novantrone, Onkotrone).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Reishi extracts may protect against immunosuppressive aspects of antineoplastic therapies and improve therapeutic outcomes. Mechanisms are multifactorial and include protection against specific toxicities, reversal of leukopenia, and preservation of cell-mediated immune responses; antioxidant scavenging of free radicals; inherent anticancer activity resulting from inhibition of transcription factors NF-κB, AP-1, and free-radical reactive oxygen species (ROS); and other mechanisms.

Research

Reishi (*Ganoderma japonicum*) increased white blood cell (WBC) count in 72.5% of 175 leukopenic patients, according to a Chinese study cited by Chen and Chen.[6] A Chinese rodent study of doxorubicin (Adriamycin) toxicity by Hongwei and colleagues, cited in detail by Upton,[2] found that oral pretreatment with reishi extract at 500 mg/kg body weight for 14 days significantly reduced histological parameters of doxorubicin-induced toxicity in cardiac, hepatic, and renal cells, compared with controls receiving doxorubicin alone. An unrelated study demonstrated dose-dependent cardioprotective activity of hot-water reishi extracts against ethanol-induced heart toxicity in rodents through antioxidative protection against lipid peroxidation.[24] This is the established mechanism of anthracycline-induced cardiotoxicity. Lu and Lin[9] demonstrated reversal of B-cell and T-cell response suppression by morphine after administration of a polysaccharide reishi extract to morphine-dependent mice. Animal studies have demonstrated radioprotective effects of reishi in recovering immunocompetence after radiation exposure.[25,26] However, this includes protection against deoxyribonucleic acid (DNA) strand breakage.[27] A murine model showed that oral pretreatment with reishi enabled a significant reduction in cyclophosphamide toxicity in terms of preventing leukopenia. An in vitro study found that reishi may inhibit the angiogenic vascular endothelial growth factor (VEGF), and theoretically, angiogenesis inhibition may interfere with postsurgical wound repair.[28]

McKenna et al.[29] reviewed two small human studies from conference reports relating to *Ganoderma* use in a clinical oncology setting. The first, an open-label trial by Kupin[30] of 48 patients with advanced cancer (renal, gastric, breast), examined the effects of coadminstering reishi extracts during chemotherapy and radiation. The WBC levels were normalized in those taking reishi compared with controls, and treatment-induced leukopenia was rapidly ameliorated in the reishi group, who also had greater appetite and higher levels of general vigor than the controls. Of those patients requiring surgery, the reishi subjects experienced faster recovery and improved wound healing compared with the control group surgical candidates. A smaller study of patients with acute myelogenous leukemia (AML) or nasopharyngeal carcinoma who were pretreated with reishi extracts for 1 week before chemo/radiotherapy, contining the extracts for 3 months after the treatments, reported similar findings in terms of increased efficacy of treatment and reduction of treatment-induced adverse effects.[31]

Clinical Implications and Integrative Therapeutics

The pluripotent anticancer effects of reishi polysaccharides and triterpenes have been subject of extensive experimental study, but to date, clinical trials have not confirmed these in vivo. Evidence for other mushroom beta-glycans is perhaps more compelling, but reasonable rationale appears to exist for combining reishi extracts into protocols designed for therapeutic protection against myelosuppression as a dose-limiting toxicity of chemotherapy. If the antiangiogenic effects of reishi are confirmed, combination with monoclonal antibody drugs targeting VEGF is theoretically a reasonable strategy.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Anticoagulants, Oral Vitamin K Antagonists

Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar), warfarin (Coumadin, Marevan, Warfilone).

Limited experimental data from aggregometry studies suggest that water extracts of reishi have some potential to induce aggregation in vitro, possibly because of an adenosine component in the extracts.[32] The effects may be related to anti-inflammatory properties of reishi acting through a thromboxane A_2 (TXA_2) pathway.[33,34] One small human study showed inhibition of adenosine diphosphate (ADP)–induced aggregation in healthy volunteers, as well as antithrombotic potential (measured by size of extracorporeal thrombi) resulting from oral administration of reishi extracts in atherosclerotic patients. The authors did not speculate on the possible mechanisms of these observed results.[35] This has led to cautions about possible interactions with anticoagulants.[2] However, recent data suggest a lack of effect on hemostatic parameters in healthy volunteers, and adverse interaction with antiplatelet or anticoagulant drugs seems unlikely.[36]

Central Stimulants; Chlorpromazine, Phenobarbital, Reserpine

Amphetamine aspartate monohydrate, amphetamine sulfate, dextroamphetamine saccharate, dextroamphetamine sulfate; D-amphetamine, Dexedrine.
Methylphenidate (Metadate, Methylin, Ritalin, Ritalin-SR, Concerta); combination drug, mixed amphetamines: amphetamine and dextroamphetamine (Adderall; dexamphetamine); chlorpromazine (Largactil, Thorazine); phenobarbital (phenobarbitone; Luminol, Solfoton); reserpine (Harmonyl).

There are limited reports that reishi extracts may exert a partial antagonism to the central stimulant effects of amphetamines as well as potentiation of the sedating effects of reserpine and chlorpromazine and increase phenobarbital-induced sleeping times.[2] Reishi is not known clinically for its sedative

effects in Western use, although it is incorporated into formulae for certain patterns of insomnia in Chinese herbal medicine. The limited available data do not suggest a straightforward pharmacological mechanism that enables extrapolation to an interaction at this time.

HMG-CoA Reductase Inhibitors (Statins) and Other Cholesterol-Lowering Drugs

Atorvastatin (Lipitor), fluvastatin (Lescol, Lescol XL), lovastatin (Altocor, Altoprev, Mevacor), combination drug: lovastatin and niacin (Advicor); pravastatin (Pravachol), rosuvastatin (Crestor), simvastatin (Zocor), combination drug: simvastatin and extended-release nicotinic acid (Niaspan).

Recent experimental evidence has confirmed the modern Chinese medical use of reishi extracts for reducing cholesterol levels, although this is not an established use in Western botanical medicine.[37,38] The mode of action is partially through the mevalonate pathway, possibly at the level of 3-hydroxy-3-methylglutaryl (HMG)–coenzyme A (CoA), but is likely multifactorial, with a beta-sitosterol–like effect on cholesterol absorption. These data have been used by secondary sources to suggest an interaction with HMG-CoA reductase inhibitor drugs (statins).[2] Reverse extrapolation from a therapeutic effect to suggest that drugs with the same action may be clinically problematic is not evidence of an interaction. The combination of statins and reishi has not been studied, although Shiao[38] suggests this combination may have an anticancer effect (presumably via farnesyl protein transferase). If used for hypocholesterolemia, the statin-reishi combination would probably have an additive effect on cholesterol levels, but to date an interactive synergy has not been demonstrated.

Insulin and Oral Hypoglycemic Agents

Evidence: Animal-source insulin (Iletin); human analog insulin (Humanlog); human insulin (Humulin, Novolin, NovoRapid, Oralin).

Extrapolated, based on similar properties: Buformin (Andromaco Gliporal, Buformina), chlorpropamide (Diabinese), glimepiride (Amaryl), glipizide (Glucotrol; Glucotrol XL), glyburide (glibenclamide; Diabeta, Glynase, Glynase Prestab, Micronase, Pres Tab), metformin (Dianben, Glucophage, Glucophage XR); combination drugs: glipizide and metformin (Metaglip), glyburide and metformin (Glucovance); phenformin (Debeone, Fenformin), tolazamide (Tolinase), tolbutamide (Orinase, Tol-Tab).

Hypoglycemic effects of reishi triterpenes have been established in animal studies.[39] The effect partly results from reishi-induced increases in insulin secretion and partly from effects on hepatic glucose metabolism.[40,41] An open-label study in eight diabetic patients reported by Teow[31] and reviewed by McKenna[29] apparently found that 1 g reishi extract daily was comparable in effect to the hypoglycemic effect of insulin (100 IU/mL) or oral hypoglycemic agents. Details were not supplied, and additional human trials are unavailable. Corroboration of hypoglycemic effects in vivo by controlled studies is required, together with analysis of the mechanism, before theoretical extrapolations to interactions can be considered more than speculative.

The 41 citations for this monograph are located under Reishi on the CD at the back of the book.

Saw Palmetto

Botanical Name: *Serenoa repens* (W. Bartram) Small.
Pharmacopoeial Name: Fructus serenoae repentis.
Synonyms: *Sabal serrulata* (Michaux) Nuttall ex Schultes.
Common Names: Saw palmetto, sabal.

HERB DESCRIPTION

Family

Arecaceae (Palmae).

Habitat and Cultivation

Native to coastal regions of southeastern United States, especially Florida; also found in the West Indies and parts of Central America, southern Spain, and North Africa.

Parts Used

Berries. Botanically, the fruit is a drupe with single seed; the oily flesh, not the seed, is used; the fruits are often called "berries."

Common Forms

Fresh or dried, whole or ground fruit, including powders or tablets.
Hydroethanolic Tincture and Fluid Extracts: 70% to 95% alcohol.
Lipid/Sterol Extract (LESP): Hexane or supercritical carbon dioxide (CO_2) extraction. LESP may be standardized to "total fatty acid content" between 70% and 95%; however, manufacturers' preparations may vary.[1]

INTERACTIONS REVIEW

Strategic Considerations

Serenoa berries have monographs by the German Commission E[2] and World Health Organization (WHO)[3] and are described in virtually all authoritative literature of Western herbal medicine. In 2002, the *United States Pharmacopeia* (*USP*)[4] reinstated an official monograph on saw palmetto, which had been deleted from editions after 1916. The primary modern use of saw palmetto extracts is for lower urinary tract symptoms (LUTS) related to benign prostatic hyperplasia (BPH). More than 20 clinical trials have now been conducted to examine the efficacy of saw palmetto for BPH and LUTS. Meta-analyses of 19 of these trials have concluded that the extract is effective for these indications.[5] Saw palmetto berries are typically used in combination with root of *Urtica dioica* L. and *Urtica urens* L. (stinging nettles) for mild BPH.[6] *Urtica radix* is indicated in monographs by the European Scientific Cooperative on Phytotherapy (ESCOP)[7] and WHO[8] for conditions of mild prostatic hyperplasia. A clinical trial using a proprietary blended product (Nutrilite) has established a slight increase in effectiveness for LUTS for the blend versus placebo, although studies comparing the combination product directly with single components are not available.[6]

The trial-supported uses of the herb are restricted, in contrast with the original uses of the plant by the indigenous cultures of the southeastern United States, who exploited all parts of the saw palmetto dwarf palm extensively, including as a food for animals and humans, as a fiber source, as well for medical purposes (although the latter are not well documented).[9] Early Western medical uses included as a digestive and respiratory remedy; nutritive to build tissues; reproductive remedy for various male and female conditions, including atrophy of the breasts, dysmenorrhea, irritation, and relaxation of the prostate; aphrodisiac; and sexual vigor and sperm production enhancer.[10,11] Modern herbalists have emphasized its anabolic nutritive properties, and general effects that extend beyond the limited view of the herb as a "BPH remedy" for men.[12]

There are no direct clinical data on interactions between saw palmetto berries and pharmaceutical drugs, nor are any interactions suggested by the major therapeutic monographs on saw palmetto. Because of the widespread use of the herb in benign prostatic hypertrophy (BPH), as well as an ingredient of herbal formulations for prostate cancer, the potential for interaction with coadministered drugs such as anti-androgens is considerable. These two clinical settings are briefly discussed here.

For mild BPH, a trial course of saw palmetto (in combination with related botanicals) may be used prior to considering drug therapy to examine whether symptoms can be controlled by herbal medication alone. If the lower urinary tract symptoms (LUTS) are refractory to botanical protocols, 5-alpha-reductase (5-AR; 5-α-reductase) inhibition drug therapy (Avodart, Proscar) might be initiated, but combination herb-drug treatments have not been demonstrated to be additive and are unlikely to be beneficial.

In prostate cancer, androgen-deprivation therapy (ADT) is a conventional approach involving one or more endocrine approaches, including luteinizing hormone–releasing hormone (LHRH) agonism (Lupron, Trelstar, Viadur, Zoladex). After causing an initial (several-week) surge in testosterone levels, LHRH agonism subsequently results in castrate levels of testosterone as long as the agent is continued. Alternately, ADT includes LHRH antagonism (Abarelix, Centrilex), antiandrogenics (Androcur, Casodex, Eulexin, Nilandron), and 5-AR inhibition (Avodart, Proscar). *Serenoa* has been anecdotally incorporated into adjunctive botanical protocols combined with ADT because the herb exhibits antiproliferative effects, such as cyclooxygenase-2 (COX-2) inhibition, as well as inhibition of insulin-like growth factor-1 (IGF-1)–mediated kinase activation that are not dependent on its antiandrogenic effects[13,14] (see PC-SPES).

Effects on Drug Metabolism and Bioavailability

Pharmacokinetic interactions between saw palmetto and prescription drugs resulting from herbal modulation of drug-metabolizing systems have not been reported. Two separate controlled trials using healthy volunteers have examined the effects of saw palmetto administration at 320 mg standardized extract daily on cytochrome P450 3A4 (CYP3A4) and CYP2D6 (14 days' administration)[15] and on CYP1A2, 2D6, 2E1, and 3A4 (28 days' supplementation).[16] Both studies used probe drug methodology to compare preadministration and postadministration pharmacokinetics of the test substrates, and both failed to find significant differences before and after saw palmetto administration compared with controls,

suggesting that the herb poses negligible risk for pharmacokinetic interactions. By contrast, an in vitro study using purified recombinant (i.e., nonhuman) CYP3A4, 2D6, and 2C9 examined the effect of a commercial saw palmetto extract on the kinetics of test substrates of these enzymes. The herb was a potent in vitro inhibitor of all three CYPs tested.[17] These researchers did not analyze the content of the saw palmetto product used in the study, and accurate molecular concentration and composition of the material were not established. Conflict between in vitro and in vivo data in this area is not uncommon, but until/unless further data to the contrary become available, saw palmetto is unlikely to exhibit marked pharmacokinetic interactions with pharmaceutical substrates of the principal CYP enzymes.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Steroidal Sex Hormones

5-Alpha (5-α)-reductase (5-AR) inhibitors: Dutasteride (Avidart, Avodart, Avolve, Duagen, Dutas, Dutagen, Duprost), finasteride (Propecia; Proscar).
Alpha-1(α_1)-adrenocceptor (A1A) antagonists: Doxazosin (Cardura), prazosin (Minipress), tamsulosin (Flomax, Flomaxtra), terazosin (Hytrin).

Various secondary sources have proposed interactions between saw palmetto and prescription medications affecting steroidal sex hormones, presumably based on extrapolations from the clinical effects of the herb. However, the precise pharmacological mechanisms by which saw palmetto berries influence the clinical course of lower urinary tract symptoms remain elusive, and plausible mechanisms underlying antiandrogenic effects (e.g., steroid 5-AR inhibition, A1A antagonism), experimentally demonstrated in vitro, have not been corroborated in human studies.[18] As a result, suggestions of interactions between saw palmetto and antiandrogenic pharmaceutical agents, such as the 5-AR inhibitor finasteride (Proscar) or A1A agents such as tamsulosin (Flomax), must be classified as "speculative." In the case of the tamsulosin, the only study that directly compared the effects of tamsulosin alone and in combination with saw palmetto extract (LESP) demonstrated an absence of additive effects for the combination.[19]

Anticoagulants, Oral Vitamin K Antagonists

Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar), warfarin (Coumadin, Marevan, Warfilone).

A suggested interaction between anticoagulant drugs and saw palmetto[20] is hypothesized in a case report claiming a possible connection between a patient's undisclosed saw palmetto use and increased intraoperative bleeding time during brain surgery.[21] This report not only fails to identify the saw palmetto product used, but does not record the dose and duration of administration or its temporal association with the adverse event. The suspected cause of the adverse event was not confirmed by rechallenge, and alternative explanations (e.g., undisclosed or forgotten aspirin or NSAID use) were not discounted; thus the report does not meet minimal criteria to substantiate an association between the adverse bleeding and saw palmetto consumption. To extrapolate this further to an interaction between saw palmetto and anticoagulant therapy is unwarranted, as confirmed by the widespread use of saw palmetto extracts, which has not yet revealed any pattern of adverse effects related to platelet dysfunction or bleeding. Another vascular adverse event was a single cerebral hemorrhage in the verum group during one clinical trial of Permixon (a hexane liposterolic extract standardized to 90% free fatty acids) for BPH, which the investigators considered not to be attributable to saw palmetto.[22]

At this time, given the absence of validated reports in the literature, the suggestion of possible interactions between anticoagulant agents and saw palmetto can be considered at best to be speculative.

Related Issue

PC-SPES

PC-SPES

A combination preparation of eight herbs including saw palmetto (PC-SPES) used in several clinical trials for prostate cancer was associated with reduction in prostate-specific antigen (PSA) in several trials for both androgen-independent and androgen-dependent prostate cancer.[23-26] The herbs in the formula were *Ganoderma lucidum* (Leyes.ex Fr) P.Karst, *Scutellaria baicalensis* Georgi., *Rabdosia rubescens*, *Isatis tinctoria* L., *Panax notoginseng* Burk., *Dendranthema morifolium* Tzvel., and *Glycyrrhiza uralensis* Fisch. The saw palmetto content (< 10%) was less than any other ingredient of the mixture. The product was manufactured in China and distributed by BotanicLab of California.

Sold as a dietary supplement, PC-SPES became popular but controversial because its mechanism, although partly estrogenic, was unclear. Adverse effects after long-term administration of PC-SPES included reports of gynecomastia, mastalgia, and decreased libido, as well as transient gastrointestinal symptoms (diarrhea, dyspepsia). Deep vein thrombosis, stroke, and pulmonary embolism were reported in patients with advanced prostate cancer while taking the preparation. Such patients are at increased risk for abnormal thrombus formation and its sequelae, and no studies were done to determine whether frequency of these effects was increased by use of PC-SPES. Several of the herbal ingredients of PC-SPES, as well as unlisted ingredients and contaminants, may have contributed to its toxicity. Small amounts of warfarin, indomethacin, diethylstilbestrol (DES), and ethinyl estradiol were found in some samples after testing by the California Department of Health Services using mass spectrometry with chromatographic techniques.[27] In February 2002, BotanicLab voluntarily withdrew PC-SPES from the market, and the product is no longer available. After several other BotanicLab products tested positively for contamination with pharmaceuticals, the company ceased trading in June 2002.

Despite this, PC-SPES still poses a complex challenge, and several issues remain. Most of the ingredients were imported from China, where combining pharmaceutical and herbal ingredients into a product is "integrative" practice. The pharmacodynamic mechanism of the formula cannot be reduced to any single component ingredient or entirely attributed to contamination with estrogenic compounds. An in vitro study on lymph node carcinoma of prostate (LNCaP) cells comparing PC-SPES with DES showed that DES could not account for the different antiproliferative actions of PC-SPES.[28] A randomized clinical trial initiated by urologic oncologist Eric Small and associates at the University of California–San Francisco (UCSF) compared treatment of patients with metastatic androgen-independent prostate cancer with PC-SPES to DES. The trial was halted on discovery

of the pharmaceuticals in PC-SPES; up to that point, however, the results suggested superior activity of PC-SPES over DES. Small et al.[23] had already published preliminary positive trial results with the extract in 2000.

The herbal combination of ingredients in PC-SPES, without pharmaceutical adulterants, still could be a synergistic mixture with in vivo activity against prostate cancer. Arguably, the combination of the herbs with estrogenic compounds, nonsteroidal anti-inflammatory drugs (NSAIDs; e.g., indomethacin), and warfarin may have increased effectiveness of the formula. In turn, this suggests a theoretically beneficial interaction between the herbal formula and these pharmaceuticals in prostate cancer, although it appears unlikely that this proposition will be investigated in the near future.

The 28 citations for this monograph are located under Saw Palmetto on the CD at the back of the book.

St. John's Wort

Botanical Name: *Hypericum perforatum* L.
Pharmacopoeial Name: Hyperici herba.
Common Names: St. John's wort, Klamath weed (historic: Fuga daemonum, herba solus).

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Alprazolam Triazolobenzodiazepines ◇◇	Drug is 3A4 substrate. St. John's wort (SJW) lowers bioavailability by inducing 3A4 enzyme production. Interaction proved experimentally; no clinical reports. May be significant for intravenous midazolam preoperatively.	Coadministration usually contraindicated. Avoid.
Amitriptyline Tertiary tricyclic antidepressants ◇◇◇	Drug 3A4/P-glycoprotein (P-gp) cosubstrate. Herb lowers bioavailability. Interaction proved experimentally; no clinical reports.	Coadministration usually contraindicated. Avoid.
Anesthesia, general X/?	Potential pharmacokinetic and pharmacodynamic interactions with premedications and anesthetics. Reports scarce.	Cessation SJW 1 to 2 weeks before procedure suggested. Disclosure essential.
Antiretrovirals Indinavir, nevirapine Protease inhibitors NNRTIs XX/XXX/◇◇	Most antiretroviral agents are 3A4/P-gp cosubstrates. Decreased bioavailability demonstrated. No clinical reports.	Generally avoid. Coadministration requires specialist supervision and monitoring of drug levels.
Cyclosporine Immunosuppressive agents XXX/◇◇◇	Cyclosporine A is cosubstrate of 3A4/P-gp. Decreased bioavailability demonstrated. Numerous serious reports of graft rejection.	Avoid.
Digoxin Cardiac glycosides XX/◇◇	Drug is P-gp substrate. Possible biphasic response, short-term increase, long-term decrease in bioavailability. Isolated report of bigeminy, short term.	If coadministered, ramp/taper the addition/cessation of herb, and monitor drug levels with vigilance during transition.
Etoposide Topoisomerase II inhibitors XX/◇◇/?	Possible combination pharmacokinetic and pharmacodynamic interaction, decreased availability (drug is 3A4 substrate), and interference with therapeutic action by hypericin, blocking topo II inhibition.	Avoid.
Fexofenadine Histamine H1-receptor antagonist antihistamine X/◇	Drug is P-gp substrate. Decreased bioavailability demonstrated. No clinical reports; minimal significance.	Unlikely to cause problems.
Imatinib Tyrosine kinase inhibitors ◇◇◇	Gleevec is 3A4 substrate; decreased drug bioavailability demonstrated. Possible compromise to targeted anticancer therapy. No case reports.	Avoid.
Irinotecan Camptothecin analogs X/◇◇◇	Variable pharmacokinetic interaction probable. Significance unknown. Camptothecin-11 responses subject to high inherent variability.	Avoid.
Omeprazole Benzimidazole Proton pump inhibitors X/◇◇	Prilosec is 3A4/2C19 substrate; SJW reduces bioavailability, as experimentally demonstrated. No clinical reports, although large size of effect may be clinically significant.	Avoid, or monitor and increase dose drug.
Oral contraceptives (OCs) X/◇◇	Steroids hormones are 3A4 substrates. SJW increases breakthrough bleeding, may reduce OC compliance. OC failure not established despite theoretical risk.	Avoid, or adopt barrier methods during coadministration.
Paclitaxel, docetaxel Taxanes ?/◇◇◇	Theoretically, induction of CYP3A4 and P-gp could influence drug disposition. Significance not established. Drug mostly eliminated via CYP2C8.	Avoid.
Paroxetine, trazodone SSRI and SSRI/SNRI antidepressants ?	Herb may lead to varying combined pharmacokinetic and pharmacodynamic interactions, at least with some SSRI/NSRI drugs. Mild symptoms of serotonergic excess possible. Several reports of varying reliability. Significance not established.	Avoid, except with professional monitoring during drug taper.
Simvastatin HMG-CoA reductase inhibitors (statins) ◇	Some older statins are cosubstrates of 3A4/P-gp. Minimal significance; no reports available.	Consider newer statins if coadministration indicated.
Tacrolimus XXX/◇◇◇	Cyclosporine A is a cosubstrate of 3A4/P-gp. Experimental evidence that tacrolimus is also 3A4 substrate, but no interactions reports for tacrolimus.	Avoid.
Verapamil Calcium channel blockers X/◇◇	Verapamil (and all calcium channel blockers) are 3A4 substrates. SJW induces intestinal 3A4 and increases drug clearance. No reports. Interaction significance not established.	Monitored coadministration unlikely to be problematic.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Voriconazole Triazole antifungals ✗/◇◇	Drug is 3A4/2C19/2C9 substrate. SJW reduces bioavailability, as experimentally demonstrated. No clinical reports, although large size of effect may be clinically significant.	Avoid.
Warfarin, Phenprocoumon Oral vitamin K antagonist anticoagulants ✗✗	Mechanism not established. Possible pharmacokinetic effect; may lead to reduced INR. Significance minimal to moderate. Reliable clinical reports or trials unavailable.	Unlikely to cause problems. If coadministered, monitor INR once or twice weekly, and titrate anticoagulant dosage when starting or stopping SJW therapy, until INR stable.

NNRTIs, Nonnucleoside reverse-transcriptase inhibitors; *SSRI*, selective serotonin reuptake inhibitor; *SNRI*, serotonin-norepinephrine reuptake inhibitor; *HMG-CoA*, 3-hydroxy-3-methylglutaryl–coenzyme A; *INR*, international normalized ratio.

HERB DESCRIPTION

Family

Clusiaceae (Guttiferae, Hypericaceae).

Habitat and Cultivation

Perennial; native in Europe Asia and North Africa; naturalized in the United States and considered a noxious weed in many areas; widespread in temperate zones, favoring disturbed ground.

Parts Used

Flowering tops.

Common Forms

Dried Plant: Flowering tops.
Tincture: 60% ethanol, 1:2 to 1:5 weight/volume.
Standardized Extract: 0.3% hypericin, 2.0% to 4.5% hyperforin.
Infused Oil: Fresh flowers, for external use.

HERB IN CLINICAL PRACTICE

Overview

A well-documented botanical medicine since Greco-Roman times, St. John's wort (SJW) has a long history of folk and traditional use as a *vulnerary* ("wound healer") and for banishing mental afflictions, particularly melancholy. For example, Gerard[1] (1633) described its use as a balm for wounds, burns, ulcers, and bites as being without equal. The oil made from the macerated flowers was listed in the first *Pharmacopoeia Londinensis* (1618). *Hypericum perforatum* was proved and introduced into the homeopathic materia medica by Muller in the mid-1800s and has been included in the *Homeopathic Pharmacopoeia of the United States* since that era, with primary indications focusing on nerve pain and traumatic injuries (e.g., concussion, coccygeal impact, sequelae).

More recently, clinical trial evidence accumulated through the 1980s and 1990s established the efficacy and safety of standardized SJW extracts for treating mild to moderate depression, and the "natural antidepressant" label propelled the herb to second-best-selling supplement in the United States by the late 1990s. In 2000, reports of serious interactions with prescription drugs began to appear, and the resulting adverse publicity caused sales of the herb to fall significantly, although SJW remains one of the top-selling U.S. botanicals. It was approved by the German Commission E for "depressive moods" (internally) and "contused injuries" (externally) in 1984.[2] The pharmacology and clinical effects of the herb are currently the focus of considerable research interest and, because of rapid accumulation of data, relatively recent literature reviews (e.g., 1997 *American Herbal Pharmacopoeia* monograph) are in some respects dated.[3] More recent reviews of the extensive literature include the 2003 European Scientific Cooperative on Phytotherapy (ESCOP) monograph[4] and a comprehensive monograph by McKenna et al.[5]

Historical/Ethnomedicine Precedent

Traditionally, SJW was used as a calming herb for symptoms of nervous tension, including anxiety and insomnia, as well as a restorative for melancholic conditions that might currently be diagnosed as depression. Folk use attributed the herb with properties of protection against enchantments, including demonic possession, and it was used for warding off evil spirits. *Hypericum* was characterized as "hot and dry" in the Galenic humoral system of medicine and has classically been associated with the liver and spleen, as well as the Sun. Historically considered a "woundwort," SJW is still used both internally and externally for pain relief, particularly neuralgic pain, shingles, mild contusions, and burns to the skin. For external use, the fresh flowers, traditionally harvested on St. John's Day (immediately following Summer Solstice), are the basis of a macerated oil, which is usually red (by the dianthrone hypericin). This red color was considered an indication of its vulnerary nature (likened to blood) by the Doctrine of Signatures. Before the modern clinical trial–driven indications of the herb for "mild to moderate depression," the nervous system indications were less clearly defined and included "psychovegetative" disorders, as well as such conditions as nocturnal enuresis and night terrors. Its psychological effects were considered much less pronounced than those of prescription medications; Weiss[6] classified the herb as a "mild (i.e., gentle) psychotropic" agent.

Known or Potential Therapeutic Uses

Analgesic, antiviral, anti-inflammatory, anxiety, coccygeal impact, concussion depression (mild to moderate), hepatoprotection, herpes simplex infection (orofacial and genital), herpes zoster (shingles and postherpetic neuralgia), menopause-related psychological symptoms, psychosomatic and somatiform disorders (mild), nervousness, neuralgia, nocturnal enuresis, photodynamic antitumor activity, premenstrual syndrome, restlessness, sacral irritation and spinal injuries, sciatica, seasonal affective disorder, tissue healing and wound repair.

Key Constituents

Characteristic napthodianthrones, including hypericin; phloroglucinols, including hyperforin and adhyperforin.
Flavonoids, including proanthocyanidin polymers of catechin and epicatechin; flavonols; phenylpropanoids; essential oil; amino acids; xanthones.

Therapeutic Dosing Range

Dried Plant: 2 to 5 g/day.
Tincture and Fluid Extract: As 1:1 equivalents, 1 to 3 mL/day.
Standardized Extracts: 900 mg/day in divided doses.
Topical: *Oleum hyperici*, oily macerate from fresh flowering tops (applied as needed).
Also used in ultradilute succussed preparations based on homeopathic indications.

INTERACTIONS REVIEW

Strategic Considerations/Background

Although an old medicine, SJW has a pivotal place in the relatively recent field of herb-drug interactions. The publication of convincing reports of interactions between SJW and digoxin[7] in 1999 and cyclosporine[8] and indinavir[9] in 2000 was seminal, initiating a widespread reevaluation of the safety of this popular herb, previously considered to be benign, in the context of conventional medications.[10] It also propelled the issue of potential interactions between botanicals and pharmaceuticals into media prominence and research focus. The subsequent years have seen increased understanding of the pharmacology of SJW, and the herb is now known to be associated with a number of clinically significant pharmacokinetic interactions, as suggested by the original reports. These interactions are mediated by its effects on several key components of drug metabolism, including the cytochrome P450 (CYP450) mixed-oxidase system, various conjugases and transferases, as well as the transporter proteins that modulate drug efflux across intestinal, renal, and biliary epithelia. These systems compose what are now often referred to as phases (or stages) I, II, and III of drug metabolism/detoxification.

The initial reports of SJW interactions with narrow-therapeutic-range drugs prompted sweeping warnings in professional and consumer media about the dangers of SJW herb-drug interactions (and often of herb-drug interactions in general). At the time, however, the actual number of reports of documented SJW-related drug interactions was, and in fact remains, relatively small, with data of widely varying reliability. Surveying the available cases in 2001, Fugh-Berman and Ernst[11] found 54 published reports claiming SJW interactions. Of these, 29 were rejected as unclassifiable, and the remaining 25 were evaluated for reliability according to the authors' "reliability rating score" system. Of these, 12 were classified as "unreliable," 11 as "possible," and only two as "likely." More recently, Meyer et al.[12] analyzed six documented potential herb-drug interactions, including SJW-cyclosporine and SJW-digoxin, across a wide range of "tertiary sources" and found high variability in the reporting of the data, with only three sources even mentioning all six known interactions. Interestingly, as recently reviewed by Izzo,[13] clinical reports of SJW-drug interactions seem to be decreasing rather than increasing in frequency.

Mills et al.[14] recently conducted a systematic review of trials investigating SJW pharmacokinetic interactions with conventional drugs. The authors found the methodological quality of the studies was limited; in particular lacking accepted controls such as correct randomization, observance of established blinding procedures, and allowance for time-dependent effects. They also found that only 15 of the 22 available studies assayed the SJW content of the preparations used, and that varied dosing regimens and duration of exposure to the herb were common, without presenting a rationale for the tested dosing patterns. These limitations mean that most trials on SJW interactions do not appear to conform to the U.S. Food and Drug Administration (FDA)–recommended standards for safeguards against bias in pharmacokinetic trials.[15] This in turn results in questions about the interpretation and applicability of the available data that can only be resolved by more and better-designed studies, as well as consistent application of necessary standards in pharmacovigilance.

Official and regulatory reaction was also triggered by the initial SJW interaction reports. In 2000 the U.K. Committee on Safety of Medicines (CSM)[16] issued a general advisory letter on SJW interactions to all physicians and pharmacists. This included a fact sheet listing medications for which SJW might interact and advised patients to "stop taking St John's Wort," while warning against immediate discontinuation in the event that drug levels might rise, causing serious adverse effects. Lists of drugs that might interact with SJW, causing "serious adverse interactions," were provided, including selective serotonin reuptake inhibitors (SSRIs), anticonvulsants, and triptans. In 2001 the Irish Medical Board (IMB)[17] restricted SJW to physician prescription only, effectively removing the herb (along with ginkgo and several others) from general public access, citing the monoamine oxidase inhibitor (MAOI) activity of SJW as potentially interacting with tyramine foods and potentiating MAOI drugs, as well as claiming SJW caused phototoxicity and other (unspecified) adverse effects. The FDA issued an advisory to health care professionals warning about the SJW-indinavir interaction in 2000, also suggesting physicians alert patients about potential drug interactions involving "any drug metabolized via the cytochrome P450 pathway."[18]

Effects on Drug Metabolism and Bioavailability

Cytochrome P450

The complete spectrum of induction and inhibition effects of SJW on the CYP450 system in vivo in humans is not yet fully characterized. Possibly because of a number of differing investigative methodologies, as well as differences between the various types of extracts used, the available studies are inconclusive. In vitro evidence exists for *inhibition* effects by crude SJW extracts, its flavonoid components, and hypericin and hyperforin on CYP450 1A2, 2C9, 2C19, 2D6, and 3A4.[19,20] In vivo studies using single probe drugs that are specific CYP substrates have found *induction* effects by SJW on 3A4,[21] and with multiprobe drug "cocktails," for 3A4, 2E1, 1A2, and 2D6[22] and 2C19.[23] By contrast, no significant effects on 2D6 and 3A4 were found by two other groups,[24,25] and a further probe cocktail study found no effect on 1A2, 2C9, or 2D6.[26] More recent studies have confirmed in vivo coordinate induction effects by SJW on hepatic and intestinal 3A4 and P-glycoprotein (P-gp).[27,28]

Summarizing the data available at this time, SJW definitely induces human 3A4; probably induces 1A2, 2C19, and 2E1; and probably does *not* significantly affect 2C9 or 2D6. It also induces P-gp and possibly other, related transporters. There is a degree of tissue specificity, with induction of both hepatic and intestinal 3A4, as well as a possible biphasic effect, at least on 3A4 and P-gp, with short-term *inhibition* followed by an *increasing induction* of enzymes over 7 to 10 days. However, evidence from isolated constituent studies suggests that hyperforin plays the main role in induction activity.[23,29-34] The initial inhibition may be caused by hypericin, but also by flavonoid constituents; a number of flavonoids are known to inhibit 3A4, with those from grapefruit and

other citrus-derived flavonoids being the best-known examples.[35,36] This "biphasic" effect of a short-term enzyme inhibition succeeded by longer-term induction has recently been demonstrated in a clinical study of voriconazole pharmacokinetics. This open-label study with 16 healthy male volunteers determined that that SJW coadministration with voriconazole (a substrate of CYP2C19) led to a short-term but clinically insignificant increase in the area under curve (AUC) of 22%, and after 15 days, AUC was reduced by 59% compared with controls.[37,38]

Pregnane X Receptor

The recent finding that hyperforin, an active phloroglucinol constituent compound of SJW, acts as a high-affinity ligand for the orphan nuclear receptor pregnane X receptor (PXR) is highly significant.[39,40] The PXR and related nuclear receptors, such as the constitutive androstane receptor (CAR) and the retinoid X receptor (RXR), have been described as "promiscuous" because of the unprecedented structural diversity of compounds that interact with their ligand-binding domain (LBD).[41-43] Activation of the PXR leads to upregulation of genes controlling multiple aspects of xenobiotic metabolism, including phase I (CYP450 1A1, 1A2, 2B6, 2C9, and 3A4) mixed oxidases, phase II conjugases (uridine diphosphate [UDP] glucuronosyltransferases, glutathione-*S*-transferases, sulfonyltransferases), and phase III drug transporters (MDR1/P-gp, MDR2, organic anion-transporting polypeptides [OATPs]).*

The implication is that the PXR and related nuclear receptors may effectively act to coordinate xenobiotic detoxification.[41-43,52-56] The PXR itself is subject to a degree of genetically determined polymorphism, the importance of which remains to be clarified, but pronounced interspecies differences are known to exist in activator compounds, with marked differences among rodent, rabbit, and human ligands.[41,57,58] Pascussi et al.[59] have aptly described expression of the genes controlling xenobiotic metabolism as a "tangle of networks of nuclear and steroid receptors, where receptors share partners, ligands, DNA response elements and target genes and where the different pathways exhibit cross-talk at several levels."

A broader view of SJW emerges from these recent developments. The herb can be conceptualized as a master inducer of detoxification, or more accurately as a *xenosensory activator*, capable of triggering the complex adaptive system evolved to metabolically eliminate toxic compounds, both endogenous and xenobiotic.[60,61] The downstream consequences of PXR activation on drug metabolism suggest that, to some extent, SJW interactions may be predicted (and thus managed) on the basis of whether a given coadministered drug is a substrate of the enzymes or transporters induced by PXR activation, particularly 3A4 and P-gp.[55,62]

P-Glycoprotein

Induction of P-gp by SJW further complicates the picture and may confound attempts to predict interactions. P-glycoprotein is a membrane-associated, adenosine triphosphate (ATP)–dependent "pumping" protein that ejects foreign or toxic compounds from cells and mediates "multidrug resistance" when induced in cancer cells. Durr et al.[28] estimated the induction of intestinal P-gp by SJW at a 1.5-fold increase in healthy human volunteers. Ernst[63] noted drugs that are dual substrates of both P-gp and CYP3A4 likely present an increased risk of pharmacokinetic interaction as a result of co-induction by SJW. However, the relative contributions of P-gp and 3A4 to drug efflux appear to be complex and differ for different agents that are dual substrates.[64]

The existence of several polymorphisms in P-gp phenotypes affects normal levels of expression of both hepatic and intestinal P-gp. These polymorphisms are known to exhibit variation with racial and gender characteristics.[65,66] As with P450 enzymes, dietary food ingredients may also affect P-gp expression; known examples include piperine from black pepper and some citrus flavonoids.[67,68] Alpha-tocopherol can also influence P-gp, probably through PXR activation.[52] Finally, the role of non–P-gp drug transporters, such as the OATP family, has recently emerged as another potential mechanism in controlling drug bioavailability, although modulating influences on OATP expression are not currently well characterized.

Overall, the interplay between CYP3A4 and P-gp (and other transporters) is not well understood, but this "drug-efflux metabolism alliance," as aptly named by Benet and Cummins,[69] remains of a crucial research area for future elucidation of drug interactions.[70,71]

Managing Pharmacokinetic Interactions

Numerous pharmaceuticals are metabolized by CYP3A4, which is a low-affinity, high-throughput P450 enzyme expressed primarily in the small intestinal mucosa and liver. This has led to suggestions that SJW may interact with more than 50% of all known drugs. Indeed, evidence is now rapidly accumulating from preclinical screening studies that confirms SJW induction effects on a range of drugs, particularly 3A4 substrates, often in the absence of any clinical interactions data. However, the magnitude of SJW induction effects is considerably less than that of other known PXR ligands, the best-known example being rifampin, a mainstay of conventional tuberculosis therapy. Rifampin is a coordinate inducer of P-gp and 3A4 with an induction effect on midazolam (a 3A4-specific substrate) that is 25 times that of SJW.[72] Red wine has similar order-of-magnitude effects as SJW on oral clearance of cyclosporine (a dual substrate).[73]

Theoretical predictions should be confirmed by clinical data before an interaction can be assumed inevitable. For example, carbamazepine is a well-known substrate and inducer of 3A4. When SJW was given for 14 days to patients previously stabilized on carbamazepine, no effect of SJW on carbamazepine kinetics or drug levels was observed.[74] This suggests that close attention must be paid to the precise metabolic pathways involved for each specific drug and to the associated effects on induction or inhibition of P450, enzymes, transferases, and transporters. Unfortunately, older drugs were not always well characterized by their manufacturers in terms of their interaction with the P450 metabolizing enzymes, leading to obvious problems for prediction and management of metabolic interactions.

Proposed coadministration should also consider different temporal patterns of combining herb and pharmaceutical agents. Three alternative scenarios are possible. First, adding an inducer (SJW) to a substrate (drug) will induce a lowering of previously stable drug levels over 1 to 2 weeks through increased drug metabolism, risking consequent loss of therapeutic efficacy. Moreover, in the case of SJW, initial inhibition may complicate this pattern, creating an apparent biphasic effect. Second, if the substrate (drug) is added to inducer (SJW), standard drug-dosing levels may be inadequate and may result in failure of therapy. Notably, this would not apply to drugs whose level is established by monitoring and

*References 19, 26, 29, 30, 32, 33, 44-51.

titration to a therapeutic endpoint (e.g., coumarin/INR value). Third, *withdrawal* of an inducer (SJW) from a regimen of previously stable coadministration with a substrate drug will reverse induction and possibly cause rebound toxicity from elevated drug levels. Theoretically, this series of patterns would be "reversed" if the drug concerned was a prodrug, depending on activation for the metabolic transformation by the CYP450 induced. Armstrong et al.[75] well describe this schema of possible pharmacokinetic interaction patterns among inducers, inhibitors, and substrates of CYP450 drug-metabolizing enzymes.

In summary, if appropriate data about metabolic pathways of a drug are available, the pharmacokinetics of any drug proposed for coadministration with SJW should be reviewed before prescription and, wherever possible, drugs metabolized by multiple routes selected. If this is not possible, and if compelling reasons exist for coadministration of the herb with the drug, precautionary measures should be adopted; this is mandatory for any drug with narrow therapeutic indices. Introduction or cessation of SJW should be ramped or tapered, respectively, and serum levels of the pharmaceutical need to be monitored to titrate drug levels and thus counter increased clearance rates. When factors such as financial cost or intermediate metabolite toxicity militate against compensatory increases in drug doses, avoidance of coadministration is the optimum management solution.

The literature on SJW interactions continues to expand, with persistent calls in secondary sources for large-scale in vitro screening of herbs to establish the "risk" of potential (pharmacokinetic) interactions with drugs. These calls ignore that drug disposition is unpredictably mediated by a wide variety of dietary[62] compounds, foods, herbs, beverages, and lifestyle products and also affected by a wide range of individual variables, from genomics through biological, lifestyle, and socioeconomic factors, all of which render meaningful screening virtually impossible.

One study analyzing responses of six different ethnic groups to SJW did not uncover significant differences in induction effects on CYP3A4 and P-gp.[76] However, Gurley et al.[77] examined CYP450 phenotypes in elderly versus younger subjects and found age-related differences in responsiveness to botanical agents regarding CYP3A4 induction, concluding that population vulnerabilities may exist in elders. The results of in vitro tests are often contradictory and may be at odds with clinical reality because of the inherent differences between experimental systems and the in vivo complexities of herbal administration; therefore these tests have limited predictive value. Butterweck et al. pointed out that logically, systematic screening for pharmacokinetic interactions should first be applied to narrow-therapeutic-index drugs.[78,79]

Some argue that understanding and managing variability in drug responses would be better than scaremongering about overstated adverse effects of herbs.[80,81] More recent mainstream papers suggest that the emphasis is beginning to shift in a more constructive direction.[62,82] Equally, the development of "low-hyperforin" extracts of SJW may provide efficacy in antidepressant indications without invoking PXR-mediated downstream effects on drug disposition.[34,83] However, hyperforin confers numerous other properties on SJW whole-plant extracts, including anti-inflammatory, antitumor, and antiangiogenic effects.[84]

Pharmacodynamic Interactions

In addition to pharmacokinetic interactions, pharmacodynamic interactions based on the antidepressant activity of SJW have been widely suggested, principally when combined with the SSRI antidepressants. The evidence for pharmacodynamic interactions is more problematic than that supporting the metabolic interactions, partly related to the general unreliability of SJW case reports, as previously noted.[11,14] Qualitative data sources such as postal surveys of psychiatrists have been used to suggest adverse reports and interactions that in effect are unassessable.[85] Safety and efficacy data from clinical trials of SJW suggest that adverse effects of the herb are an order of magnitude less (1%-3%) than those of pharmaceutical antidepressants.[86] Despite the known interactions issues, SJW remains a first-line treatment for mild to moderate depression in Europe.[87] Significantly, the adverse effect data from clinical trials of the herb suggest a completely different profile of adverse effects than with common antidepressant drugs. This correlates with current understanding of the underlying mechanisms of SJW's observed antidepressant effects. The herb is now believed to work through novel and apparently complex mechanisms, dissimilar to those of known pharmaceutical antidepressants.

Initial research presumed a typical druglike biogenic amine mechanism for SJW, but early in vitro data suggesting MAOI activity have not been substantiated by in vivo studies. Reports of hypertensive MAOI-SJW interactions are lacking, as are reliable reports of interactions between SJW and tyramine-containing food substances[88,89] (see also Theoretical, Speculative, and Preliminary Interactions Research later). Extensive research in vitro and on animals has examined the effects of both full-spectrum SJW extracts and isolated constituents on neurotransmitter uptake for serotonin, dopamine, noradrenaline, gamma-aminobutyric acid (GABA), and L-glutamate.[90-100] The emerging conclusion is that the phloroglucinol-derivative hyperforin acts as a synaptosomal uptake inhibitor for all five of these neurotransmitters. Müller[97] has described this effect as "broad-band" reuptake inhibition. The molecular mechanism of the "pseudo-nonselective reuptake" effect is thought to be related to activation by hyperforin of a sodium ion channel that causes an increase in intracellular sodium content, modifying the sodium gradient that is the common basis of all neuronal neurotransmitter transport proteins.[90,92,99,100]

Although hyperforin appears to be unique in having an approximately equal inhibitory effect on all five neurotransmitters, its effects also are at least an order of magnitude less than that of pharmaceutical antidepressants when quantified in vitro.[97] The improbability of achieving in vivo concentrations of hyperforin from oral SJW consumption that could correspond to effects of synthetic neurotransmitter uptake inhibitors is rarely considered when suggestions of "serotonin syndrome" are made relating to SJW interactions.[89] Serotonin syndrome, first characterized by Sternbach[101] in 1991, was initially described as the result of the adverse interaction of SSRIs with MAOI drugs. The clinical concept of serotonin syndrome has been overused and frequently misapplied in the drug interactions literature.[102] The concept has been reviewed and revised by Radomski et al.,[103] who found a high level of misdiagnosis and distinguished several subsets of the serotonin syndrome based on symptom severity, from transient mild symptoms to fatal toxic states. The latter must also be differentiated from neuroleptic malignant syndrome.[104]

Although hyperforin appears to be the only constituent that can affect uptake of all five neurotransmitters, it cannot be considered responsible for all the observed antidepressant effects of SJW. In some animal behavioral models of depression (e.g., the Porsolt test), hyperforin-free extracts exhibited significant activity, suggesting that other constituents have an effect. Clinical trials

with a low-hyperforin extract also demonstrated antidepressant activity against placebo, fluoxetine, and imipramine.[105,106] Furthermore, methodological controversy continues to surround clinical trials comparing SJW with placebo and pharmaceutical antidepressants, particularly because of the well-documented, powerful placebo responses associated with these trials.[107,109]

Despite the absence of definitive understanding of the mechanism of SJW antidepressant activity, caution regarding potential interactions with pharmaceutical antidepressants is more than warranted. Also, several classes of psychiatric drugs are substrates or inhibitors of CYP3A4 and P-gp, suggesting combined pharmacokinetic and pharmacodynamic interactions with SJW. Common agents likely to be encountered in general and psychiatric practice include triazolobenzodiazepines (alprazolam, estazolam, midazolam, triazolam), which are substrates of 3A4, as are the nonbenzodiazepine hypnotics zolpidem and zaleplon and the "atypical" anxiolytic buspirone.

HERB-DRUG INTERACTIONS

Alprazolam, Midazolam, and Related Triazolobenzodiazepines

Evidence: Alprazolam (Xanax), midazolam (Hypnovel, Versed). Extrapolated based on similar properties: Adinazolam (Deracyn), brotizolam (Lendormin), estazolam (ProSom), triazolam (Halcion).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

Probability: 2. Probable

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Alprazolam, midazolam, and related triazolobenzodiazepines are specific substrates of CYP450 3A4, which is induced by SJW. If the drug is added to SJW, standard dosing levels may be ineffectively low. Conversely, if SJW is added to the drug, plasma levels will be reduced after 7 to 10 days.

Research

Markowitz et al.[110] conducted an open-label preclinical study with 12 healthy volunteers using dextromethorphan and alprazolam probes as markers of CYP2D6 and CYP3A4 activity. Alprazolam was chosen because it is metabolized specifically by 3A4 and is not known to be a cosubstrate of P-gp. The oral preparation of SJW, LI60, was standardized to 0.3% hypericins and administered at 300 mg three times daily for 14 days; the probe was a single oral dose of 2 mg generic alprazolam. The measurements showed a twofold decrease in AUC for alprazolam versus time and shortening of mean half-life to 50% of the baseline. No significant differences were found between baseline and post-SJW maximum plasma levels or time taken to attain them. The kinetics of 2D6, as measured by urinary dextromethorphan, were unaffected by SJW. The study did not distinguish between intestinal mucosa and hepatic 3A4 effects. This result contrasted with an earlier study by the same group in 2000 that failed to demonstrate significant effects of SJW coadministration on alprazolam kinetics; however, the SJW administration period in that trial was only 3 days.[24]

Wang et al.[26] also studied midazolam, using both oral and intravenous doses of the drug before and after 14 days of SJW administration. They found a comparable 50% reduction in oral AUC, corresponding to a twofold clearance increase. Intravenous bioavailability was reduced 21%, suggesting significant intestinal as well as hepatic 3A4 effects.[26] Considerable interindividual variability in the level of 3A4 induction was noted in this study, and another study found a significant difference between healthy female and male subjects in the level of induction of 3A4 by SJW. This second study used a single time point, "phenotypic ratio" methodology and a drug cocktail probe that included midazolam, after 28 days of SJW administration.[22]

Although they did not find the same gender differences, Dresser et al.[64] established oral and parenteral values for midazolam kinetics after 12 days of pretreatment with SJW in 21 healthy subjects; however, interindividual differences were higher for oral than intravenous route. Their data confirmed the large decreases (55%) in oral bioavailability after SJW pretreatment reported by other investigators.

Clinical Implications and Adaptations

There are no clinical reports of this interaction, which was experimentally established by pharmacokinetic "probe" studies of P450 effects with the drug. Theoretically, the consequences of adding triazolobenzodiazepines to a stable SJW regimen are that normal drug-dosing levels will result in insufficient sedation. Conversely, inhibition rather than induction of 3A4 can cause enhanced effects, such as delirium and excessive sedation; for example, grapefruit juice with midazolam or triazolam.[111] In practice, the interaction is probably of minimal clinical significance. Intravenous midazolam is extensively used in preoperative sedation, and SJW use by elective surgical patients should be checked routinely.

Amitriptyline and Related Tertiary Tricyclic Antidepressants

Evidence: Amitriptyline (Elavil).
Extrapolated, based on similar properties: Amitriptyline combination drug: amitriptyline and perphenazine (Etrafon, Triavil, Triptazine), clomipramine (Anafranil), doxepin (Adapin, Sinequan), imipramine (Janimine, Tofranil), trimipramine (Surmontil).

Interaction Type and Significance

◇◇◇ **Impaired Drug Absorption and Bioavailability, Avoidance Appropriate**

Probability: 3. Possible

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

A complex pharmacokinetic interaction occurs between the tertiary tricyclic amitriptyline and its metabolites, including the active secondary tricyclic metabolite nortriptyline, with involvement of P450 and P-gp, resulting in decreased oral bioavailability of the drug.

Research

One preclinical study examined the effect of adding SJW at 900 mg once daily for 14 days to 12 healthy subjects pretreated with 12 days of oral amitriptyline at 75 mg twice daily. The AUC values for amitriptyline were reduced by 22% and for nortriptyline by 41%. The reduction in nortriptyline was evident after only 3 days of SJW administration. Urinary and plasma amounts of amitriptyline and metabolites varied directly with administration of its SJW. The authors suggested a P450 and P-gp mechanism would explain the observed decreases in AUC.[112]

Clinical Implications and Adaptations

There are no clinical reports of this interaction. The metabolism of tricyclic antidepressants (TCAs) is rather complex; amitriptyline is initially hydroxylated by CYP2D6 to nortriptyline, a secondary TCA which is further demethylated by other P450 enzymes before conjugation. However, nortriptyline is also an inhibitor of 2D6, which is a high-affinity, low-capacity enzyme and the rate-limiting step in transformation of TCAs. SJW is not known to affect 2D6. CYP3A4 may play a secondary "backup" role in hydroxylation. Both amitriptyline and nortriptyline are also P-gp substrates, whereas amitriptyline is a P-gp inhibitor. Polymorphisms in 2D6 are well known, and the complexity of the metabolic picture suggests that clinical consequences of coadministration are unpredictable. The conventional drug-drug interactions literature has established the potential seriousness of 2D6 *inhibition* (e.g., by fluoxetine) as a potentially serious interaction with TCAs; however, there is no obvious drug-drug precedent for P-gp/3A4 *induction*-driven interactions with TCAs. Given the unpredictable outcome of coadministration, avoiding this interaction would be a prudent strategy.

Anesthesia, General

Anesthesia, General

Related but evidence lacking for extrapolation: Halogenated inhalational anesthetic agents: Desflurane (Suprane), enflurane (Ethrane), halothane (Fluothane), isoflurane (Forane), sevoflurane (Sevorane, Ultane).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

? **Interaction Likely but Uncertain Occurrence and Unclear Implications**

Probability: 6. Unknown

Evidence Base: ☐ **Inadequate**

Effect and Mechanism of Action

Theoretically, variable pharmacokinetic and interactions with common preoperative and anesthetic agents are possible, depending on the particular agent and individual factors. Central pharmacodynamic effects have also been suggested, based on animal data for sedation times. The incidence, effects, and significance of the potential interactions are unknown.

Research

Evidence for pharmacokinetic interactions with anesthetic agents is mixed, but circumstantially compelling. The CYP3A4 probe midazolam (Versed) is used preoperatively, and its metabolism is significantly affected by SJW. The halogenated anesthetics are metabolized by CYP2E1, which has more recently been demonstrated subject to SJW induction.[22] Pharmacodynamic effects are not established, although an animal study suggested that ethanolic extracts of SJW prolong sleeping time induced by phenobarbital in rats.[113]

Reports

A patient experienced a severe episode of hypotension during a routine surgical procedure and was initially unresponsive to intravenous epinephrine, which the author attributed to SJW after the patient admitted to regular SJW use in the 6 months before the procedure (dose and preparation unspecified). The author suggested that adrenergic modulation by the herb had affected the sympathetic responsiveness to the drug, and that the herb was the only logical "offending agent," having failed to find alternative explanations for the mechanism of circulatory collapse.[114] This speculation does not appear to have any foundation in the known pharmacology of the herb, and attributing causation involves implausible logic. Further investigations in animal models would be appropriate.

Clinical Implications and Adaptations

Disclosure of all herbal and nutrient consumption is accepted as mandatory before elective surgery, the primary objective being to audit for possible disturbances in normal hemostasis induced by herbal medicines and similar agents before the procedure.

Induction effects of SJW on P450 and P-gp may be considered sufficiently complex by some anesthesiologists to mandate patient cessation of SJW before surgery, which would require at least 10 days for complete reversal of enzyme induction. This is arguably a judgment call that could be made on the basis of individual case history and indications for antidepressant therapy, as well as expert knowledge of the pharmacokinetics of the drugs to be used. Exaggeration of possible dangers from herbal consumption may be counterproductive by reinforcing patient reluctance to disclose usage. Pharmacodynamic interactions with central sedation from SJW seem improbable from the known pharmacology of the herb, and any minor effects would be unlikely to present untoward management issues in the context of high-profile inpatient clinical settings such as surgical procedures.

Antiretrovirals: Protease Inhibitors and Nonnucleoside Reverse-Transcriptase Inhibitors

Evidence: Indinavir (Crixivan); nevirapine (Viramune).

Similar properties but evidence lacking for extrapolation:

Protease inhibitors: Amprenavir (Agenerase), atazanavir (Reyataz), brecanavir, darunavir (Prezista), fosamprenavir (Lexiva), neltinavir (Viracept), ritonavir (Norvir), saquinavir (Fortovase, Invirase), tipranavir (Aptivus); combination drugs: lopinavir and ritonavir (Aluvia, Kaletra), saquinavir and ritonavir (SQV/RTV).

Nonnucleoside reverse-transcriptase inhibitors (NNRTIs): Delavirdine (Rescriptor), efavirenz (Sustiva).

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

Probability: 2. Probable

Evidence Base: ○ **Preliminary** (although apparently ● **Consensus**)

Effect and Mechanism of Action

All known protease inhibitors and nonnucleoside reverse-transcriptase inhibitors (NNRTIs) are metabolized by CYP3A4 and are also probable cosubstrates of P-gp. It is established that SJW increases oral clearance of the typical representative of both classes of antiretrovirals (indinavir and nevirapine), although evidence for other drugs in either class is lacking. Theoretically, this may lead to decreased therapeutic efficacy; however, case reports are lacking.

Research

The first study to investigate this interaction remains the most quoted. Piscitelli et al.[9] reported a small, open-label "before and after" trial in 2000, in which eight healthy male volunteers were administered 800 mg oral indinavir for 2 days to establish baseline kinetics of the protease inhibitor. From day 3, participants were given SJW (0.3% hypericin) 300 mg three times daily for 14 days, then another 800 mg oral dose of indinavir was given, for which AUC of the drug decreased by 57% compared to baseline.[9] The authors did not comment on indinavir being both a highly potent inhibitor of 3A4, which it also moderately induces, and an inhibitor of intestinal P-gp.[115,116] These factors suggest that extrapolation from this study to in vivo steady-state coadministration is not possible.

A case-series analysis by de Maat et al.[117] used retrospective nonlinear analysis of variance on a cohort of human immunodeficiency virus (HIV) patients whose serum nevirapine had been checked routinely every 3 months. The authors reviewed five patients who admitted concomitant use of SJW (dose and preparation not specified), with at least one serum reading reflecting a period of SJW coadministration and one of nevirapine alone. These patients showed a significant increase in oral clearance (35%; $p = 0.02$) of nevirapine during SJW use. Nevirapine is also a moderate autoinducer of the two P450 enzymes of which it is a substrate, 3A4 and 2B6.

Clinical Implications and Adaptations

The interaction with indinavir was highly publicized, and advisories from regulatory bodies in the United Kingdom and United States recommended that coadministration of all antiretrovirals with SJW be avoided.[16,18] Management by avoidance may be an appropriate strategy to eliminate interaction, but this official consensus was based on a single preclinical study of one protease inhibitor. The authorities did not mention that the clinical pharmacology of HIV and acquired immunodeficiency syndrome (AIDS) is a field in which complex interactions are the norm. The antiretrovirals in particular display a wide range of highly volatile and variable interactions, both pharmacokinetic and pharmacodynamic, with other drugs as well as with each other. Pharmacogenomic factors also play a major but currently little-acknowledged role in treatment of individuals with HIV/AIDS.[118]

This interactivity of the antiretroviral drugs is well known among HIV/AIDS specialist providers and many HIV/AIDS patients. The pharmacokinetic effects of the drugs on P450 enzymes are extensive and vary considerably between different drugs; for example, indinavir potently inhibits and induces 3A4, whereas ritonavir is a powerful pan-inhibitor of most P450 enzymes and a specific inducer of 3A4, 1A2, 2C9, and 2C19. Pronounced interactions of antiretrovirals with each other and many drugs are well established, and prescribing regimens for HIV and AIDS patients often involve empirical antiretroviral drug cocktails. Additional polypharmacy with other drugs is also likely, depending on individual status. Viral load is invariably monitored as an indicator of antiviral therapeutic efficacy. Serum drug levels are often monitored directly, and serum dosage, timing of administration, and drug combinations may be adjusted accordingly and frequently. Extrapolation from the one available (and limited) study on one agent to all known antiretrovirals is at best an oversimplification, at worst a suspect (and potentially counterproductive) judgment call.

St. John's wort aroused interest in the late 1980s and early 1990s because of its potential as an antiretroviral agent, but preliminary studies with both the herb and synthetic hypericin (the purportedly active anti-HIV constituent) were disappointing. Nonetheless, patients may incorporate SJW by self-prescription into their treatment protocols for indications such as depression. Such cases would require vigilant attention to viral load monitoring or (preferably) serum drug levels before and after initiation of SJW. Theoretically, once a stable level of SJW administration was established, long-term management issues of coadministration would be routine for clinicians experienced in the field, although financial costs may also be a significant factor if substantial increases in drug dose were required to maintain therapeutic levels.

Cyclosporine

Cyclosporine (Ciclosporin, cyclosporin A, CsA; Neoral, Sandimmune, SangCya).

Interaction Type and Significance

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

◇◇◇ **Impaired Drug Absorption and Bioavailability, Avoidance Necessary**

Probability:
1. Certain

Evidence Base:
● **Consensus**

Effect and Mechanism of Action

Cyclosporin A (CsA) is a dual substrate of both P-glycoprotein and of CYP450 3A4, both of which are induced by SJW. Addition of SJW to previously stable cyclosporine patients will result in significant reductions in drug levels and the possibility of therapeutic failure of immunosuppression. The interaction is well documented and considered established.

Research

The induction effects of SJW on 3A4 and P-gp are established. Cyclosporine is a cosubstrate whose disposition is controlled by both proteins, with P-gp (MDR1) affecting intestinal absorption and biliary excretion, and intestinal and hepatic 3A4 both contributing to first-pass metabolism.[119-121] Bauer et al.[122] recently described a case series of 11 renal graft patients maintained with immunosuppressive regimens incorporating CsA who were administered relatively low doses of SJW (600 mg once daily) for 14 days. Dose-corrected CsA levels decreased more than 40%, and CsA had to be increased from 2.7 to 4.1 mg/kg/day to maintain therapeutic levels. Interestingly, these figures correspond closely to the increase in clearance for cyclosporine found by Dresser et al.[27] in a preclinical study designed to quantify the relative levels of P-gp and 3A4 induction in the effects of SJW. They estimated induction effects of SJW on cyclosporine to be 1.6-fold after oral administration.[27] The authors note that unexplained discrepancies remain in data on the effects of coordinate induction on dual-substrate compounds. According to their results, increased cyclosporine clearance caused by SJW is not only less than that of a unique 3A4 substrate, such as midazolam, but also an order of magnitude less than that induced by pretreatment with rifampin, also a SXR/PXR ligand, as is hyperforin.[72] Dresser et al.[27] conclude that other, as yet undefined, mechanisms (e.g., OATPs) may be involved.

Reports

The multiple case reports of the cyclosporine-SJW interaction make it the best documented of the SJW pharmacokinetic interactions. The initial *Lancet* report in early 2000 by Ruschitzka et al.[8] described two cardiac transplant patients who developed acute rejection responses after starting SJW. Serum levels of cyclosporine were depressed, and after

intensification of immunosuppressive therapy and cessation of the herb, the acute rejection responses were reversed, and plasma cyclosporine levels returned to normal. Fugh-Berman and Ernst[11] rated this report as "likely" with a maximum score of 9/9 points on their reliability rating scale; however, other reports have been poorly documented, providing minimal data for evaluation. In a more recent review of 11 available reports, Ernst[63] concluded that the clinical evidence for actual decreases in cyclosporine levels in transplant patients was conclusive, and that the risk of acute rejection was significant. Several reports noted decreased serum levels of cyclosporine after SJW administration in renal and cardiac graft patients, fortunately before rejection episodes.[122-125] Since the original Ruschitzka report,[8] two other cases of acute rejection have been documented, one involving a renal-pancreatic graft and the other a hepatic graft patient.[126,127]

Clinical Implications and Adaptations

The addition of SJW to previously stable regimens of immunosuppression based on CsA will clearly cause serum levels of the drug to fall, approximately 1.5-fold according to the available data. This is considerably less than the effect of known pharmaceutical inducers and about equivalent to the effect of consuming red wine.[73] Cyclosporine levels are regularly monitored in transplant patients, so theoretically, coadministration with professional management does not present insurmountable problems. Upward adjustment in oral dosing of the drug sufficient to maintain effective plasma levels to compensate for the metabolic induction by the herb should, all other factors being equal, maintain immunosuppression if coadministration were to be adopted. However, because the metabolites of cyclosporine also exhibit nephrotoxicity, increased drug ingestion to maintain therapeutic levels may risk increased toxic effects; furthermore, because the drug is expensive, cost factors would not favor this approach.

In reality, risks from the cyclosporine interaction are most likely with undisclosed self-prescription of the herb by allograft patients unaware of the potential dangers; this has been the case with all the reported cases of graft rejection to date. The real risk of acute rejection in such patients has led to publicity emphasizing the need for disclosure and the counseling of transplant patients on potential dangers of adding SJW to immunosuppressive protocols. (See also Tacrolimus later.)

Digoxin, Digitoxin, and Related Cardiac Glycosides

Evidence: Digoxin (Digitek, Lanoxin, Lanoxicaps, purgoxin), digitoxin (Cystodigin).
Related but evidence lacking for extrapolation: Deslanoside (cedilanin-D), ouabain (g-strophanthin).

Interaction Type and Significance

✗✗ **Potentially Harmful or Serious Adverse Interaction—Vigilance Necessary**
◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

Probability: 1. Certain

Evidence Base: ▽ **Mixed**

Effect and Mechanism of Action

A pharmacokinetic interaction arises because digoxin is a specific substrate for P-gp, which is induced by SJW. The effects of coadministration may be biphasic, depending on the sequence and manner of combining herb and drug. The clinical significance of the interaction is not established.

Research:

The induction effects of SJW on intestinal P-gp are known (see Strategic Considerations earlier). Digoxin and related cardiac glycosides are substrates of P-gp, and the inhibition of P-gp by cardiac drugs such as verapamil and quinidine is the known mechanism of several well-established drug interactions involving digoxin that lead to increased cardiac glycoside toxicity. The original study by Johne et al.,[7] implicating SJW in a pharmacokinetic interaction with digoxin, found a 25% decrease in digoxin AUC after 10 days of treatment with oral SJW, 900 mg once daily, in healthy subjects with previously stabilized digoxin levels by serum monitoring. Importantly, a 10% increase in digoxin levels was found with single-dose addition of SJW, but this value was not statistically significant and is never reported in the secondary literature. A subsequent "before and after" study by Durr et al.[28] examined the induction effects of SJW on intestinal P-gp/MDR1 and intestinal and hepatic 3A4. After 14 days of SJW administration in healthy volunteers, SJW increased intestinal P-gp by 1.4-fold and decreased the AUC of a standard 0.5-mg digoxin dose by 18% compared with baseline.[28]

Although these two studies are in broad agreement about the long-term effects of SJW on digoxin kinetics, it is possible that the effect of SJW on digoxin may be biphasic, mirroring the behavior of fexofenadine (Allegra), another P-gp specific substrate that has been used as a probe in experimental investigations of P-gp. Wang et al.[26] investigated this hypothesis in a study that confirmed the biphasic effects of SJW on drug transporter kinetics. They found the effect of a single oral dose of SJW (900 mg) administered within 1 hour of 60 mg fexofenadine decreased the clearance of the drug by 20%, resulting in a 45% *increase* in serum drug level ($p < 0.05$). Long term, however, there was a 35% *decrease* in maximum plasma concentrations after 14 days of SJW administration at 900 mg once daily.[26]

A recent study by Mueller et al.[128] examined the effects of 10 forms of SJW preparation and different doses of several forms on digoxin kinetics. The preparations included SJW dried herb tea, powdered crude herb, fresh plant juice, standardized extracts with high and low hyperforin content (LI60, Ze 117), and infused oil, as well as a placebo control. Healthy volunteers ($n = 93$) were stabilized on digoxin at 0.2 to 0.3 mg three times daily for 1 week, followed by adding SJW concurrently for 14 days. Only two of the SJW preparations tested, the LI60 and high dose of *Hypericum* powder (4 g once daily, with comparable hyperforin content to LI60), produced comparable and significant reductions in digoxin maximum concentration (C_{max}) and $AUC_{0\text{-}24}$. The reductions in AUC were approximately 25% and in C_{max} approximately 37%, with 95% confidence interval (CI). The dose of the SJW preparations that failed to generate significant changes in digoxin pharmacokinetics correspond to dosage levels given for traditional use in therapeutic monographs, such as Commission E and ESCOP (2-4 g crude herb daily),[2,4] suggesting a probable difference in the capability to induce interaction effects between traditional herbal prescription and hyperforin/hypericin standardized concentrated extracts.

At present, data are insufficient to characterize fully the mechanisms of the interaction. However, the OATP family, in addition to P-gp, may be implicated. There is a specific transporter for digoxin (OATP-8),[129] and digoxin transport was shown to be more affected by naturally occurring

bioflavonoids operating on P-gp than on OATP in an in vitro model.[130] In a recent poster study, SJW completely abolished P-pg–mediated digoxin transport in vitro.[50] A recent immunohistochemical study identified another transporter, OATP-4C1, that mediates digoxin, ouabain, triiodothyronine, and methotrexate transport in a sodium-dependent manner and is located in the proximal tubule of the human nephron.[131] Further research is required to fully elucidate the various mechanisms of digoxin disposition.

Reports

Case reports of subtherapeutic digoxin levels after addition of SJW to previously stable digitalized patients are unavailable. A single report is available that describes the predicted pattern of cessation of an inducer (SJW) causing rebound drug toxicity. An 80-year-old man stable on digoxin consumed 2000 mL of SJW tea daily. On cessation of the tea, he developed nodal bradycardia and bigeminy, which was treated successfully with digoxin (FAB). The original report is in Serbian and unavailable for full evaluation.[132]

Clinical Implications and Adaptations

Addition of SJW to a stable digoxin level may result in a short-term increase in drug levels potentially capable of inducing classic digitalis toxicity. However, longer-term coadministration risks inducing a decline in drug levels after induction of transporter proteins. This could theoretically lead to therapeutic failure if not corrected.

Introduction of SJW to patients already stabilized on digoxin should therefore initially follow a ramped dose increase of the herb over several days, rather than starting at 100% of the target dose, to avoid possible short-term inhibitory effects on drug transport. Once stable therapeutic doses are attained, serum digoxin level monitoring should drive any adjustment in cardiac glycoside dosage to compensate for transporter induction. Discontinuation of the herb must also be tapered, to avoid rebound digitalis intoxication resulting from the reversal of induction.

Patients stable on cardiac glycoside therapy must be counseled on the potential risks of unsupervised addition or withdrawal of SJW. However, the order of magnitude of these effects is similar to that resulting from dietary ingredients, particularly citrus bioflavonoids and red wine,[35,51,130,133] and is not itself a compelling reason to avoid coadministration if clinically indicated.

Etoposide and Related Topoisomerase II Inhibitors

Evidence: Etoposide (Eposin, Etopophos, Vepesid, VP-16). Extrapolation based on similar properties: DNA topoisomerase II inhibitors: Daunorubicin (Cerubidine, DaunoXome), doxorubicin (Adriamycin, Rubex), doxorubicin, pegylated liposomal (Caelyx, Doxil, Myocet), epirubicin (Ellence, Pharmorubicin), idarubicin (Idamycin, Zavedos), mitoxantrone (Novantrone, Onkotrone), teniposide (Vumon).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

? **Interaction Likely but Uncertain Occurrence and Unclear Implications**

Probability: 4. Plausible

Evidence Base: ☐ **Inadequate**

Effect and Mechanism of Action

Combined pharmacokinetic and pharmacodynamic interaction is possible. Etoposide is partially metabolized through CYP3A4 and is therefore subject to SJW induction, while the naphthadianthrone constituent hypericin pharmacodynamically interferes with the etoposide-mediated cytotoxicity in vitro. The clinical significance of this plausible interaction is not established.

Research

Peebles et al.[134] investigated the mechanism of action by which hypericin interfered with the topoisomerase (topo) II poisons, using an HL-60 cell-line model. The study was partially motivated by the initial hypothesis that hypericin may exhibit leukemogenic toxicities, because these are known to be associated with topo II agents. The mechanism of action of hypericin was unlike that of etoposide (and amsacrine), resembling the effect of topo II catalytic inhibitors that operate upstream of etoposide to inhibit etoposide effects, protecting the HL-60 cells from etoposide-mediated damage.[134] Methodologically, extrapolations are not directly possible to in vivo situations with oncology patients, and the dose-response curves of the hypericin effects were not established. However, as Block and Gyllenhaal[135] noted in a review of herb-drug interactions in cancer chemotherapy, etoposide is also metabolized by 3A4 before renal elimination.

Clinical Implications and Adaptations

Cancer patients are likely candidates for self-prescription of SJW, and concurrent use of botanical and dietary agents during chemotherapy should be audited closely. Information about putative antitumor activity of hypericin is available on the Internet, and purified hypericin can currently be obtained as a "dietary supplement," suggesting the possibility of undisclosed self-prescription. At present, insufficient data are available to establish the in vivo effects of hypericin and SJW interactions with any chemotherapy agents (see also Irinotecan [CPT-11] discussion), although the potential clearly exists for a reduction of cytotoxic efficacy through several pharmacokinetic mechanisms, and in the case of etoposide, additional pharmacodynamic factors may be involved. Combining nutritional and botanical agents with chemotherapy is a specialist field, and professionals experienced in integrative oncology should be involved in any decisions on coadministration.

Fexofenadine

Fexofenadine (Allegra)

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

◇ **Impaired Drug Absorption and Bioavailability, Negligible Effect**

Probability: 3. Possible

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

The histamine H_1-receptor antagonist fexofenadine hydrochloride is a documented substrate of P-gp that is induced by SJW, and the herb is known to be capable of modifying fexofenadine levels. The clinical effect and significance are likely minimal because of the wide therapeutic index of the drug.

Research

Fexofenadine is a specific substrate of P-gp and is eliminated without undergoing significant metabolism. It has been used as

a probe drug in preclinical investigations of P-gp pharmacokinetics because of its high specificity for the transporter and because it is relatively well tolerated, with few adverse effects over a widely varying dose range. Notably, the manufacturer's information suggests an absence of effects on QT interval for doses ranging from 60 to 400 mg twice daily in healthy individuals. The innocuous characteristics of the drug have been used to analyze the behavior of P-gp substrates with a much narrower therapeutic index, such as digoxin (see previous SJW-digoxin section).[27,51,133,136]

Clinical Implications and Adaptations

Despite substantial evidence of the ability of SJW to affect fexofenadine levels, the interaction itself lacks case reports and is probably of minimal clinical significance. Given the wide therapeutic index of the drug in clinical practice, as well as the likelihood of patient self-adjustment of drug dosage levels to treat allergic symptoms as required, coadministration with SJW appears unproblematic. The inclusion of this interaction in lists of SJW interactions without qualification in the secondary literature is arguably a case of "overstatement." (See Theoretical, Speculative, and Preliminary Interactions Research later.)

Imatinib

Imatinib (Gleevec, Glivec)

Interaction Type and Significance

◇◇◇ **Impaired Drug Absorption and Bioavailability, Avoidance Appropriate**

Probability:
3. Possible

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

A pharmacokinetic interaction in which SJW may reduce serum levels of the active metabolite of the tyrosine kinase inhibitor, causing possible decrease in drug exposure. Preliminary evidence supports the interaction, and imatinib is known to be metabolized by 3A4.

Research

A study recently reported by Frye et al.[137] investigated the possible interaction of SJW and the 3A4 substrate imatinib with 12 healthy volunteers, comparing single-dose oral clearance of the drug (400 mg) before and after 14 days of SJW (300 mg three times daily) pretreatment. Clearance was increased by 44%, AUC decreased by 30%, and the half-life and C_{max} were also decreased. Cytochrome P450 3A4 is the primary metabolic pathway that has been described for the drug, although individual variability in response to the drug (resistance) may result from pharmacogenomic mechanisms not yet adequately described. The 3A4-inducer phenytoin has also been shown to reduce AUC of imatinib to about 20% of the typical AUC_{24}, and this was reversed by ketaconazole.[138]

Clinical Implications and Adaptations

Given the serious indications for Gleevec, including chronic myelogenous leukemia (CML) and gastrointestinal stromal tumors (GIST), accurate dosage levels should be confidently maintained for the clinical populations involved. Cancer patients are arguably likely to self-prescribe with SJW for depression and should be cautioned to avoid the herb during Gleevec treatment. Alternatively, if preexisting treatment with SJW has had significant positive impact on quality of life, and if alternative approaches have been poorly tolerated, higher doses of imatinib, with serum drug level monitoring, would be indicated.

Irinotecan

Irinotecan (Camptothecin-11, CPT-11; Campto, Camptosar).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

◇◇◇ **Impaired Drug Absorption and Bioavailability, Avoidance Appropriate**

Probability:
4. Plausible

Evidence Base:
☐ **Inadequate**

Effect and Mechanism of Action

SJW may reduce serum levels of the active metabolite of the camptothecin analog CPT-110. The mechanism of interaction is complex, and pharmacogenetic factors can cause high individual variability in drug levels. A resultant decrease in tumor cytotoxic exposure is possible. Because of the known complexity of irinotecan metabolism and the wide variability in individual responses to the drug, the clinical significance of the interaction is not known.

Research

One small, unblended, crossover study involved five cancer patients treated with intravenous CPT-11 before and after SJW administration for 18 days at 900 mg once daily. Serum concentrations of the active cytotoxic metabolite SN38 (7-ethyl-10-hydroxy CPT) were reduced by a mean of 42% after SJW administration. Myelosuppression was less in the SJW phase, indicating a reduced chemotoxicity. This is significant because toxicity (NCI Common Toxicity Grading Criteria) often governs dose adjustment in irinotecan chemotherapy regimens. In fact, the statistical mean of this small sample of patients was derived from a range of 14% to 79%, typical of the wide interindividual variation in responses to the drug.

Clinical Implications and Adaptations

Irinotecan pharmacokinetics have been well documented and are known to be highly complex.[139-141] The prodrug is converted to the active compound SN38 by serum carboxylases; subsequent metabolism is through hepatic UGT1A1 glucuronidation and biliary excretion, which depends on a canalicular multispecific transporter (cMOATP). The conjugated form undergoes enterohepatic recirculation. The prodrug is secondarily transformed by 3A4 into two inactive metabolites, APC and ANC, which form 2% to 8% of the eliminated compounds. Finally, SN38 is 94% albumin bound in plasma. Considerable potential metabolic variability exists; hepatic microsomes display a thirteenfold variation in rate of SN38 formation, and genetically determined polymorphisms of UGT1A1 play a role in response variation. Significant pharmacokinetic interactions with conventional drugs have been observed with competitors and inducers of the glucuronidation process more than with 3A4-specific inducers, and P-gp induction (biliary) may also play a part in irinotecan interactions.[142]

More data are required before the effects of SJW on irinotecan metabolism can be accurately identified. Several authors have raised important questions about the possibility of SJW interactions with chemotherapeutic agents through induction of metabolism and transport.[135,143,144] The area is important, especially because of the possible effects of SJW on multidrug resistance through P-gp; oncologists, as well as integrative primary care providers supporting cancer patients undergoing

conventional chemotherapies, should be cognizant of the issues, despite the lack of definitive data. Dosing of these agents by body surface area seems a seriously outmoded practice, given the narrow therapeutic index of cytotoxic chemotherapy agents, the well-established wide variations in serum drug levels caused by genetic polymorphisms of drug-metabolizing enzymes, and the potential interactions with other drugs and dietary components as well as with herbal and nutritional agents (many as yet unknown), often unreported by patients to their oncologists.

The development of widely available clinical laboratory tests for cytotoxic chemotherapy drug levels and their routine utilization should be encouraged to enhance efficacy and reduce toxicity in the clinical practice of medical oncology. Such tests have been routinely used for decades with agents of much larger therapeutic indices, such as phenytoin (Dilantin) and digoxin. Development and utilization of serum chemotherapy drug levels tests would greatly simplify management of the underlying genetic polymorphisms affecting these levels and would help uncover covert use of self-prescribed herbal and nutritional agents, as well as allowing prescribers to compensate for such coadministration when indicated or reasonable.

Omeprazole and Related Proton Pump Inhibitors

Evidence: Omeprazole (Losec, Prilosec).
Extrapolated, based on similar properties: Esomeprazole (Nexium), lansoprazole (Prevacid, Zoton), pantoprazole (Protium, Protonix, Somac), rabeprazole (AcipHex, Pariet).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

Probability:	Evidence Base:
2. Probable	○ **Preliminary**

Effect and Mechanism of Action

A pharmacokinetic interaction occurs between SJW and omeprazole, and possibly with related benzimidazole drugs, which are metabolized by 3A4 and 2C19, resulting in a lowering of drug levels caused by enzyme induction by SJW. The interaction is experimentally confirmed, but clinical reports are lacking to date.

Research

A recent, randomized, crossover trial examined the effects of SJW pretreatment (300 mg three times daily) for 14 days on the single-dose kinetics of 20 mg oral omeprazole and its metabolites.[23] The 12 healthy volunteers were phenotyped for 2C19 polymorphisms because these are known to affect the metabolism of the substrate omeprazole. The drug is metabolized by two routes, involving sulfoxidation by 3A4 and hydroxylation by 2C19, so the separate metabolites (5-hydroxymeprazole and omeprazole sulfone) were measured in plasma by high-performance liquid chromatography (HPLC) along with the parent drug. Substantial decreases in omeprazole C_{max} (37.5%) and AUC (49.6%) [$p < 0.001$] were found with SJW pretreatment. The wild-type variants of 2C19 or "extensive metabolizers" (EMs) also displayed significant increases in 5-hydroxy metabolite levels, but "poor metabolizer" (PM) phenotypes showed lower effects. Xie[145] elaborated on the authors' interpretation of this study, noting that the 3A4 pathway is a minor metabolic route, and because omeprazole is also a competitive inhibitor of 2C19, as well as a substrate and inhibitor of the efflux transporter P-gp, that the disposition of the drug involves integrated effects of multiple pathways.

Clinical Implications and Adaptations

The authors of the previous study suggest that SJW induces 3A4 and also 2C19, the latter in a genotype-dependent manner, to the extent that significant increases in drug doses would be necessary during herb-drug coadministration to compensate for the induction effects by the herb.[23] The benzimidazoles do not have a narrow therapeutic index, and there are currently no clinical reports of this interaction; however, the size of the observed experimental effects suggests that the interaction could be clinically significant. Physicians prescribing proton pump inhibitors must consider the need for increased dose levels if there is prior stable usage of SJW, and adding SJW to omeprazole may significantly reduce previously stable drug levels.

Oral Contraceptives and Related Estrogen-Containing and Synthetic Estrogen and Progesterone Analog Medications

Evidence: Oral contraceptives: monophasic, biphasic, and triphasic estrogen preparations:
Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCept 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).
Related but evidence lacking for extrapolation:

Progestin-only oral contraceptives, implants, and postcoital contraceptives: Etonogestrel, implant (Implanon); levonorgestrel, implant (Jadelle, Norplant; Norplant-2); levonorgestrel, oral postcoital contraceptive (Duofem, Escapelle, Levonelle, Levonelle-2, Microlut, Microval, Norgeston, NorLevo, Plan B, Postinor-2, Vika, Vikela); medroxyprogesterone, injection (Depo-Provera, Depo-subQ Provera 104); medroxyprogesterone, oral (Cycrin, Provera); NES progestin, implant (ST-1435, Nestorone); norethindrone, oral (norethisterone; Aygestin, Camila, Errin, Jolivette, Micronor, Nor-QD, Ortho-Micronor); norethindrone, injectable (NET EN; Noristerat); norgestrel, oral (Ovrette).

Hormone replacement therapy (HRT), estrogens: Chlorotrianisene (Tace); conjugated equine estrogens (Premarin); conjugated synthetic estrogens (Cenestin); dienestrol (Ortho Dienestrol); esterified estrogens (Estratab, Menest, Neo-Estrone); estradiol, topical/transdermal/ring (Alora Transdermal, Climara Transdermal, Estrace, Estradot, Estring FemPatch, Vivelle-Dot, Vivelle Transdermal); estradiol cypionate (Dep-Gynogen, Depo-Estradiol, Depogen, Dura-Estrin, Estra-D, Estro-Cyp, Estroject-LA, Estronol-LA); estradiol hemihydrate (Estreva, Vagifem); estradiol valerate

(Delestrogen, Estra-L 40, Gynogen L.A. 20, Progynova, Valergen 20); estrone (Aquest, Estragyn 5, Estro-A, Estrone '5', Kestrone-5); estropipate (Ogen, Ortho-Est); ethinyl estradiol (Estinyl, Gynodiol, Lynoral).

HRT, estrogen/progestin combinations: Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); conjugated equine estrogens and norgestrel (Prempak-C); estradiol and dydrogesterone (Femoston); estradiol and norethindrone, patch (CombiPatch); estradiol and norethindrone/norethisterone, oral (Activella, Climagest, Climesse, FemHRT, Trisequens); estradiol valerate and cyproterone acetate (Climens); estradiol valerate and norgestrel (Progyluton); estradiol and norgestimate (Ortho-Prefest).

HRT, estrogen/testosterone combinations: Esterified estrogens and methyltestosterone (Estratest, Estratest HS).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

◈◈ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

Probability: 3. Possible

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

A pharmacokinetic interaction may theoretically result from SJW induction of estrogen and progestin metabolism, causing increased clearance and lowered serum drug levels, resulting in "breakthrough bleeding" and theoretically a risk of contraceptive failure, although failure is not established. Variability in oral contraceptive (OC) product formulations and known interindividual variability of responses to exogenous hormones confounds simple interpretation of the currently available data. Clinical significance of the interaction is not established.

Research

The metabolism of OCs is highly complex and incompletely characterized; the pharmacokinetics of steroidal hormones is subject to considerable interindividual variability because of the sheer complexity and number of metabolic pathways involved and the polymorphisms they exhibit. Also, significant differences in formulation exist between different OC products. By consensus, 3A4 is considered to the major P450 enzyme for metabolic transformation of both estrogens and progestins. However, the original OC estrogenic compound mestranol is in fact activated by 2C9 to ethinyl estradiol (EE). Similarly, the common progestin ingredient desogestrel is also a prodrug, metabolized by 2C9 to the active metabolite 3-ketodesogestrel. Glucuronidation and sulfation by the relevant transferase enzymes adds further variability because of polymorphisms in the transferase enzyme systems, which are also subject to induction and inhibition. Finally, conjugated EE is also hydrolyzed by bowel flora and undergoes enterohepatic recirculation, unlike the progestins. In turn, OCs themselves are mild inhibitors of 3A4 and more pronounced inhibitors of 1A2 and 2C19, although their effects on the clearance of other drug substrates of these enzymes are not well researched.

One pilot study has examined the effects of SJW on concentrations of circulating androgens by immunoassay after administration of the herb to healthy volunteers (six female, six male) for a 14-day period sufficient for CYP3A4 induction. No significant changes in androgen levels resulted from SJW administration, although there was a small reduction in the level of 5α-reduced androgens, more so in women than in men.[146]

Two recent controlled studies addressed the effects of SJW on combination OC therapy with regard to ovarian activity, the possibility of contraceptive failure, and the kinetics of the steroidal components of the OC products used.[147,148] The clinical findings of both trials were similar and confirmed that SJW coadministered with combination OCs increased breakthrough bleeding but did not result in ovulation (as recorded by endosonographic measurement). The studies differed significantly in other findings.

Pfrunder et al.[148] found no changes in ethinyl estradiol AUC with SJW coadministration, at either 600 mg or 900 mg SJW daily doses with a combination OC (EE/desogestrel), but the progestin metabolite 3-ketodesogestrel decreased significantly at both these dosage levels. This metabolite is generated by 2C9 (and possibly 2C19), then further metabolized by 3A4. The authors suggested that 2C9 may be inhibited by hyperforin or apigenin constituents of SJW because of in vitro evidence for 2C9 inhibition,[19] or that 3A4 induction was responsible for the decrease, despite the apparent lack of effect on EE. This study did not examine hyperforin or hypericin levels, although the extract used (LI160) had high hypericin and hyperforin content.

Hall et al.[147] coadministered 900 mg SJW once daily for two cycles with Ortho-Novum (a combination OC containing EE/norethindrone) and examined a more comprehensive set of parameters. These included hyperforin levels, follicle-stimulating hormone (FSH), luteinizing hormone (LH), progesterone, pharmacokinetic parameters for norethindrone and EE, and oral and intravenous values for the 3A4 probe midazolam.[147] The clearance of EE was increased by 47% by SJW coadministration, but this was not deemed significant ($n = 12$). Norethindrone clearance increased by 16%. The midazolam probe data suggested that the changes were caused by intestinal rather than hepatic 3A4 induction, since systemic clearance was not changed but oral clearance increased by 50%. Hyperforin levels averaged a steady-state level of 20 ng/mL; however, a large (threefold) variation was noted between the subjects in hyperforin levels, which may reflect the variability in response rates. Breakthrough bleeding was positively correlated with significantly higher midazolam oral clearance. Larger studies are needed to confirm definitively whether SJW will permit ovulation during OC therapy, but both trials suggest that this is unlikely.

Reports

Despite media publicity, anecdotal reports of "miracle babies" born to women using SJW concurrently with OC therapy remain unsubstantiated.[149] Reports in the professional literature are sparse and contribute no useful data to establishing the incidence and significance of the possible SJW-OC interaction. The earliest report was in correspondence to the *Lancet* in 1999 that gave no details for three purported cases of breakthrough bleeding associated with combination OCs and SJW coadministration.[10] Another *Lancet* letter contained a report from Sweden by Yue et al,[150] (see also warfarin-SJW later) that mentioned "eight cases of intermenstrual bleeding and one report of changed menstrual bleeding from manufacturers of SJW products."[121] Patient history, details of the OC preparation, and SJW form and dose were not given. No contraceptive failure was mentioned. Fugh-Berman and Ernst[11] later classified the Yue reports as "unreliable."

A single case of contraceptive failure involved a 36-year-old patient with a history of depression and use of pharmaceutical antidepressants who stopped all pharmaceutical

treatment in favor of SJW (1700 mg once daily, a high dose). After 3 months, while still taking a combination OC (EE/dienogestrel), she conceived unexpectedly.[64] A midwifery magazine article also reports unwanted pregnancies as occurring while SJW was used, citing cases drawn from several government agency reports: from the U.K. Medicines Control Agency (MCA; seven cases) and from Sweden and Germany (four cases). None of these has been documented in professional literature, except the Swedish reports already mentioned, although the British MCA warned that the SJW-OC interaction would result in risk of unintended pregnancy in its advisory letter to practitioners and pharmacists.[16]

Clinical Implications and Adaptations

In the conventional drug interactions literature, induction of CYP450 3A4 and uridine glucuronosyltransferase (UGT) has been shown to increase EE and progestin clearance and is typically associated with increased symptoms of breakthrough bleeding. Ovulation parameters have not been well studied in this area, but ovulation with pharmaceutical 3A4/UGT inducers has not been reported.[151,152] The few reports of pregnancies resulting from combining conventional drugs with OCs are rare and almost impossible to evaluate. The situation appears similar with SJW-OC interactions. The risk of actual unwanted pregnancy seems small, but unquantifiable, at present.

Breakthrough bleeding, although associated with initial phases of OC therapy alone, appears to be increased by SJW coadministration. Bleeding is also associated with decreased compliance with OC therapy and thus indirectly with increased risk of contraceptive failure as other, less reliable alternative forms of contraception are adopted to avoid undesirable symptoms. Despite the lack of solid evidence for failure of contraception due to SJW, women using OCs concurrently with the herb should be advised about the risks and should consider the simultaneous use of barrier methods.

Given the contemporary trend toward "ultra-low" dosage of EE in commercial OC preparations because of concerns over adverse effects, the risks of contraception failure may be marginally higher than with the earlier, higher-dose products. Most available data relate only to combination products. Extrapolations to progestin-only minipills, to implants, and to postcoital "morning-after" pills cannot be drawn from current data.

The effect of SJW on hormone replacement therapy (HRT) has not been studied, although SJW is likely to have some impact on estrogen clearance in HRT. Because this population has no vulnerability to unwanted pregnancy, it would appear to be a lower priority for further research. The complex field of sex steroid molecular biology and metabolism will presumably yield more conclusive data in the future.

Paclitaxel, Docetaxel: Taxane Microtubule-Stabilizing Agents

Evidence: Docetaxel (Taxotere), paclitaxel (Paxene, Taxol). Similar properties but evidence lacking for extrapolation: Paclitaxel, protein-bound (Abraxane).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

◇◇◇ **Impaired Drug Absorption and Bioavailability, Avoidance Necessary**

Probability:
3. Possible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

This possible pharmacokinetic interaction could influence drug availability, although biotransformation of taxanes is primarily through CYP2C8. Multiple mechanisms are thought to underlie response variability and drug resistance to taxanes.

Research

Komoroski et al.[153] used a human hepatocyte model to test the effects of rifampin and hyperforin on the induction of docetaxel metabolism compared with controls. Hyperforin addition increased metabolism of the drug in a dose-dependent manner, with 1.5-micromolar hyperforin causing a sevenfold increase over control. The rifampin increased drug metabolism by a factor of 32. The authors concluded that chronic coadministration of SJW with docetaxel may reduce drug bioavailability to subtherapeutic levels. Wada et al.[154] used an MDR1-overexpressing line of HeLa cancer cell model and found that both hypericin and SJW lowered the antiproliferative activity of paclitaxel while inhibiting MDR1-mediated drug transport.

Clinical Implications and Adaptations

The taxanes are widely used in the treatment of breast, prostate, lung, and ovarian cancers. Body surface area (BSA) dosing is standard practice, but variability in responsiveness and resistance to the drugs is well documented. Paclitaxel is metabolized by CYP2C8, with minor CYP3A4 and CYP3A5 involvement, whereas docetaxel is primarily metabolized by 3A4 and 3A5. Administration of docetaxel with ketoconazole leads to a significant decrease in drug clearance (49%), suggesting that docetaxel disposition will be affected by 3A4 inducers and inhibitors in vivo.[155] Paclitaxel, although primarily metabolized by 2C8, has been shown to be influenced by 3A4 induction.[138] Further complexity arises when considering taxane resistance, which is thought to be at least partly caused by drug efflux pump mechanisms.

At present, avoidance of SJW with taxane administration is indicated. Modulation of taxane metabolism by induction of CYP450 by SJW has been emphasized as a problem (e.g., see Sparreboom et al.[144]). In context, however, there is considerable potential for improving the taxane-based pharmacotherapy by application of pharmacogenomics data to dosing.[156] Information about the difference, if any, between the traditional taxane drugs and the novel liposomal forms in terms of their metabolic degradation pathways is unavailable at this time.

Paroxetine and Related Selective Serotonin Reuptake Inhibitor and Serotonin-Norepinephrine Reuptake Inhibitor (SSRI and SSRI/SNRI) Antidepressants and Nonselective Serotonin Reuptake Inhibitors (NSRIs)

Evidence: Paroxetine (Aropax, Deroxat, Paxil, Seroxat); nefazodone (Serzone), trazodone (Desyrel).
Extrapolated, based on similar properties: Bupropion (Wellbutrin), citalopram (Celexa), duloxetine (Cymbalta), escitalopram (*S*-citalopram; Lexapro), fluoxetine (Prozac, Sarafem), fluvoxamine (Faurin, Luvox), mirtazapine (Remeron), sertraline (Zoloft), venlafaxine (Effexor).

Interaction Type and Significance

? **Interaction Likely but Uncertain Occurrence and Unclear Implications**

Probability:
3. Possible

Evidence Base:
○ **Preliminary** (arguably □ Inadequate)

Effect and Mechanism of Action

These complex, potential interactions involve variable pharmacokinetic and pharmacodynamic factors, depending on the specific serotonin uptake drug, the timing and manner of herb-drug coadministration, concurrent comedications, and individual factors. "Serotonin syndrome" has been suggested as a possible clinical outcome of the interaction, but this is controversial and poorly documented, and precise mechanisms for such effects are not consistent with known SJW pharmacology. Few clinical reports are available and are of variable quality. Overall, the clinical significance of the interaction may be overstated.

Research

This proposed interaction was originally based on early assumptions about SJW pharmacology that have not been confirmed by recent research. The first was the erroneous belief that SJW functions as a MAOI-like agent, and the interaction with SSRIs was simply an assumed extrapolation from the known drug-drug MAO-A inhibitors and serotonin reuptake agents. The in vitro findings of MAO inhibition have not been replicated and have been suggested by Cott[89] to be artifactual (see Theoretical, Speculative, and Preliminary Interactions-Research later). The second assumption was that SJW exerts its antidepressant effects through a druglike serotonin uptake inhibition, thus leading to excessive serotonin levels, and the possibility of serotonin syndrome if combined with a pharmaceutical SSRI. As previously noted, the neurotransmitter effects of SJW do not appear to be homologous to any pharmaceutical drug action on specific neurotransmitter pathways; rather, this appears to be a "broad-band" effect on the reuptake of all five main central neurotransmitters.[94] Finally, "serotonin syndrome" may have been overenthusiastically reported; a significant proportion of cases probably resulted from misdiagnosis, according to Radomski et al.[103] (see Reports).

Given the likelihood that SJW extracts may act biphasically, inhibiting 3A4 in acute short-term doses, with progressive induction of P-gp and 3A4 at 7 to 10 days, adverse reactions caused by the addition of SJW to preexisting SSRI regimens may be the result of a short-term pharmacokinetic interaction, parallel to the digoxin-SJW interaction. This hypothesis might help explain the effects reported by Lantz (see Reports), which are more like enhanced adverse effects of the drug than "serotonin syndrome." Because each of the six principal SSRI drugs has different routes of metabolism, as well as different inhibitory profiles on P450 enzymes, the situation becomes more complex if the interaction is indeed pharmacokinetic. The respective CYP450 metabolic properties and pathways of the selective and nonselective serotonin uptake drugs are listed in the table.[157]

As data in the table show, none of the serotonin reuptake inhibitor (SRI) drugs is an exclusive substrate of 3A4; that nefazodone and norfluoxetine (the active metabolite of fluoxetine) are potent inhibitors of 3A4; and that nefazodone, trazodone, and venlafaxine also induce P-gp. It therefore seems unlikely that short-term inhibition would inevitably produce excessive serotonin levels, whereas the predominant effect of long-term coadministration should be for SSRI drug levels to be lowered by SJW induction, with a consequent decrease in serotonin levels. Further research is needed to clarify the precise extent and role of pharmacokinetic factors in different SJW-SRI drug combinations.

Reports

Reports of serotonin syndrome (SS) arising from the coadministration of SJW and SSRI/NSRI drugs are rare, particularly in Europe.[86] However, ominous warnings of the potentially fatal consequences of SS often accompany secondary accounts of SJW interactions in the United States. This appears unnecessarily alarmist because all six of the known fatalities in the toxicology literature for SS were caused by toxic encephalopathy (on postmortem examination), and five were deliberate drug overdoses involving the MAO-A inhibitor moclobemide with citalopram or clomipramine.[158] Other severe symptoms of toxic SS include disseminated intravascular coagulation (DIC), resulting in renal failure. These should be distinguished from the common symptoms of mild SS, which include myoclonus, tremor, diaphoresis, and restlessness, all of which are transient and self-limiting and do not usually require medication changes or supportive treatment.[103]

A frequently cited U.S. case series is from a geriatric care facility reported by Lantz in 1999; four elderly patients

Metabolism of Serotonin Reuptake Inhibitor Drugs

Drug	Major P450 Metabolism Site(s)	Inhibits	Induces
Selective Serotonin Reuptake Inhibitors (SSRIs)			
Citalopram	2C19, 2D6, 3A4	2D6	
Escitalopram	2C19, 2D6, 3A4	2D6	
Fluoxetine	2C9, 2C19, 2D6, 3A4	1A2, 2B6, 2C9, **2C19**, **2D6**, 3A4 (+ norfluoxetine)	
Fluvoxamine	1A2, 2D6	**1A2**, 2B6, 2C9, **2C19**, 2D6, 3A4	
Paroxetine	2D6	1A2, **2B6**, 2C9, 2C19, **2D6**, 3A4	
Sertraline	2B6, 2C9, 2C19, 2D6, 3A4	1A2, 2B6, 2D6, glucuronidation	
Nonselective Serotonin Reuptake Inhibitors (NSRIs)			
Bupropion	2B6	**2D6**	
Mirtazapine	1A2, 2D6, 3A4		
Nefazodone	3A4, 2D6	**3A4**, P-gp (acute)	P-gp
Trazodone	3A4, 2D6		P-gp
Venlafaxine	2D6	2D6	P-gp

Modified from Cozza.[157]
Bold-face text denotes pronounced effects; *P-gp*, P-glycoprotein.

who were stable on sertraline commenced SJW and experienced symptoms diagnosed by the author as "central serotonergic syndrome." However, the data for at least one of the four cases were inadequate, according to the Ernst and Fugh-Berman criteria (failure to list comedications), and in none of the cases was the herbal preparation fully identified.[11] The primary symptoms for all four were nausea and in three, vomiting. These symptoms alone are atypical of SS; according to a detailed review of all 62 published cases from 1982 to 1995 by Radmoski et al.,[103] nausea occurred in only 6%, and vomiting was never recorded. The fifth elderly woman in the same series was stable on nefazodone and experienced the same symptoms after adding SJW. The case presents problems of interpretation, even assuming a short-term pharmacokinetic inhibition of CYP 3A4. Nefazodone is a powerful 3A4 inhibitor and only likely to exhibit interactions with a more potent inhibitor than itself,[157] which rules out a SJW effect. Sertraline is cometabolized by multiple P450 CYPs (2B6, 2C9, 2C19, 2D6, *and* 3A4; see table), which suggests it would only be vulnerable to pharmacokinetic interactions with pan-inhibitors or pan-inducers, which excludes SJW. This suggests that the interaction may have been pharmacodynamic, but the antidepressant effects of SJW in vivo are mild, take several weeks to manifest, and are not equivalent to the pharmaceutical SSRI/NSRI drug mechanisms. Despite its frequent invocation as confirming the SJW-SSRI interaction, the Lantz report is inconclusive, and the authors' explanations are not consistent with the currently understood pharmacology of SJW.

Another case report involved a woman who became lethargic, having discontinued paroxetine (40 mg once daily) after 8 months, and who began 600 mg of SJW powdered herb daily (preparation unspecified) 10 days later. On the second day of this regimen she also took a single dose of paroxetine (20 mg) to help with insomnia. The next day she was almost unable to rise from bed and was groggy and incoherent but arousable. Two hours later she still complained of fatigue, weakness, and nausea, although her vital signs and mini–mental status examination were normal. Twenty-four hours later she had no remaining ill effects.[159] The reporting physician described this as resembling a "sedative/hypnotic syndrome" intoxication. Interpretation of this case must account for paroxetine being a potent inhibitor of 2D6, the enzyme of which it is a substrate; the 10-day washout after the prolonged paroxetine therapy may have caused 2D6 to rebound, rendering the patient hypersensitive to a subsequent repeat dose of the SSRI. CYP2D6 is well known to exhibit "slow" and "fast" polymorphisms. This report is probably a case of excessive sedation resulting from enhanced effects of the drug, rather than a pharmacodynamic SJW interaction. Several in vivo studies have examined short-term and long-term effects of SJW on 2D6, the current consensus being a lack of observable effect for short-term inhibition or longer-term 2D6 induction.[24,26,31,29]

Nirenberg et al.[160] recorded mania in two depressive patients in temporal association with SJW consumption. Both patients had initially been diagnosed with major depression, and before initiating prescription psychiatric drugs, they had experimented with SJW. In an interesting conjecture, the authors suggested the resulting manic episodes were caused by an "unmasking" of rapid-cycling bipolar disorder, supported by both patients subsequently responding to lithium therapy. The authors advise that patients should be screened for episodes of hypomania and mania by their physician before the recommendation of SJW for depression.

A brief French report, drawn from the official Marseilles pharmacovigilance database, described a 32-year-old man with a history of depression who added SJW "mother tincture" to his regimen of venlaxafine.[161] In herbal pharmacy practice, "mother tincture" refers to 1:10 hydroethanolic extract of crude fresh herb. After 3 days of SJW at 200 drops three times daily, the patient developed symptoms of anxiety, hyperhydrosis, and tremor. These reversed on cessation of the SJW tincture. The authors note that the normal dose of this type of SJW preparation is 160 drops total per day, and the dose taken was 600 drops, more than triple the recommended level. The symptoms, however, do correspond to those described for mild SS. Venlafaxine is also a potent inhibitor not only of serotonin reuptake, but also of dopamine, which might make it more prone to interact with the pan-neurotransmitter reuptake inhibitor effects of SJW.

Integrative Therapeutics, Clinical Concerns, and Adaptations

The nature of the SJW-SRI interaction remains controversial, although enhanced serotonin effects appear probable under some circumstances. Further data are required before the mechanisms, incidence, and clinical significance can be adequately characterized. Physicians and psychiatrists experienced in psychopharmacology are usually aware of potential drug-drug interactions. The notoriety of SJW as a potential interactor with antidepressants is well known among mental health professionals, many of whom prescribe SJW alone as first-line therapy for mild depression, particularly in Europe.[85]

At a professional level, SJW coadministered for specific therapeutic goals does not present significant problems, given appropriate monitoring. Specifically, SJW may be used empirically before starting pharmaceutical antidepressant therapy, or it may be used to assist tapered withdrawal from antidepressant therapy, particularly with SSRIs, which are subject to withdrawal symptoms of varying severity. An alternative viewpoint adopted by some providers is to "err on the side of caution," refrain from using SJW to support withdrawal, and only commence herbal therapy following a suitable washout period after cessation of the SRI, usually 3 weeks. Polypharmacy presents challenges that are unpredictable, as illustrated in the report by Spinella and Eaton[162] involving ginkgo, SJW, fluoxetine, and buspirone (see Buspirone later).

Simvastatin and Related HMG-COA Reductase Inhibitors (Statins)

Evidence: Simvastatin (Zocor).

Extrapolated, based on similar properties: Atorvastatin (Lipitor), lovastatin (Altocor, Altoprev, Mevacor); combination drug: lovastatin and niacin (Advicor); simvastatin combination drug: simvastatin and extended-release nicotinic acid (Niaspan).

Similar properties but evidence indicating no or reduced interaction effects: Fluvastatin (Lescol, Lescol XL), pravastatin (Pravachol), rosuvastatin (Crestor).

Interaction Type and Significance

◈ **Impaired Drug Absorption and Bioavailability, Negligible Effect**

Probability:
3. Possible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Simvastatin is a prodrug and cosubstrate for 3A4 and P-gp. Serum levels of active metabolite may be lowered by concomitant administration with SJW because of the induction of drug

efflux and metabolism. Clinical effects of the interaction have not been established. Different statins are metabolized quite differently, and the interaction cannot be extrapolated to all 3-hydroxy-3-methylglutaryl–coenzyme A (HMG-CoA) reductase inhibitors as a class.

Research

A single, small, double-blind crossover trial used two groups of eight healthy volunteers to investigate the effects of SJW versus placebo pretreatment on single-dose simvastatin (10 mg) and pravastatin (20 mg) kinetics. SJW was administered at 300 mg three times daily for 14 days and 24-hour blood samples taken. No changes were found for pravastatin, but the active metabolite simvastatin hydroxy acid (SVA) showed a significant decrease in AUC after SJW compared with placebo.[163] Simvastatin, lovastatin, and atorvastatin are all similar lactone prodrugs and cosubstrates of P-gp and 3A4, showing similar responses to 3A4/P-gp inhibitors such as itraconazole. CYP3A4 is probably only involved with a minor degree of transformation of pravastatin and fluvastatin, neither of which are prodrugs, and which do not appear to affect P-gp.[164]

Clinical Implications and Adaptations

Lowering of SVA levels by concomitant administration with SJW suggests theoretically that lipid-lowering targets may not be achieved because of underexposure to the drug. Clinical data are not available and would not necessarily be expected to emerge from case reports, given other known issues for statin therapy failure, such as poor long-term compliance. Duration of SJW administration, if taken for mild depression indications, can be many months, and statin therapy is often similarly continued for extended periods. If long-term coadministration is proposed, statins such as pravastatin or fluvastatin should be selected because these do not share the 3A4/P-gp characteristics of simvastatin and lovastatin. Newer statin drugs such as rosuvastatin have different P450/P-gp characteristics and may also be selected over simvastatin or lovastatin.

Tacrolimus

Tacrolimus (FK-506, fujimycin; Prograf).

Interaction Type and Significance

✗✗✗ Potentially Harmful or Serious Adverse Interaction—Avoid

◇◇◇ Impaired Drug Absorption and Bioavailability, Avoidance Necessary

Probability: 1. Certain

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

Tacrolimus is a macrolide immunosuppressant that is a dual substrate of P-gp and 3A4, both of which are induced by SJW. Addition of SJW to previously stable tacrolimus regimens will result in significant reductions in serum drug levels and the risk of therapeutic failure and nephrotoxicity because of its narrow therapeutic and toxicological indices.

Reports

A single case report suggested that a renal graft patient previously stable on tacrolimus took SJW, 600 mg once daily for a month, and serum drug levels were depressed, reversing after cessation of the herb.[165]

Research

Two studies have confirmed this important interaction. A small preclinical "before and after" investigation on 10 healthy volunteers examined tacrolimus single oral doses before and after 18 days of SJW administration at 300 mg three times daily. Oral tacrolimus clearance was significantly increased by 59% and AUC significantly reduced by 50% after SJW administration.[166] Mai et al.[167] studied a case series of renal graft patients stable on a combination of tacrolimus and mycophenolic acid to examine the effects of adding SJW (300 mg twice daily, a lower-than-usual dose); after 14 days of SJW administration, tacrolimus levels decreased significantly from 180 to 75.9 ng/mL/hour. The median dose adjustment of tacrolimus to correct the herb induction effects was almost double, from 4.8 to 8.0 mg once daily.[167] Mycophenolic acid levels were unaffected.

Clinical Implications and Adaptations

The tacrolimus interaction is analogous to that of SJW-cyclosporine, as discussed earlier. Both agents are used in allograft patients for suppression of cell-mediated immunity, and the risks of therapeutic failure (acute graft rejection) are potentially fatal. Clinical case reports of rejection reactions caused by SJW interactions with tacrolimus are lacking. Whether this is caused by widespread avoidance of coadministration following publicity of the SJW-cyclosporine interaction is unknown.[63] The nephrotoxicity of tacrolimus is high, and upward adjustment of dose to compensate for pharmacokinetically induced increases on oral clearance will increase risks of toxicity.[165] This toxicity potential as well as the increased financial cost of higher dose regimens suggests that despite the theoretical possibility of steady-state coadministration with SJW being managed using routine serum monitoring of drug levels, in practice this is not a feasible option, and the combination should be avoided.

Verapamil and Related Calcium Channel Blockers

Evidence: Verapamil (Calan, Calan SR, Covera-HS, Isoptin, Isoptin SR, Verelan, Verelan PM).

Extrapolated, based on similar properties: Amlodipine (Norvasc); combination drug: amlodipine and benazepril (Lotrel); bepridil (Bapadin, Vascor), diltiazem (Cardizem, Cardizem CD, Cardizem SR, Cartia XT, Dilacor XR, Diltia XT, Tiamate, Tiazac), felodipine (Plendil), combination drugs: felodipine and enalapril (Lexxel), felodipine and ramipril (Triapin); gallopamil (D600), isradipine (DynaCirc, DynaCirc CR), lercanidipine (Zanidip), nicardipine (Cardene, Cardene I.V., Cardene SR), nifedipine (Adalat, Adalat CC, Nifedical XL, Procardia, Procardia XL); combination drug: nifedipine and atenolol (Beta-Adalat, Tenif); nimodipine (Nimotop), nisoldipine (Sular), nitrendipine (Cardif, Nitrepin); verapamil combination drug: verapamil and trandolapril (Tarka).

Interaction Type and Significance

✗ Potential or Theoretical Adverse Interaction of Uncertain Severity

◇◇ Impaired Drug Absorption and Bioavailability, Precautions Appropriate

Probability: 2. Probable

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

A pharmacokinetic interaction between SJW and verapamil may be by induction of presystemic drug metabolism at the

intestinal mucosa by SJW. The interaction is experimentally confirmed with verapamil, but clinical reports are lacking to date. The interaction is likely to occur with related calcium channel blockers, most of which are substrates of CYP450 3A4.

Research

A pharmacokinetic study used a jejunal perfusion technique to examine the pharmacokinetics of racemic verapamil before and after SJW treatment (14 days, 300 mg three times daily) in eight healthy volunteers.[168] By comparing the levels of verapamil and its 3A4 metabolite norverapamil in perfusate and plasma, the investigators were able to localize the site and mechanism of the interaction. They concluded that the notable reduction in AUC (approximately 80%) of both *R*- and *S*-enantiomers of verapamil after pretreatment with the herb was caused by presystemic metabolism by 3A4, primarily at the intestinal wall.

Clinical Implications and Adaptations

Verapamil is a well-known substrate of 3A4, as are the majority of calcium channel blockers. *R*-/*S*-verapamil is also metabolized to some extent by 2C9 and by 2E1, unlike most other calcium channel blockers. Verapamil is also an inhibitor of 3A4, although not as potent as diltiazem. The related calcium channel blocker mibefradil was withdrawn because of the severity of its 3A4 and 2D6 inhibition-related adverse interaction effects. Verapamil is also an inhibitor of P-gp. The single available study does not illuminate the kinetics of sustained in vivo coadministration of SJW and the drug, and predicting the net results of combined autoinhibition of 3A4 and P-gp by the drug, with SJW induction of the same metabolic factors, is problematic.

Verapamil is well known in the conventional literature to exhibit metabolic interactions with digoxin, beta blockers, antineoplastic agents, and alcohol. Theoretically, coadministration with SJW may increase drug levels required for management of the condition, typically angina (including variant or Prinzmetal's angina), hypertension, atrial flutter or fibrillation, and supraventricular tachycardia. At present, given the lack of reports of the interaction, normal standards of vigilance and monitoring relating to calcium channel blocker polypharmacy are probably adequate until evidence to the contrary becomes available.

Voriconazole and Related Triazole Antifungal Agents

Evidence: Voriconazole (Vfend).
Extrapolated, based on similar properties: Fluconazole (Diflucan), itraconazole (Sporanox), posaconazole (Noxafil).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

Probability:	Evidence Base:
2. Probable	○ **Preliminary**

Effect and Mechanism of Action

A pharmacokinetic interaction between SJW and voriconazole, which are metabolized by CYP450 3A4, 2C9, and 2C19, resulting in a lowering of drug levels due to enzyme induction by SJW. The interaction is experimentally confirmed, but clinical reports are lacking to date.

Research

Rengelshausen et al.[87] examined the disposition of single doses of voriconazole in 16 healthy male volunteers stratified by CYP2C19 genotype on day 1 and day 15 of concomitant SJW administration (300 mg three times daily, extract LI160). They found an overall decrease in AUC at day 15 of up to 59%, broadly equivalent to the effect of SJW on tacrolimus and cyclosporine. In addition, they found that 2C19 wild type (extensive metabolizer) exhibited the lowest exposure to the antifungal drug. The clearance data revealed an initial but insignificant increase in plasma levels of the drug after onset of SJW administration. This is a predictable result of the "biphasic" effect of SJW flavonoids mechanistically inhibiting CYP450, followed by a more potent effect of induction (see Effects on Drug Metabolism and Bioavailability).[38]

Clinical Implications and Adaptations

The novel antifungal voriconazole is used in patients with invasive aspergillosis and other serious fungal invasions. Therapeutic dosing is critical and, in SJW coadministration, should be avoided. The manufacturer's data on voriconazole do not recommend 2C19 phenotyping, although the wild-type polymorphism would appear to be at risk for lowered drug exposure.

Warfarin and Oral Vitamin K Antagonist Anticoagulants

Evidence: Phenprocoumon (Jarsin, Marcumar), warfarin (Coumadin, Marevan, Warfilone).
Extrapolated, based on similar properties: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan).

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

Probability:	Evidence Base:
5. Improbable	▽ **Mixed**

Effect and Mechanism of Action

This suggested pharmacokinetic interaction could result in a pharmacodynamic decrease in the international normalized ratio (INR) because of lowered drug levels. Theoretically, the risk is decreased anticoagulation, but clinical reports of thrombosis caused by coadministration are lacking. The incidence and significance of the interaction are not established.

Research

A poster study examined the kinetics of single-dose oral phenprocoumon after SJW administration in 10 healthy males age 18 to 50 years.[169] SJW was given at 300 mg three times daily for 10 days, and the dose of phenprocoumon was 12 mg on day 11. AUC of phenprocoumon was significantly decreased ($p = 0.0007$) in the SJW group. Phenprocoumon is a warfarin analog unavailable in the United States but widely used in Europe. It is pharmacodynamically identical in action to warfarin but is well known to have different pharmacokinetics, its half-life being considerably longer than that of warfarin.[170] As with *S*-warfarin, it is metabolized by 2C9, but evidence indicates that the active sites on the 2C9 enzyme are different for warfarin and phenprocoumon, which may account for the difference in kinetics.[171] Currently available direct evidence suggests SJW in vivo lacks effect on either 1A2 or 2C9.[26] Cott[89] suggested that P-gp effects may cause a reduction in absorption at the enterocyte level, resulting in reduced drug levels. Circumstantial support for this hypothesis comes from a rodent model in which oral warfarin levels were reduced after

SJW treatment, but hepatic microsomal levels of CYP450 were unaltered.[172]

A human study examining warfarin pharmacogenomics showed that a specific haplotype for ABC1 (the *mdr1* gene encoding for P-gp) was consistently overexpressed in a "low-dose" warfarin group; at present, however, it is not clear whether warfarin isomers are substrates of P-gp transporters or other, as-yet uncharacterized transporters.[173] It is known that the principal pharmacogenetic determinants of variability in warfarin kinetics are older age and the common 2C9 polymorphisms, 2C9*2 and 2C9*3.[174-177] A subsequent open-label trial examined the effects of ginseng and SJW pretreatment on warfarin kinetics in 12 healthy volunteers, using laboratory parameters (INR, derived from prothrombin time) and pharmacokinetic data (plasma levels of *S*- and *R*-enantiomers of warfarin and urinary *S*-7-hydroxywarfarin levels). Pretreatment with SJW resulted in significant effects on clearance of warfarin and reduction in INR.[178] However, the INR changes were a mean of 21%, well below the value suggested by Wells et al.[179] for "level 1 evidence" of a substantive interaction between warfarin and another agent. The ginseng pretreatment had no effect.

Reports

The only available and often-cited report of warfarin-SJW interaction is a case series summarized in a 2000 letter to the *Lancet* from Yue and colleagures[180] of the Swedish Medical Products Agency in a correspondence generated by the commentary on SJW safety by Ernst.[10] The series involved seven patients (six elderly, three male and four female) who apparently experienced reductions in previously stable INR after starting SJW (preparation, dose, and duration unspecified). None of the patients experienced thromboembolic episodes, and dose adjustment or cessation of herb apparently restabilized INR in all cases, although details were not given. Fugh-Berman and Ernst[11] later reviewed this report in their survey of interaction report reliability and found the Swedish reports scored "unreliable" and were effectively unevaluable. In an original and rigorous literature survey of warfarin drug-food interactions, Wells et al.[179] suggested that because of the variability of warfarin responses, only twofold INR changes (i.e., 50% or 200% stable value) should be admitted as "level 1 evidence" of an interaction on warfarin induced by another agent. In fact, three of seven INR values in the Swedish series met this criterion. However, comedications, comorbidities, and patient histories, as well as dose, preparation form, and duration of SJW administration, were not recorded, and the report must remain classified as unreliable.[11]

Clinical Implications and Adaptations

The absence of reliable reports of the interaction, especially given that warfarin is the most widely prescribed anticoagulant in the Western world and SJW remains a popular herbal medication, suggests that the interaction has minimal clinical significance, if it indeed exists. The phenprocoumon trial indicates some effect in younger healthy patients, but the use of this drug in Germany (Jarsin) has not been associated with adverse reports in combination with SJW, at an incidence level of two cases per million prescriptions of Jarsin, according to figures given at a recent ESCOP symposium.[180] If SJW has an induction effect on warfarin pharmacokinetics, there may be some reduction in drug levels if SJW is added to stably warfarinized patients. The degree of INR change is probably relatively small, about 20%, according to available preclinical data (males). Because INR monitoring is essential as a concomitant of warfarin therapy, however, management of coadministration should theoretically present no problems if monitoring procedures are maintained or increased, with dose-adjustment corrections made accordingly. Discontinuation of SJW from a stable regimen of coadministration would be more critical, potentially resulting in excessive anticoagulation and the risk of bleeds. However, this appears to be a theoretical concern at present, particularly compared to the many known determinants of anticoagulation variability in response to warfarin, from 2C9 polymorphisms through dietary factors and numerous drug-drug interactions.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Buspirone

Buspirone (Buspar).

In a survey of SJW interactions by Izzo,[13] buspirone-SJW was listed as an interaction. This was based on an isolated case report by Spinella and Eaton,[162] reporting "hypomania" after the addition of both SJW and ginkgo to buspirone. The patient was in fact comedicated with fluoxetine, and paradoxical interactions between fluoxetine and buspirone have been recorded in the conventional drug literature, including adverse reactions, the mechanism of which is not understood.[113] Although buspirone is metabolized by CYP3A4, the interaction cannot be reliably deduced from this report. Fluoxetine is also well known to precipitate manic episodes in patients with bipolar disorders misdiagnosed as unipolar depressive disorders.

Chlorzoxazone

Chlorzoxazone (Paraflex, Parafon Forte, Relaxazone, Remular-S).

The antispasmodic skeletal muscle relaxant chlorzoxazone is metabolized exclusively by CYP2E1 and used experimentally as a probe for phenotyping poor and fast metabolizing expressions of this enzyme. The recent investigation of the effect of several herbs on P450 phenotyping probes by Gurley et al.[22] was the first demonstration of a possible in vivo induction of 2E1 by SJW using chlorzoxazone as a probe drug. Interactions of the drug are rare, and human case reports are lacking. The induction of 2E1 by SJW appears unlikely to constitute a clinically significant interaction. The effect of SJW is probably no greater than induction of 2E1 by chronic ethanol consumption or tobacco use. The most significant established interaction involving induction of 2E1 is in the production of *N*-acetyl-*p*-benzoquinone imine (NAPQI), the hepatotoxic metabolite of acetaminophen. NAPQI is produced when acetaminophen intoxication exceeds available glutathione stores and is metabolized by 2E1 instead of glutathione-*S*-transferase, resulting in fulminant hepatic failure. At present, however, the SJW-chlorzoxazone interaction is overstated, and potential for SJW involvement in acetaminophen hepatotoxicity remains conjectural.

Loperamide

Loperamide (Imodium A-D, Imodium A-D Caplets, Kaopectate 1-D, Maalox Anti-Diarrheal, Pepto Diarrhea Control).

Loperamide is an opioid derivative lacking central nervous system (CNS) effects that is used for treatment of diarrhea. It is metabolized by CYP3A4 and is a substrate of P-gp (thus does not cross the blood-brain barrier). A letter described a single case of delirium in a 39-year-old woman with a history of migraines and depression, apparently stable on a regimen of "two tablets of St. John's wort and a valerian tablet daily" (preparation and dose not specified) for 6 months. She was admitted to the emergency room in a confused, disoriented state. She was

afebrile and tachycardic with elevated blood pressure, and a toxicology screen was positive for opioids. Subsequent history revealed she had taken loperamide for diarrhea. The patient had a previous history of admission because of Demerol (meperidine) intoxication. The authors suggested that the interaction was a MAOI type between SJW and loperamide.[181] This is speculation unsupported by the known pharmacology of SJW; further aspects of the report are "unreliable" in that doses of SJW and loperamide were not given, and the access of the patient to Demerol and her history of drug use increase the possibility of covert meperidine use. Pharmacokinetic interaction with SJW can be ruled out; it would have decreased rather than increased drug toxicity. Nonetheless, this speculative interaction is usually included without comment in secondary reviews.[78]

Monoamine Oxidase (MAO) Inhibitors

MAO-A inhibitors: Isocarboxazid (Marplan), moclobemide (Aurorix, Manerix), phenelzine (Nardil), procarbazine (Matulane), tranylcypromine (Parnate).
MAO-B inhibitors: Selegiline (deprenyl, L-deprenil, L-deprenyl; Atapryl, Carbex, Eldepryl, Jumex, Movergan, Selpak); pargyline (Eutonyl), rasagiline (Azilect).

Early recommendations that SJW should not be coadministered with MAO inhibitors were based on extrapolation of putative MAOI and catechol-*O*-methyltransferase (COMT) activity from in vitro studies, which have not been substantiated experimentally or demonstrated in vivo (see Strategic Considerations earlier). In a survey, 862 psychiatrists in Australia and New Zealand were questioned about SJW use and adverse effects. No cases of hypertension were noted, although two (<1%) claimed reports of palpitations as an adverse effect of SJW alone. Five reports of interaction with moclobemide were noted, but these could not be evaluated due to lack of details.[85]

There is a brief report of otherwise-unexplainable hypertension associated with prescribed SJW alone (Ze 1117, 250 mg twice daily for 1 week) that reversed on cessation of the herb. The herb was self-prescribed for stress, and the patient lacked previous cardiovascular history and took no other drugs.[182] The correspondent speculatively attributed this episode to norepinephrine uptake inhibition by SJW. Another case described a 41-year-old man admitted to the emergency room with confusion, disorientation, tachycardia, and hypertension (blood pressure, 210/140) who was negative for toxicology screen and numerous other laboratory and diagnostic tests, which ruled out pathological causes. He apparently took no concurrent medications or nutritional supplements. History revealed use of SJW (dose and preparation not specified) and consumption of cheese and red wine immediately before the episode.[183] This report is the only one suggesting a tyramine food interaction with SJW, but unfortunately the dose and preparation of the herb (and possible other ingredients) were not identified, and thus the report is not evaluable. At this time, advice to avoid tyramine-containing foods with SJW seems unnecessary.

Photosensitizing Agents

Delta-aminolevulinic acid (d-ALA)

Phototoxicity is frequently suggested as a possible adverse effect of SJW, although published human case reports are lacking. According to official German adverse drug interaction (ADR) data reviewed by Schulz,[86] reversible skin photosensitization responses have been reported at a rate of less than one per 300,000 doses of SJW between October 1991 and December 1999, during which an estimated 8 million patients were treated with SJW. Hypericin, the naphthodianthrone constituent of SJW, in fact exhibits photodynamic properties, and it has been used in oncological research as an investigational cytotoxic agent in photodynamic therapy (PDT) and as an imaging agent in photodiagnosis (PD).[184]

Delta-aminolevulinic acid (d-ALA) is a precursor compound used to enhance endogenous synthesis of the photosensitizer protoporphyrin IX through the heme pathway. There is one report of a possible interaction between d-ALA and SJW in a dermatological case in which excessive skin erythema occurred after topical irradiation.[185] Currently, these uses of ALA are confined to specialized clinical environments.[186] If the photosensitizer d-ALA becomes more generally used in photodynamic imaging studies, potential interactions with SJW should be considered, and avoidance may be prudent pending further data.

Theophylline/Aminophylline

Theophylline/aminophylline (Phyllocontin, Slo-Bid, Slo-Phyllin, Theo-24, Theo-Bid, Theocron, Theo-Dur, Theolair, Truphylline, Uni-Dur, Uniphyl); combination drug: ephedrine, guaifenesin, and theophylline (Primatene Dual Action).

Several secondary sources have repeated a suggested interaction between theophylline and SJW. However, the suggestion is derived from a single case reported in a letter from Nebel et al.[187] in 1999. Theophylline is metabolized by CYP1A2 and has a relatively narrow therapeutic index in that toxicity can arise from marginally supranormal plasma levels. The patient in the case report smoked half a pack of cigarettes daily (tobacco smoke induces 1A2 via the arylcarbon receptor) and was taking 11 concurrent prescription medications, including the leukotriene antagonist zafirlukast, which is a 1A2 inhibitor and interacts with theophylline.[111] Other medications included morphine, amitriptyline, valproate, and zolpidem. With a polypharmaceutical regimen that includes multiple substrates, inducers, and inhibitors of multiple metabolic enzymes and transporters, several of which are known to interact with each other, the report is unevaluable as evidence of a putative SJW-theophylline interaction, despite the authors' suggestion that theophylline levels increased after cessation of SJW (dose and preparation unrecorded).

A recent study by Morimoto et al.[188] has confirmed the lack of clinically significant interaction with theophylline. After 15 days of pretreatment with 300 mg SJW three times daily, healthy Japanese male volunteers showed no significant change in urinary concentrations of theophylline or its metabolites after a single 400-mg oral dose.

The 188 citations for this monograph are located under St. John's Wort on the CD at the back of the book.

Turmeric/Curcumin

Botanical Name: *Curcuma longa* L.
Pharmacopoeial Name: Curcumae longae rhizome.
Synonym: *Curcuma domestica* Valeton.
Common Names: Turmeric, Indian saffron.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Bleomycin Cytotoxic antibiotics ⊕/☼	Herb may reduce drug-induced pulmonary toxicity. Clinical significance not established.	Consider coadministration only under specialist professional management.
Cisplatin Platinum chemotherapy compounds ⊕	Herb may reduce drug-induced renal and neurotoxicities. Clinical significance not established.	Consider coadministration only under specialist professional management.
Cyclophosphamide Alkylating agents ?	Herb may reduce drug-induced toxicity but may also reduce effectiveness of drug. Conflicting data; clinical significance not established.	Avoid until further data available.
Cyclosporine Immunosuppressive agents ⊕/✗/◇/◇/⊕	Herb may enhance immunosuppressive efficacy of drug, but also risks possible reduction in drug bioavailability. Clinical significance not established.	Consider coadministration only under specialist professional management with serum monitoring of drug levels.
Doxorubicin Anthracycline chemotherapy ?/⊕/✗	Herb protects against and reduces drug-induced cardiotoxicity and may reduce drug-induced resistance. Effect on drug efficacy controversial. Clinical significance not established.	Avoid coadministration, until further data available. Consider before and after chemotherapy.
Ethanol ☼/⊕⊕	Herb reduces alcohol-related pathologies in liver, pancreas, and central nervous system. Clinical significance not established.	Incorporate into natural treatment protocols for alcohol-related conditions.
Indomethacin Nonsteroidal anti-inflammatory drugs (NSAIDs) ⊕/☼	Herb may reduce incidence and promote healing of drug-induced gastric ulceration. Clinical trial suggests turmeric no different than antacids for healing ulcers.	Consider coadministration with ulcerogenic NSAIDs to prevent gastropathies.
Paclitaxel Taxanes ⊕	Herb may chemosensitize malignant cells to drug. Clinical significance not established.	Consider coadministration only under specialist professional management.
Vinblastine Vinca alkaloids ⊕	Herb may reduce drug resistance by inhibition of efflux mechanisms.	Consider coadministration only under specialist professional management.

HERB DESCRIPTION

Family

Zingiberaceae.

Related Species

Curcuma aromatica Salisbury, *Curcuma xanthorrhiza* Roxb.

Habitat and Cultivation

Native to tropical zones in India and Southeast Asia; cultivated for culinary and medicinal purposes for many centuries; now imported principally from India, China, and Indonesia.

Parts Used

Rhizome.

Common Forms

Dried: Rhizome, powdered.
Oleoresin or essential oil.
Tincture, Fluid Extract: Dried or fresh rhizome, 45% ethanol.
Standardized Extract: Solid extracts, concentrated and standardized to 95% curcuminoids, as curcumin.

Note: Experimental studies often use purified laboratory-grade diferuloylmethane or curcumin-I only; semisynthetic derivatives are also available.

HERB IN CLINICAL PRACTICE

Overview

Although in medicinal use in Asia for more than a millennium, turmeric is probably better known in the West as a common yellow spice from the ginger family, used as a pungent flavoring ingredient in curries, which is also widely used in the U.S. food industry as a coloring agent. Until recently, Western medicine viewed turmeric primarily as a spice with minor aromatic digestive stimulant and hepatic stimulant properties, indicated but little used for functional hepatobiliary disorders. In 1985 the German Commission E approved "Turmeric Root" for dyspeptic conditions,[1] although the herb was absent from both the 1983 and the 1996 edition of the *British Herbal Pharmacopoeia*. The World Health Organization (WHO) monograph repeats the Commission E indications.[2]

Pharmacological investigations into the anticancer and anti-inflammatory properties of the herb and its constituents began to attract research interest in the 1980s. Currently, curcumin is regarded as a natural compound of great interest and of considerable therapeutic potential because of its multiple properties, which include antioxidant, anti-inflammatory, chemopreventive, antimutagenic, anticarcinogenic, antimetastatic, antiangiogenic, and cardioprotective activities. Although this research currently constitutes a rapidly expanding body of literature, a 2003 therapeutic monograph on turmeric by the European Scientific Cooperative on Phytotherapy (ESCOP)[3] echoes the original 1985 Commission E indications for "symptomatic treatment of mild digestive disturbances and minor biliary dysfunction." Aggarwal et al.[4] recently reviewed the chemopreventive and anticancer molecular biology of curcumin. The majority of recent scientific studies on turmeric employed purified laboratory-grade diferuloylmethane or curcumin-I, which should be noted before extrapolating to mixtures of curcuminoids or to crude whole-herb extracts.

Historical/Ethnomedicine Precedent

In Ayurveda, turmeric is used internally for digestive problems and is considered a blood purifier and antimicrobial. Externally it is used for skin problems, as well as for sprains and strains. The powdered herb is often administered in a base of dietary ingredients, such as milk or honey, or in slaked lime for topical applications.[5] In classical Chinese medicine, turmeric invigorates the *xue* (blood) and relieves pain, especially related to liver *(Gan)*; it clears heat and cools the blood, clears the heart *(Xin)* (which helps with psychological problems), and benefits the gallbladder *(Dan)* and treats jaundice.[6]

Known or Potential Therapeutic Uses

Abdominal pain, adjunctive cancer treatment, antimicrobial, arthritis, cardiovascular disease prophylaxis, chemoprevention, chemosensitization, cholestasis, dyspepsia, ethanol-related hepatic conditions, hyperlipidemia, inflammation, jaundice, radiosensitization.
Topically for skin conditions, sprains, and strains.

Key Constituents

Curcuminoids (diferuloylmethanes), including curcumin and its methoxylated derivatives (2%-5%), are the yellow pigments and principal actives. Sometimes designated as curcumins I to IV: I, curcumin; II, desmethoxycurcumin; III, bisdesmethoxycurcumin; and IV, cyclocurcumin.
Essential oil (3% and 5%), including sesquiterpene ketones and monoterpenes.

Therapeutic Dosing Range

Powdered Rhizome: Up to 12 g daily by decoction.
Tincture, Fluid Extract: 5 to 15 mL daily (as 1:1 equivalent).
Standardized Extract: Equivalent of 400 to 600 mg curcumin three times daily.

INTERACTIONS REVIEW

Strategic Considerations

No interactions with prescription drugs are noted in the available therapeutic monographs on turmeric. Both Western and Chinese herbal authorities have advised using caution when coadministering turmeric with antiplatelet or anticoagulant drugs and avoiding higher doses of the herb in such settings.[7,8] No interaction with anticoagulant or antiplatelet medications has been reported clinically or described experimentally, and the suggested interaction is classified here as "overstated/speculative" (see Theoretical, Speculative, and Preliminary Interactions Research).

The primary clinical context for current use of curcumin extracts is inflammatory conditions and the integrative oncology setting. Curcumin has innumerable effects on a wide range of signal transduction pathways and molecular targets affecting cell growth, multiplication, differentiation, and apoptosis, including inhibition of nuclear factor kappa B (NF-κB) and activating protein-1 (AP-1).[4,9-13] Experimental evidence is emerging for potential interactions with a variety of cytotoxic drugs, as well as radiotherapy. A novel interactions issue, unaddressed by research to date, is how curcumin, known to inhibit a number of molecular targets involved in angiogenesis, including vascular endothelial growth factor (VEGF), might interact with the newer generation of antiangiogenic agents such as the monoclonal antibody bevacizumab (Avastin).[14,15] Despite the rapidly expanding basic science research on the molecular targets affected by curcumin, extrapolation to clinical settings is problematic given the lack of large-scale trial evidence. Curcumin is incorporated with other natural compounds into adjunctive anticancer protocols on an anecdotal clinical basis, and preliminary data support synergistic combination of curcumin with genistein.[16-18]

Although several potentially beneficial interactions with chemotherapeutic agents are listed later, these interactions have not been well studied, particularly in vivo. One research group has questioned the advisability of combining curcumin with alkylating agents such as cyclophosphamide, which induces apoptosis through activation of Janus kinase (JNK), which may be inhibited by relatively low doses of curcumin.[19] The same authors raised concerns about the advisability of coadministering curcumin with chemotherapy agents, which increase activation of NF-κB. Even though this may reduce drug-induced NF-κB–mediated drug resistance, the activation of NF-κB may be an important (but not exclusive) part of the cytotoxic mechanism of these drugs (e.g., doxorubicin), although this study has been criticized.[20] However, until further data are available with respect to specific chemotherapy agents and specific malignancies, decisions regarding coadministration of curcumin with chemotherapy need to be made in conjunction with practitioners experienced in the integrative oncological setting. There is also evidence, not detailed here, that curcumin may have beneficial interactions with radiotherapies.[21-23]

Effects on Drug Metabolism and Bioavailability

Turmeric potentially exerts concerted effects on all three phases of drug metabolism. As with many herbs, the clinical implications of in vitro data remain to be established, and the interpretation of some studies is particularly controversial because of the extremely low bioavailability of curcumin. Biphasic effects have also been reported. In a Phase I study of 25 patients with various premalignant diagnoses, Cheng et al.[24] established that single oral doses of 8000 mg curcumin resulted in peak plasma concentrations of only 1.77. In colorectal adenocarcinoma patients who were administered curcumin for 7 days at 3600 mg/day, levels of curcumin were 2.5 times higher in malignant colorectal cells than in normal colon

tissue, at 12.7 nmol/g in the form of sulfate and glucuronide conjugates. The effect of curcumin was to decrease levels of an oxidative deoxyribonucleic acid (DNA) adduct marker of cyclooxygenase-2 (COX-2) expression, which was not affected.[25,26] In a rodent model, Shoba et al.[27] showed that coadministration of piperine (20 mg/kg) with curcumin increased the bioavailability of the herb by a factor of 154% in a single-dose pharmacokinetic study; in humans, 20 mg piperinen increased the bioavailability of curcumin by 2000%.[27] The low bioavailability results from rapid glucuronidation both hepatically and directly at the intestinal wall.

Effects on cytochrome P450 (CYP450) enzymes have been documented. Two different research groups used a rodent hepatocyte model to demonstrate curcumin inhibited both the induction and the activity of CYP450 1A1and 1A2, 2B1 and 2B2, and 2E1.[28-30] The inhibitory effects were weak to moderate, except for 1A1/1A2, for which inhibition was more potent. These CYP450 enzymes are particularly related to metabolism of carcinogens, including the polycyclic aromatic hydrocarbons (PAHs). Using human oral mucosa cells and oral squamous cell carcinoma (SCC) cells, Rinaldi et al.[31] demonstrated induction of the nuclear translocation of the aryl hydrocarbon receptor (AhR), a process that leads to downstream activation of phase I and phase II AhR-responsive carcinogen-metabolizing enzymes. They also demonstrated increased CYP1A1 activity in oral SCC cells, combined with a decrease in carcinogen bioactivation, as well as an increase in intracellular reduced-glutathione (GSH) levels. The authors concluded that curcumin has a significant ability to modulate carcinogen activation in the human oral cavity. In a study by Raucy[32] using human hepatocytes, curcumin did not demonstrate any induction effects on CYP3A4, suggesting negligible interactions with the many drugs metabolized by this enzyme. Animal studies corroborate a significant effect of curcumin on phase II enzymes, particularly glutathione-*S*-transferase, and the ability of the curcuminoids to increase intracellular glutathione has been documented in several experimental models.[30,33,34]

Several studies have demonstrated pronounced inhibitory effects of curcumin on P-glycoprotein (P-gp) in several cell lines, with dose-dependent effects at concentrations between 1 and 15 micromolar (μM).[35,36] Anuchapreeda et al.[37] found that in human cervical carcinoma cells (KB-VI), pretreatment with curcumin at 1 to 10 μM for up to 72 hours significantly lowered MDR1 gene expression. Curcumin also inhibited rhodamine-123 efflux from these cells but had no effect on wild-type KB-3 cells that do not overexpress P-gp. The same research group later established that curcumin-I was the most effective inhibitory compound among the curcuminoids I to III, and that vinblastine sensitivity was increased in the homologous but drug-resistant KB-VI line.[38] Nabekura et al.[36] established similar results for daunorubicin accumulation in the same drug-resistant cell line.

HERB-DRUG INTERACTIONS

Bleomycin

Bleomycin (Blenoxane).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Curcumin reduces the characteristic bleomycin-induced pulmonary fibrosis toxicity, according to animal data. The mechanism is not understood but may result from antioxidant and anti-inflammatory effects of curcumin.

Research

Two studies using rodent models have demonstrated that oral curcumin pretreatment for 10 days before bleomycin, and continued during the drug treatment for up to 1 month, reduces pulmonary fibrosis, inflammation, and other markers of lung toxicity, including alveolar macrophage tumor necrosis factor alpha (TNF-α) release and superoxide and nitric oxide induction. Total lung hydroxyproline was also significantly reduced with curcumin coadministration. In both studies the oral doses of curcumin were high, 300 mg/kg/day and 550 nmol/kg/day.[39,40]

Clinical Implications and Integrative Therapeutics

Pulmonary fibrosis is a well-documented adverse effect of bleomycin. Data are lacking on whether curcumin will affect the cytotoxic action of bleomycin. However, because the agent is often administered in combination with doxorubicin and vinblastine, and in vitro data suggest these agents may be more effective with curcumin administration, it may be beneficial to incorporate curcumin as an adjuvant/protective in protocols such as ABVD (Adriamycin, Blenoxane, vinblastine, dacarbazine), but clinical trial support is unavailable.

Cisplatin and Related Platinum Chemotherapy Compounds

Evidence: Cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ).
Extrapolated, based on similar properties: Carboplatin (Paraplatin), oxaliplatin (Eloxatin).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Curcumin combined with cisplatin results in synergistic antitumor activity in experimental models.

Research

Navis et al.[41] analyzed tumor markers in liver and kidney homogenates of rats with experimentally induced fibrosarcoma that was treated with cisplatin or a cisplatin-curcumin combination versus controls. Cisplatin alone reduced the markers, but the effect of the combination was to restore markers to control levels. Notarbartolo et al.[42] examined the antitumor effects of curcumin alone and in combination with cisplatin on a hepatocellular carcinoma line that constitutively overexpressed NF-κB. They found a sequence-dependent synergy effect of the herb-drug combination on apoptosis, which depended on pretreatment with curcumin and was not observed during simultaneous coadministration. The effect was partially reversed by adding the antioxidant *N*-acetylcysteine (NAC) and involved caspase-dependent and caspase-independent mechanisms, as well as reduction in the gene expression of several inhibitor of apoptosis proteins (IAPs). Interestingly, the effects of curcumin alone on NF-κB were

temporally biphasic, with an initial increase followed by a decrease. The concentrations of curcumin that were effective ranged from 10 to 25 μM.

Clinical Implications and Integrative Therapeutics

Preliminary evidence suggests that curcumin pretreatment may act as a chemosensitizer to cisplatin therapy. The clinical significance of this potentially beneficial interaction, demonstrated in vitro for hepatocellular carcinoma, remains to be established.

Cyclophosphamide

Evidence: Cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox).

Extrapolated, based on similar properties: Irinotecan (camptothecin-11, CPT-11; Campto, Camptosar); bleomycin (Blenoxane; see earlier section).

Interaction Type and Significance

? **Interaction Likely but Uncertain Occurrence and Unclear Implications**

Probability: **4. Plausible**

Evidence Base: **▽ Mixed**

Effect and Mechanism of Action

An experimental reduction in cyclophosphamide-induced lung toxicity is likely mediated by the anti-inflammatory and antioxidant effects of curcumin. The interaction parallels that between bleomycin and curcumin. However, curcumin may reduce the effects of alkylating agent–induced apoptosis mediated through the JNK pathway.

Research

Venkatesan and Chandrakasan[43] used a rodent model to show that 7 days of pretreatment with curcumin in healthy rats prevented lung damage from one intraperitoneal dose of cyclophosphamide, measured by bronchopulmonary lavage fluid levels of angiotensin-converting enzyme (ACE), lactate dehydrogenase (LDH), alkaline phosphatase, lipid peroxide, glutathione, and ascorbate. Somasundaram et al.[19] questioned the advisability of combining curcumin with alkylating agents such as cyclophosphamide, which induces apoptosis through activation of the JNK pathway, based on preliminary in vivo rodent data. Using human MCF-7 and BT-474 breast cancer cells xenografted into nude mice, oral feeding of low doses of curcumin prevented cyclophosphamide (single dose intraperitoneally) from decreasing tumor size after 24 and 48 hours. This study has been criticized for the short duration of administration of both curcumin and cyclophosphamide and the low doses of curcumin used.[20] (See also Theoretical, Speculative, and Preliminary Interactions Research.)

Clinical Implications and Adaptations

Further research is needed to establish whether the potential reduction of cyclophosphamide toxicity by curcumin is demonstrable in vivo without any countervailing reduction of therapeutic effect of the compound.

Cyclosporine and Related Immunosuppressive Agents

Evidence: Cyclosporine (Ciclosporin, cyclosporin A, CsA; Neoral, Sandimmune, SangCya).

Extrapolated, based on similar properties: Mycophenolate (CellCept).

Interaction Type and Significance

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **4. Plausible**

Evidence Base: **○ Preliminary**

Effect and Mechanism of Action

In a mixed pharmacodynamic and pharmacokinetic interaction, curcumin may enhance immunosuppressive activity of cyclosporine while reducing its bioavailability. The interaction has not been demonstrated clinically to date.

Research

Chueh et al.[44] used a rodent cardiac allograft model to demonstrate that curcumin could effectively synergize with cyclosporine. Curcumin alone prolonged survival time of allograft rats compared with controls, but when combined with subtherapeutic doses of cyclosporine, the recipient animals survived longer than those with curcumin alone. Cytokine analysis suggested reduced levels of interleukin-2 (IL-2), interferon gamma (IFN-γ), and granzyme B in both the combination and the curcumin-only animals versus controls. Ranjan et al.[45] showed in vitro with human lymphocytes that curcumin inhibits T-cell activation through the CD28/B7 co-stimulation pathway. This pathway is resistant to cyclosporine suppression and synergistic suppression of T-cell responses. In a later study the same group showed curcumin suppressed NF-κB–mediated IL-2 release in response to mitogen activation by various stimuli.[46]

Additional, if circumstantial, evidence for immunosuppressive effects comes from the ability of curcumin extracts to inhibit experimental allergic encephalomyelitis (a standard animal model of multiple sclerosis); this was mediated by interleukin-12–signaling blockade, resulting in decreased T-cell proliferation and T helper cell type 1 (Th1) differentiation.[47] A complication of any in vivo coadministration of cyclosporine with curcumin is that the drug is a substrate of P-gp, which is inhibited by curcumin, thus potentially decreasing bioavailability of cyclosporine. This was demonstrated, as an incidental finding, in an animal study examining the (lack of) effect of curcumin on cyclosporine-induced cholestasis and hypercholesterolemia.[48]

Clinical Implications, Adaptations, and Integrative Therapeutics

Insufficient data are available to establish the clinical significance of this interaction. However, given the practice of measuring serum values for cyclosporine concentration during immunosuppressive therapy, the problems of adjusting to pharmacokinetic variation caused by P-gp inhibition are theoretically manageable. At present, the beneficial effect of the combination shown experimentally remains to be confirmed by clinical studies. Other evidence suggests a renal-protective effect of curcumin, renal toxicity being a known effect of cyclosporine.

Jones and Shoskes[49] showed that several plant-derived compounds reversed renal ischemia and reperfusion injury induced by mycophenolate (CellCept). Coadministration should be considered only with profession management, including monitoring of serum cyclosporine levels by the transplant providers.

Doxorubicin and Related Anthracycline Chemotherapy

Evidence: Doxorubicin (Adriamycin, Rubex).
Extrapolated, based on similar properties: Daunorubicin (Cerubidine, DaunoXome), epirubicin (Ellence, Pharmorubicin), idarubicin (Idamycin, Zavedos), mitoxantrone (Novantrone, Onkotrone).
Similar properties but evidence lacking for extrapolation: Doxorubicin, pegylated liposomal (Caelyx, Doxil, Myocet).

Interaction Type and Significance

? **Interaction Likely but Uncertain Occurrence and Unclear Implications**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

Probability: **4. Plausible**

Evidence Base: ▽ **Mixed**

Effect and Mechanism of Action

In this complex multifactorial interaction, curcumin may reduce the known cardiotoxicity of doxorubicin and may also counter the development of drug resistance by inhibiting doxorubicin-induced NF-κB activation. However, curcumin may lower drug efficacy under some circumstances.

Research

Rodent studies demonstrated that both acute cardiotoxicity (measured by serum creatine kinase, LDH, and malondialdehyde levels) and nephrotoxicity (measured by proteinuria, albuminuria, hypolipemia, and urinary *N*-acetyl-β-glucosaminidase excretion) caused by single-dose intraperitoneal Adriamycin (30 mg/kg) were significantly reduced by oral curcumin pretreatment (200 mg/kg) 7 days before and 2 days after drug administration.[50,51] The mechanism likely involves antioxidant effects of the curcuminoids, particularly the lowering of lipid peroxidation in cardiomyocytes. Chuang et al.[52] used multiple human cancer cell lines to examine the various chemotherapeutic drugs clinically associated with the ability to induce drug resistance (doxorubicin, 5-fluorouracil, cisplatin, paclitaxel). Drug resistance was accompanied by transient increases in NF-κB. When doxorubicin (1 μM) was combined with curcumin (10 μM), NF-κB production was inhibited significantly more than by curcumin alone. The effect was not mediated by TNF-α, and the authors suggested that the effect of curcumin on NF-κB may be important in overcoming drug resistance. Other mechanisms, including glutathione-*S*-transferase modulation, may be important to the inhibition of doxorubicin resistance by curcumin.[53]

Another study provides conflicting data. Somasundaram et al.[19] found that doxorubicin-induced apoptosis of MCF-7 cells may be significantly reduced by curcumin at low levels in a time- and dose-dependent manner (1.0-10.0 μM). Because the curcumin concentrations used approach those found in human pharmacokinetic studies, the authors advise that patients with breast cancer (and other malignancies) should not concurrently use curcumin with chemotherapy until further investigations clarify the situation. These conclusions have been criticized as generalizations that disregard the methodology of the in vitro model, particularly the temporal kinetics based on very-short-term effects, low doses of curcumin, and a failure to account for the multifactorial mechanisms involved.[20] The issues remain unresolved.

Notarbartalo et al.[42] examined the complexity of this interaction in relation to the relative role of NF-κB and other factors using a hepatic cancer cell line. Messenger ribonucleic acid (mRNA) analysis suggested that expression of multiple genes in various pathways is modulated by the combination of agents, with effects that are in part additive and in part antagonistic.

Clinical Implications and Adaptations

Although the protective action of curcumin against doxorubicin toxicity is plausible, the effects on drug efficacy have been questioned. Extrapolations from limited in vitro data to clinical settings (especially on dose levels) are problematic, and further data are needed to characterize the interaction. Curcumin may in addition have a role in anthracycline protocols that have exhibited the emergence of drug resistance. Decisions whether to adopt concurrent use of curcumin will also likely depend on the role assigned to dietary antioxidants (vitamins A, C, and E; carotenoids) during anthracycline chemotherapy, itself a controversial topic.

Ethanol

Ethanol

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability: **1. Certain**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

In an experimentally demonstrated interaction, curcumin treatment prevents or reduces ethanol-induced toxicities in various organs and tissues (e.g., hepatic, neural, pancreatic) through multiple mechanisms.

Research

Rodent models of experimentally induced alcoholic liver disease demonstrate the efficacy of curcumin in prevention of ethanol-induced pathology.[54-56] Similar studies show related effects in ethanol-induced and non-ethanol-induced pancreatitis, as well as in ethanol-induced neural damage.[57,58] Along with several in vitro investigations, these studies reveal a variety of mechanisms involved in mediating the protective effects. These include suppression of NF-κB activated proinflammatory genes, including inducible nitric oxide synthase (iNOS) and COX-2, as well as antioxidant activity and matrix metalloproteinase (MMP) inhibition.[54,59-61]

Clinical Implications and Integrative Therapeutics

Turmeric extracts and curcumin may be useful adjuncts in the treatment of acute and chronic alcohol-related liver and pancreatic disease.

Indomethacin, Related Nonsteroidal Anti-Inflammatory Drugs (NSAIDs), and Other Ulcerogenic Substances

Evidence: Indomethacin (indometacin; Indocin, Indocin-SR).
Extrapolated, based on similar properties: NSAIDs:

COX-1 inhibitors: Diclofenac (Cataflam, Voltaren), combination drug: diclofenac and misoprostol (Arthrotec), difunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), furbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen);

combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen); ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Aleve, Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Saltlex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).

COX-2 inhibitor: Celecoxib (Celebrex).

Ethanol (see earlier section).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **1. Certain**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

This interaction was serendipitously discovered while using indomethacin as an ulcerogenic agent in a rodent model of acute gastric ulceration. Curcumin prevents indomethacin ulceration and accelerates ulcer healing. The mechanism is multifactorial and includes suppression of MMP-9 and iNOS (regulated by NF-κB activation).

Research

In a rodent model, turmeric extracts at an oral dose of 500 mg/kg produced significant antiulcerogenic activity in animals subjected to a variety of ulcer-inducing agents, including indomethacin and reserpine.[62] The mechanism has recently been shown to involve the inhibition of MMP-9 and MMP-2.[63] A clinical open-label trial attempting to establish the efficacy of turmeric (1000 mg/day) compared with antacids in 50 patients over 6 weeks found that the antacid was superior to turmeric in inducing ulcer healing. However, this trial was not related to indomethacin-induced ulcers, and the mechanism may be relatively specific to ulcers caused by chemical agents (involving MMP-9 inhibition).

Clinical Implications and Integrative Therapeutics

This interaction has been cited as a demonstration of the antiulcerogenic effects of curcumin, but the available clinical trial evidence shows turmeric ineffective in healing gastric ulcers.[64] The interaction appears is specific to ulcers caused by iatrogenic agents such as NSAIDs. Involvement of the MMPs (especially MMP-9) would predict that curcumin likely has antimetastatic activity, which has indeed been demonstrated.[65] Similar mechanisms are involved in the protective effects of curcumin against ethanol-induced toxic damage. (See also previous ethanol-curcumin discussion.) If ulcerogenic drugs likely to induce gastropathic ulceration are administered chronically, turmeric coadministration would appear to be warranted, despite the lack of evidence for turmeric effect on stress ulcers.

Further evidence for the general applicability of these findings to iatrogenic mucosal damage is provided by a study of intestinal mucositis induced by methotrexate. The villous atrophy that resulted from methotrexate damage was partially inhibited by curcumin coadminstration.[23] This suggests a possible role for curcumin in the amelioration of cytotoxic chemotherapy-induced mucositis.

Paclitaxel and Related Taxanes

Evidence: Paclitaxel (Paxene, Taxol).

Extrapolated, based on similar properties: Docetaxel (Taxotere); paclitaxel, protein-bound (Abraxane).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

An experimentally demonstrated chemosensitization by curcumin to paclitaxel (Taxol)–induced cytotoxicity; the mechanism is independent of microtubule polymerization.

Research

Bava et al.[66] tested HeLa cells with paclitaxel (Taxol) alone and Taxol in combination with curcumin and found that the combination exerted synergistic effects on cell kill, and that this was accompanied by caspase activation and cytochrome c release. Taxol-induced NF-κB activity was reduced by curcumin coadministration. There appeared to be no effect on tubulin polymerization or cyclin-dependent CdC2 activation induced by Taxol.

Clinical Implications and Integrative Therapeutics

Coadministration of curcumin with taxanes may result in increased efficacy of the drug. Clinical trial support is not available. The known pharmacology of curcumin does not suggest interference with microtubule mechanisms affected by the taxane class of chemotherapy agents.

Vinblastine, Related Vinca Alkaloids, and Platinum Chemotherapy Compounds

Evidence: Vinblastine (Alkaban-AQ, Velban, Velsar).

Extrapolated, based on similar properties: Vincristine (Leurocristine, Oncovin, Vincasar PFS), vinorelbine (Navelbine); Platinum chemotherapy compounds: Carboplatin (Paraplatin), cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), oxaliplatin (Eloxatin).

Interaction Type and Significance

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

In this experimentally demonstrated pharmacokinetic interaction, curcumin may increase the bioavailability of vinblastine by inhibition of P-glycoprotein.

Research

The inhibition of P-gp by curcuminoids is well documented (see Effects on Drug Metabolism and Bioavailability). Anuchapreeda et al.[67] tested the ability of curcumin to decrease P-gp–mediated drug resistance in a human cervical carcinoma line and established that curcumin increased their sensitivity to vinblastine, which was consistent with an

observed intracellular increase in rhodamine-123 (a P-gp substrate).[37] The same group later established that curcumin-I was more effective than curcumin-II and -III in causing retention of vinblastine by the same cell line. There was no effect on a wild-type variation of the same cell line that lacked drug resistance.[38]

Clinical Implications and Integrative Therapeutics

There is growing interest in the potential of natural compounds as potential modulators of drug resistance mediated by the ABC (ATP-binding cassette) family of drug transporters. Coadministration of curcumin with vinca alkaloids may reduce drug resistance to these agents, and the curcuminoids are not known to interfere with the activity of microtubule inhibitors. In vivo studies are necessary to confirm the clinical efficacy of the combination, but curcumin administration may be considered if drug resistance appears responsible for lack of efficacy in malignancies previously responsive to vinblastine.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Anticoagulants and Antiplatelet Drugs

Several experiments using animal models (rodents and simians), as well as one study with washed human platelets, have demonstrated that curcumin can inhibit platelet aggregation induced by arachidonate, adrenaline, collagen, and platelet-activating factor (PAF) through modulation of eicosanoid biosynthesis, particularly prostaglandin I_2 (PGI_2; prostacyclin) and thromboxane A_2 (TXA_2) inhibition.[67-69] Doses of curcumin used in rats and monkeys were between 100 and 300 mg/kg orally, and no measurements were made of bleed times or other coagulation parameters. Shah et al.[70] found that 20- to 25-μM concentrations were effective at inhibiting PAF and arachidonic acid (AA)–induced aggregation, but that much higher doses were needed for collagen and adrenaline.[70] These doses are higher than those likely to be attained in vivo. Studies testing combinations of turmeric or curcumin coadministration with antiplatelet or anticoagulant drugs are unavailable to date. In the absence of corroboration, extrapolated warnings that turmeric should be avoided with antiplatelet drugs can be considered speculative and overstated.[7]

Irinotecan/Camptothecin, Mechlorethamine

Irinotecan (camptothecin-11, CPT-11; Campto, Camptosar). Mechlorethamine (nitrogen mustard; Mustargen).

These two agents were included the in vitro but not in vivo rodent phase of a group of tests conducted by Somasundaram et al.[19] No other data are available on these particular drugs, although countervailing data exist for other agents included in this study. Apoptosis induced by the drugs was reduced by addition of curcumin. As noted earlier, because the curcumin concentrations used approach those found in human pharmacokinetic studies, the authors suggest that patients with breast cancer (and other malignancies) should not concurrently use curcumin with these chemotherapies until further studies clarify the situation.[19] Derivative sources have repeated these conclusions as definitive interactions without qualification. The Somasundaram study conclusions have been criticized as being generalizations that disregard the methodology employed in the in vitro model, particularly the temporal kinetics based on very-short-term effects, low doses of curcumin, and a failure to account for the multifactorial mechanisms.[20] The situation is complex, as illustrated by the analysis of Notarbartolo et al.[42] (see Cyclophosphamide and Doxorubicin).

Oral Hypoglycemic Agents and Insulin

Buformin (Andromaco Gliporal, Buformina), chlorpropamide (Diabinese), glimepiride (Amaryl), glipizide (Glucotrol; Glucotrol XL), glyburide (glibenclamide; Diabeta, Glynase, Glynase Prestab, Micronase, Pres Tab), insulin (animal-source insulin: Iletin; human analog insulin: Humanlog; human insulin: Humulin, Novolin, NovoRapid, Oralin), metformin (Dianben, Glucophage, Glucophage XR); combination drugs: glipizide and metformin (Metaglip), glyburide and metformin (Glucovance); phenformin (Debeone, Fenformin), tolazamide (Tolinase), tolbutamide (Orinase, Tol-Tab).

Experimental data on diabetic mice suggest that chronic curcuminoid consumption may have beneficial effects on blood glucose levels.[71,72] These data have been "reverse extrapolated" to imply an adverse interaction with oral hypoglycemics. The possibility of interaction may be different in acute administration versus chronic dietary curcumin consumption, and diabetic patients monitoring blood glucose are generally familiar with compensating for dietary-induced variations in blood sugar. In fact, a more appropriate characterization would be that turmeric and curcumin as dietary ingredients are protective against pathological diabetic sequelae and help maintain glucose homeostasis, as well as being hypocholesterolemic.[73-75]

The 75 citations for this monograph are located under Turmeric/Curcumin on the CD at the back of the book.

Valerian

Botanical Name: *Valeriana officinalis* L.
Pharmacopoeial Name: Valerianae radix.
Common Name: Valerian.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Diazepam Benzodiazepines ☼/⊕	Herb may reduce side effects of benzodiazepine withdrawal acting as partial agonist at $GABA_A$-benzodiazepine receptor complex, as well as antidepressant, muscle relaxant, and other effects.	Consider incorporating valerian into nutritional/botanical support protocols for drug tapers.
Barbiturates Central nervous system (CNS) depressants ✗	Herb will combine additively with centrally acting depressants at multiple receptor subtypes (5-HT, $GABA_A$, H_1, D_2, and adenosine). Effects shown to be additive not supra-additive.	Avoid herb-drug coadministration except in short-term/acute circumstances or specialized settings with professional management. (See benzodiazepines.)

GABA, Gamma-aminobutyric acid; 5-HT, hydroxytryptamine (serotonin); H, histamine; D, dopamine.

HERB DESCRIPTION

Family

Valerianaceae.

Related Species

There are several hundred members of the *Valeriana* genus, and several species are traded as medicinal valerian root. In North America these include Mexican valerian (*V. edulis* Nutt.); Indian valerian (*V. wallichi* DC) and Pacific valerian (*V. sitchensis* Bong). Ornamental Valerianaceae genera such as *Centranthus* may sometimes be called "valerians," but these are nonmedicinal.

Habitat and Cultivation

Valerian is cultivated widely in Europe and North America and Russia, with Europe providing the bulk of the commercial material.

Parts Used

Fresh or dried rhizomes, roots, and stolons.

Common Forms

Dried Root: Cut or powdered.
Tincture, Fluid Extract: 70% ethanol.
Solid Concentrates: Between 4:1 and 7:1. Standardization to total valerenic acid (0.8%) has been suggested, but a consistent standard has not been established to date. Manufacturers' preparations may vary.

HERB IN CLINICAL PRACTICE

Overview

Valerian root is widely known as a mild sedative-hypnotic herb with a strong, characteristic odor when dried. It is used medicinally to reduce sleep latency, to treat mild to moderate insomnia, and to relieve spasmodic conditions of the smooth muscle. The herb is chemically and pharmacologically complex, and its sedative mechanisms are not fully understood. Herbalists consider that valerian is capable of producing paradoxical effects, but it is not established whether this is caused by the variability in constituent composition resulting from differences in growing conditions, harvesting times, and preparation methods or by constitutional variability among patients or consumers, or both. There is known chemotypic variation in the quantity and distribution of sesquiterpenes and valepotriates among different species, and polyploidal variants exist within species, including *V. officinalis*. Chemical differences between fresh and dried root preparations caused by the instability of the monoterpene valepotriates add to the overall variability. In clinical practice, valerian is usually combined with other sedative herbs, such as hops, passionflower, or lemon balm, rather than used alone.

Valerian has therapeutic monographs from the German Commission E,[1] World Health Organization (WHO),[2] European Scientific Cooperative on Phytotherapy (ESCOP),[3] and the *American Herbal Pharmacopoeia* (*AHP*).[4] Literature reviews are available by Houghton,[5] Morazzoni and Bombardelli,[7] and McKenna et al.[8] The established indications for valerian root are sleep promotion, relief of temporary mild anxiety, and reduction of sleep latency. More than a dozen clinical trials support the use of valerian for insomnia, although a systematic review found the overall evidence for efficacy of the herb was inconclusive based on nine trials included in the metastudy.[9]

Historical/Ethnomedicine Precedent

Valerian has been in documented use in Western herbal medicine since Greco-Roman times. It was initially used as an aromatic and digestive remedy and subsequently became known as a treatment for epilepsy and for various nervous disorders. It was listed in the *United States Pharmacopeia* (*USP*) from 1820 to 1930 and continues to be listed in the *British Pharmacopoeia* and the major homeopathic materia medicas.[10] The Eclectic physicians used valerian for patients with impaired cerebral circulation associated with depression.[11] It has a traditional history of popular use in the United Kingdom, reputedly for treatment of "shell shock" in both world wars and as a home remedy for promotion of sleep, without addictive effects or cognitive impairment.[12] Valerian root is unusual in that the traditional alcoholic tincture remains a favored preparation, partly because of the complex chemistry of the root, which defies straightforward standardization to a unique "active" ingredient.

Known or Potential Therapeutic Uses

Anxiety; epileptic seizure; fibromyalgia; gastric spasm and colic hyperactivity; infantile convulsions; insomnia; menstrual cramps; mild tremor; nervous asthma; nervous tension; post-traumatic stress disorder (PTSD), including "combat fatigue;" sleep disturbances; spasmodic conditions of the gastrointestinal and urogenital tracts.

Key Constituents

Essential oil (0.1%-2.0%), containing three classes of sesquiterpenes (kessane, valerenic aid, valerononе skeletons) and monoterpenes, principally bornyl acetate.
Valepotriates (0.5%-14.5%): epoxy iridoid esters and their degradation products (baldrinals).
Amino acids, including arginine, γ-aminobutyric acid (GABA), glutamine.
Alkaloids (0.01% to 0.05%), lignans, and flavonoids.

Therapeutic Dosing Range

Dried Root: 3 to 9 g daily
Tincture: Based on 1:1 equivalent, 1 to 3 mL three times daily
External (Bath): 100 g per bath

INTERACTIONS REVIEW

Strategic Considerations

The majority of authoritative monographs on valerian maintain that the herb does not exhibit any notable interactions with pharmaceutical drugs. This is corroborated by an absence of any clear-cut case reports in the literature. However, the central nervous system (CNS) depressant properties of the herb have been substantiated, and as a result, several secondary sources including the *USP*, suggest that the herb may potentiate the effects of a variety of CNS depressant drugs.[12,13] Also, valerian may interfere with antiepileptic medications[14]; this speculation has been eloquently refuted by Eadie[15] in a historical review that concluded valerian is in fact antiepileptic. Although inconclusive, experimental data from the 1980s and 1990s tended to favor a GABAergic mechanism of the sedative effects of the herb.[16] Reverse extrapolations from this putative pharmacological mechanism have also been used to support suggestions of interactions with CNS depressants that act at the GABA-benzodiazepine-chloride channel complex.[13] This includes speculations that the herb will interact with anesthetics.[17] Such reverse extrapolations are better described as "potential contraindications" rather than interactions. Although the possibility of additive effects with CNS depressant drugs is examined as a potential interaction here, the available evidence suggests that synergistic interactions (vs. simple additive effects) between valerian and pharmaceutical sedatives do not exist.

The more recent ligand-binding studies suggest multiple possible actions at different neural receptors, including melatonin and serotonin subtypes, as well as partial $GABA_A$ receptor agonism and H_1 histamine and D_2 dopamine receptor binding.[18-24] In clinical practice, valerian has been used, as with kava, to facilitate withdrawal from benzodiazepenes.[25] In this context the clinical coadministration of herb and drug is a valid exception to the general rule of avoiding concomitant use of herbs and drugs that have similar neurotransmitter effects. (See also benzodiazepines section of the Kava monograph.)

The "psychiatric" indications for valerian are anecdotally well known by the herb-consuming public. Populations who have previously used psychiatric drugs such as sedatives and anxiolytics are arguably more likely to self-prescribe valerian. This may lead to inadvertent additive effects from what would be regarded as contraindicated herb-drug combinations in a professional setting. Unfortunately, literature reviews such as the recent survey by Ernst[26] suggest valerian is ineffective as an anxiolytic, confusing the issue, even if strictly correct in terms of meta-analysis methodology. The poor quality of trials on valerian as a single agent is likely to produce such a conclusion; in practice, valerian is used in combination with other sedative or anxiolytic herbs. Generally, combinations of "nervine herbs," such as hops, lemon balm, and passionflower, with valerian demonstrate greater efficacy than single agents.[27-29]

Effects on Drug Metabolism and Bioavailability

Several in vitro studies have examined the effects of valerian extracts on cytochrome P450 (CYP450) enzymes. Strandell et al.[30] used fluorometric screening methodology and found a moderate inhibition of recombinant human microsomal CYP450 3A4 with a dimethyl sulfoxide (DMSO) extract derived from one of two valerian preparations tested, whereas no effect was found on CYP450 2C19 or 2D6. The effect was not observed when an ethanol extract rather than DMSO was used, and the second valerian product exhibited no inhibitory effects on CYPs. Lefebvre et al.[31] also used fluorometric assay methodology to examine the effects of 14 different commercial preparations of valerian on CYP3A4. They noted wide variation in the composition of the valerian products, with valerenic acid content varying from 21 to 2661 ppm. They found an inhibitory effect on CYP3A4 and also on P-glycoprotein (P-gp), using an ATPase-dependent assay system with a verapamil control. The effect varied with solvents used, with water being the least inhibitory and acetonitrile the most inhibitory. By contrast, earlier fluorometric study of 3A4 inhibition by Budzinski et al.[32] found that both valerian extract and pure valerenic acid were unable to inhibit 3A4 at clinically relevant concentrations and were the weakest inhibitors of the various herbs and pure compounds tested.

Gurley et al.[33,34] performed a study on valerian (and three other herbs) with 12 healthy volunteers consuming the extract for a month. Preadministration and postadministration data for a variety of probe substrates relating to CYP450 3A4, 1A2, 2E1, and 2D6 were determined. No significant changes were found for valerian (125 mg three times daily for 28 days), and the authors concluded that valerian is unlikely to cause pharmacokinetic interactions mediated by the major CYP450 enzymes. Donovan et al.[35] used higher doses of herb (1000 mg containing 11 mg valerenic acid) taken every night for 14 days by 12 healthy volunteers. They used probe drugs (dextromethorphan and alprazolam) to test for effects on CYP2D6 and CYP3A4. No significant changes in baseline preadministration levels were found.

From the available data, clinically significant pharmacokinetic interactions between valerian and prescription drugs appear to be unlikely despite conflicting results from in vitro studies.

HERB-DRUG INTERACTIONS

Benzodiazepines

Evidence: Diazepam (Valium).
Extrapolated, based on similar properties: Alprazolam (Xanax), bromazepam (Lexotan), chlordiazepoxide (Librium),

clonazepam (Klonopin, Rivotril), clorazepate (Gen-Xene, Tranxene), estazolam (ProSom), flurazepam (Dalmane), lorazepam (Ativan), medazepam (Nobrium), midazolam (Versed, Hypnovel), oxazepam (Serax), prazepam (Centrax), quazepam (Doral), temazepam (Restoril), triazolam (Halcion).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **3. Possible**
Evidence Base: **○ Preliminary**

Effect and Mechanism of Action

In a beneficial interaction specific to settings of withdrawal from benzodiazepine drugs, the effects of valerian reduce benzodiazepine withdrawal symptoms. A GABAergic mechanism has been proposed. The herb also has other potentially beneficial effects on typical withdrawal symptoms, such as antidepressant and antispasmodic activity.

Research

Andreatini et al.[36] used a behavioral test with a rodent model designed to differentiate between anxiolytic and anxiogenic responses to study the effects of a valepotriate preparation (80% dihydrovaltrate, 15% valtrate, 5% acetovaltrate) on the effects of benzodiazepine withdrawal. After treating a group of animals for 28 days with diazepam intraperitoneally (IP), withdrawal symptoms were induced by complete cessation of the drug. Low-dose diazepam (2.5 mg/kg IP) was compared to both 6 mg and 12 mg/kg valepotriates IP. The withdrawal groups given low-dose diazepam and high-dose valepotriates were comparable and exhibited significantly lower anxiety response rates than the control or low-dose valepotriate groups. The authors concluded that valepotriates may be useful in benzodiazepine withdrawal.[36]

A review article by Rasmussen[25] reported clinical work in a drug detoxification setting using botanicals as adjunctive treatment for withdrawal. Valerian and kava were both used extensively in benzodiazepine tapers. The author suggested that duration of use should be limited to 2 to 3 months of continuous administration, although valerian extracts are free from the dependency issues associated with benzodiazepines.

Reports

One case report suggests the "reverse" interaction, in which a patient taking valerian extracts (unspecified) up to five times daily for many years presented with delirium and cardiac failure. The valerian was stopped, and the patient was treated successfully with midazolam and lorazepam, followed by clonazepam (0.5 mg twice daily), and was stable at 8 and 20 weeks after discharge on this regimen.[37] The case is impossible to evaluate, however, because the patient was concurrently taking numerous drugs, including digoxin, benazepril, furosemide, ibuprofen, nitrates, and multiple vitamin and mineral supplements.

Clinical Implications and Integrative Therapeutics

A case can be made for using valerian extracts in clinical settings of benzodiazepine withdrawal to reduce the severity of withdrawal symptoms and increase the likelihood of successful treatment. Long-term dependency on benzodiazepines constitutes a significant problem and is also likely to be seen in the drug detoxification setting. Anecdotal evidence suggests that valerian (as well as kava and other sedative herbs) may be of use in this context where substitution of another, potentially dependency-inducing drug, would be undesirable. Outside the drug taper-withdrawal setting, coadministration of valerian and benzodiazepines is arguably contraindicated because of additive sedative effects, although there is no evidence for synergistic interaction. (See next section.)

Barbiturates and Other Central Nervous System Depressants

Evidence: Phenobarbital (phenobarbitone; Luminal, Solfoton), thiopental (Pentothal).
Extrapolated: CNS depressants, sedative-hypnotics, anticonvulsants, preanesthetics, adrenergic antagonists and related agents.

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability: **6. Unknown**
Evidence Base: **▽ Mixed**

Effect and Mechanism of Action

Extrapolating from experimental extension of barbiturate sleeping times by valerian extracts administered IP in rodent experiments and the clinically established sedative effects of the herb, potentiation of various classes of CNS depressants has been hypothesized. Available evidence suggests predictable additive effects, but synergistic interactions have not been demonstrated.

Research

Animal studies have shown moderate increases in sleeping time when barbiturates were administered with valerian ingredients. However, doses were relatively high and administered IP (50 and 100 mg/kg valerenic acid).[38,39] Hiller and Zetler[40] found that valerian extract at 100 mg/kg IP was equivalent to diazepam at 0.2 mg/kg IP in prolonging anesthesia in mice induced by thiopental. A controlled clinical trial by Kohnen and Oswald[41] examined the effects of valerian extracts (100 mg orally) compared with valerian extracts combined with propranolol (20 mg) in 48 healthy volunteers subjected to stress-inducing tests. No drug interaction was found with the combination, and the researchers concluded that the agents had independent but similar actions, based on the objective and subjective measures used. Low doses of valerian were used in this trial because the researchers decided that higher doses would be excessively sedative, as opposed to lower doses being anxiolytic.

Ugalde et al.[42] used a rigorous experimental design to examine the possible interactions between hydroethanolic extracts of *Valeriana edulis* and six common CNS depressant drugs (diazepam, ethanol, pentobarbital, buspirone, haloperidol, diphenhydramine). The median effective dose (ED_{50}) for dose-dependent sedative effects was established in the rodent model for each drug and for the valerian extracts. Equally effective doses of each drug were then combined with valerian extract in fixed 1:1 ratio, and the combined drug-herb effects were analyzed by isobolographic methodology. This simple mathematical method analyzes fixed-ratio combinations of agents in terms of whether their combined effects are linearly additive (noninteractive) or superadditive (interactive, synergistic) across a range of dose-response data.[43] The researchers found that the combinations of valerian coadministered with each of the six classes of CNS drugs exhibited only linear additive effects. From this point of view, valerian can be said not to display interactions (in a strict supra-additivity sense) with the CNS drugs used. In addition, valerian may be hypothesized to have

multiple mechanisms across a range of receptors, as represented by the diverse neurotransmitter and receptor mechanisms of the six drugs employed. Isobolographic analysis has been theoretically established as a tool for inferring pharmacological mechanisms from dose-response relations of drug combinations.[44]

Clinical Implications and Adaptations

From a clinical perspective, valerian extracts may have additive effects with a range of CNS depressant drugs, although these are not strictly classifiable as interactions, but rather simple linear effects. Warnings to avoid valerian before anesthesia are appropriate, although risks in this setting are unlikely to be significant. Chronic coadministration with sedative-hypnotic, anxiolytic, or anticonvulsant medications is contraindicated.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Anticonvulsants

Some suggest that valerian may exacerbate seizures, thus compromising efficacy of anticonvulsant medications.[14] Not only is there no experimental or clinical evidence for this speculation, but traditional use and neuropharmacology suggest that the herb has anticonvulsive properties.[15] (See Barbiturates.)

Anesthesia

Related but evidence lacking for extrapolation: Halogenated inhalational anesthetic agents: Desflurane (Suprane), enflurane (Ethrane), halothane (Fluothane), isoflurane (Forane), sevoflurane (Sevorane, Ultane).

Concerns regarding use of herbal sedatives before surgical procedure are based on presumptions of the risk of excessive sedation. Given the mild effects of valerian and the high level of available technical monitoring in the operative setting, these risks may be overstated.[45] Reports of perioperative problems with valerian are not available. The use of low doses of herbal anxiolytics before elective surgery could even be argued as potentially beneficial for stress reduction, with minimal effects on sedation.

The 45 citations for this monograph are located under Valerian on the CD at the back of the book.

Vitex

Botanical Name: *Vitex agnus-castus* L.
Pharmacopoeial Name: Agni casti fructus.
Common Names: Chaste tree, chaste berry, agnus-castus, vitex, monk's pepper.

HERB DESCRIPTION

Family

Verbenaceae.

Related Species

Vitex negundo L., *V. trifoliate* L., *V. rotundifolia* L., *V. pediuncularis* Wall., *V. jeguado* L. var *cannabifolia*.[1]

Parts Used

Fruit.

Common Forms

Dried or fresh ripe fruit for decoction.
Tincture, Fluid Extract: Of dried or fresh fruit, 50% to 70% alcohol.
Standardized Extract: 6:1 to 12:1 standardized to casticin 0.6% (e.g., PreMens by Zeller AG).

INTERACTIONS REVIEW

Strategic Considerations

Vitex has an ancient reputation as a "galactogue" and long been considered to suppress sexual excitability. It was more recently popularized in Germany and approved by the Commission E in 1985 for menstrual irregularities.[2,3] Vitex is currently used primarily as a gynecological herb for cyclical problems, including dysmenorrhea, amenorrhea, oligomenorrhea, corpus luteum insufficiency (and infertility related to luteal insufficiency), hyperprolactinemia, premenstrual syndrome (PMS), acne, mastalgia and mastodynia, and lactation issues. The constituents of the fruit are complex, including diterpenes, irdoid glycosides, lipophilic flavonoids, triglycerides, and essential oil. The active constituents are poorly characterized, although the lipophilic components, especially diterpenoids such as rotundifuran, are thought to be important for its effects. Several significant research reports are in German; comprehensive reviews of the data have been published by the *American Herbal Pharmacopoeia (AHP)*,[4] McKenna et al.,[1] and European Scientific Cooperative on Phytotherapy (ESCOP).[5]

No interactions for vitex are documented; this was confirmed by a recent survey on the safety of the herb.[6] The authors confirmed, however, the cautionary note originating from the 1992 revised Commission E monograph, that because of recorded dopaminergic effects in animal experiments, vitex may interact with pharmaceutical dopamine receptor agonists. The Commission E also noted there were no reports of such interactions.[3] The dopamine-binding caution is now widely repeated in the derivative interactions literature, and some sources also suggest that interactions may occur with oral contraceptives (OCs) and hormone replacement therapy (HRT) or with monoamine oxidase inhibitors (MAOIs), selective serotonin reuptake inhibitors (SSRIs), and tricyclic antidepressants (TCAs). However, no interactions reports are associated with vitex. Reviewing the known pharmacology from an integrative perspective will contextualize these speculations.

The emerging consensus is that dopaminergic effects of vitex may be partly responsible for its prolactin-inhibiting actions. Several experimental studies using rodent striatum, calf striatum, and human recombinant dopamine D_2 receptors with two different ligand probes, sulpiride and spiroperidol, suggest that a variable degree of binding occurs between crude extracts and diterpene fractions of vitex.[7,8] However, reviews of all the data, including German unpublished material, suggest an order of magnitude variation (IC_{50} 40-500 µg/mL) in dose required for receptor binding for whole-plant extracts.[1,4,5] Additionally, isolated constituent studies for the diterpene rotundifuran (considered by some to be the most important dopaminergic compound in the crude herb) show an order of magnitude or more difference, with 100 micromolar (µM) rotundifuran about equivalent to 1 µM dopamine (data from Christoffel et al., 1999; reviewed by Upton[4]). It is also unclear whether the receptor binding is in fact agonistic or antagonistic in vivo, and evidence suggests that dose-response kinetics are biphasic. Weak binding also takes place with other receptor subtypes, including mu (µ) and kappa (κ) opioid receptors, as well as to estrogen receptors.[7,9,10] In clinical practice, vitex seems to effect moderate prolactin inhibition and may be clinically appropriate in mild hyperprolactinemia, and the herb will have fewer adverse effects than bromocriptine for such indications.[11]

The D_2 family of receptors are also targets for neurological drugs (antiparkinsonian) and psychiatric (antipsychotic) drugs, such as L-dopa and haloperidol. This has given rise to more speculation on possible interactions between vitex and such psychopharmaceuticals. Clinically, the most typical prescribing patterns for vitex extracts by English-speaking herbal practitioners involve the use of small doses, 0.5 to 5.0 mL crude herb in a single dose, taken in the morning on rising. With this approach, the latency of herb effects on cyclical irregularities and related menstrual problems is extended, typically requiring at least three menstrual cycles to achieve a stable situation.[12,13] This is also seen in the results of clinical trials, where herb effects on both symptom reduction and prolactin secretion became significant over three cycles.

The relation between this pattern of moderate vitex prescription and a slow modulation of cyclical irregularity (or prolactin level normalization) interacting with pharmaceutical agents is difficult to assess. A German report of a trial by Wuttke and colleagues in 1997 is discussed at length in the AHP monograph[4]; measurable reductions of prolactin levels were achieved after 3 months with vitex preparations compared to placebo. However, metoclopramide-induced prolactin secretion did not differ between the treatment and placebo groups. A 2-week trial in 20 healthy males (presumed to lack the cyclical hormone fluctuations in women) found a biphasic response to thyrotropin-releasing hormone (TRH)–stimulated prolactin levels among three groups administered vitex extract at different doses. A low dose (120 mg/day) increased the area under curve (AUC) for prolactin, a high dose (240 mg/day) reduced AUC, but a median dose (240 mg/day) did not differ

from controls.[14] Therefore, the simple view of vitex having a "bromocriptine"-like dopamine agonism apparently is inappropriate, and extrapolating interactions on the assumption that it is a pharmaceutical-level agent is not justifiable. Also, the pharmacology of the herb remains incompletely characterized. Emerging experimental data suggest that vitex extracts may act as agonists to the μ-opiate receptor, although the levels required to achieve median inhibition concentration (IC_{50}) were higher than those likely to be attained in vivo; at this time a role for opiate receptor agonism for vitex in vivo cannot be considered established.[15]

Given that the median age of onset for Parkinson's disease is 57 years, it is unlikely a significant population of female parkinsonian patients would present with typical gynecological indications for vitex. In the psychiatric category, the effects of various antipsychotics and neuroleptics on in vivo dopamine remains poorly understood. The "dopamine hypothesis" of schizophrenia is increasingly considered a controversial oversimplification. Because of the high frequency of pharmacokinetic and pharmacodymanic interactions exhibited by many classes of psychiatric medications, prudence would suggest monitoring usage of all coadministered herbs, and vitex interactions with neuroleptic agents having dopamine D_2, D_3, and D_4 subtypes must remain speculative at this time.

The currently known pharmacology of the herb suggests that the common interactions extrapolated from putative pharmacology between pharmaceuticals and vitex should be considered unproven, or overstated until substantial evidence becomes available.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Analgesic and Anticonvulsant Medications

A research group from India published two related reports in which an extract of *Vitex negundo* was found to potentiate the effects of the anticonvulsant drugs valproate and dihydrophenytoin against electrically induced seizures in a murine model. The same group also established a potentiating effect of the same extract with analgesics drugs (meperidine and aspirin) in an animal test. Until further corroboration of these preliminary reports is available, this cannot be considered an established interaction; it is nonetheless interesting in relation to the different central effects of vitex.[16,17]

Dopamine Agonists and/or Antagonists

Although vitex is sometimes cited as interacting with, for example, anti-Parkinson's medications, reports are absent. (See Strategic Considerations for a discussion of neurotransmitter data.)

Oral Contraceptives and Related Estrogen-Containing and Synthetic Estrogen and Progesterone Analog Medications

Early suggestions that vitex had significant effects on follicle-stimulating hormone (FSH) and luteinizing hormone (LH) have not been substantiated. The herb has been described as "progesteronic," but this is clearly a result of multifactorial effects, including on hypophyseal dopamine levels. Extremely weak binding to recombinant human estrogen receptor (ER) alpha and ER beta has been noted, with IC_{50} levels of 46 and 64 μg/mL, respectively. Weak activity was also found with Ishekawa endometrial carcinoma cell line (ER/PR+).[10] The controlled trial on vitex for PMS symptoms by Berger et al.[18] included 13 subjects concurrently using OCs. No effects were noted on any parameters in the study that were confined to the OC subjects.[18] Suggestions of interactions are hypothetical, and the available evidence would suggest that this is unlikely. In any event, for the majority of situations, coadministration of vitex with exogenous sex hormones could be described as "clinically inappropriate" and does not constitute normal practice.

The 18 citations for this monograph are located under Vitex on the CD at the back of the book.

Beta-Carotene

Nutrient Name: Beta-Carotene
Synonyms: β-carotene, b-carotene, *trans* beta-carotene, provitamin A, betacarotenum.
Related Substances: Other provitamin A carotenoids: alpha-carotene, cryptoxanthin, lutein, lycopene, zeaxanthin; retinol (preformed vitamin A).

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Anthelmintic drugs ⊕⊕⊕	Vitamin A deficiencies are associated with increased risk of parasitic infections. Combining anthelmintic agents with increased beta-carotene (and vitamin A) intake can reduce symptoms of intestinal parasites while supporting epithelial integrity and immune response, especially when combined with increased fat intake.	Coadminister beta-carotene and/or vitamin A and/or foods with accompanying lipid intake. Follow with improved nutrient intake (quality and quantity) to reduce susceptibility.
Chemotherapy Cytotoxic agents ☼/⊕⊕/✗/⊕✗	Administration of beta-carotene before, during, and/or after cytotoxic chemotherapy can mitigate adverse effects (particularly oral mucositis) and may enhance outcomes. Risk of interference of cytotoxic action through antioxidant effects increasingly appears less likely but remains contentious; evidence inconclusive and not likely to be uniform for all agents, conditions, or patients.	Coadministration may be appropriate in some cases. Carotenoid use requires supervision by experienced clinicians collaborating in applying an integrative strategy, particularly given significant risk of toxicity. Multiple nutrients providing a network effect are preferred when antioxidants deemed appropriate.
Cholestyramine Colestipol bile acid sequestrants ≈≈≈/◈	By reducing fat absorption, bile acid sequestrants can significantly reduce absorption, assimilation and transport of beta-carotene and, to varying degrees, other fat-soluble nutrients. Beta-carotene absorption appears more likely than vitamin A (and less likely than other nutrients) to be adversely effected to a clinically significant degree, though that may vary depending upon the agent used, diet and supplemental intake, and patient characteristics. Available research inconclusive and limited by subject population characteristics, duration and scope; further research warranted.	During extended therapy, concurrent administration of multivitamin formulation providing modest levels of carotenoids, along with vitamins A, D, E, and K, folate, and mixed tocopherols, can counter potential adverse effects with little risk and minimal expense. Separate intake.
Colchicine ≈≈≈/◈	Oral colchicine may induce intestinal malabsorption of beta-carotene (and other nutrients) and block hepatic release of retinol-binding protein. Clinical trials warranted to assess frequency and circumstances of occurrence and determine clinical significance.	During extended therapy, coadministration of multivitamin formulation including carotenoids can counter potential adverse effects with little risk and minimal expense.
Medroxyprogesterone ≈≈/☼	Medroxyprogesterone as injectable contraceptive or oral HRT, may elevate serum retinol levels, possibly also retinol-binding protein. Clinical significance of elevated levels and possible alteration in vitamin A function is unclear; however, serum carotenoids may decrease as a result of competition and/or altering vitamin A transport. Response likely to depend on multiple factors including diet and patient characteristics. Further research warranted.	Conservative practice suggests carotenoid support may be indicated. Generally avoid high-dose retinol unless otherwise indicated; if used, monitor carefully when patient has compromised liver function.
Methyltestosterone ◈≈≈/≈≈	Single case report suggests methyltestosterone may impair visual function by altering serum levels and metabolism of beta-carotene and vitamin A. This minimal evidence may represent atypical pharmacogenomic response but indicates need for further investigation, including potential benefit of nutrient supplementation.	Discontinuation of drug therapy indicated on appearance of adverse effects.
Mineral oil ✗/≈≈≈	Mineral oil may interfere with or otherwise alter absorption of many nutrients, especially with simultaneous intake and extended use. Mixed evidence suggests impact on various nutrients may vary, possibly decreasing beta-carotene levels and elevating serum retinol levels. Further research warranted; timing, dosage, duration, diet, and other factors likely to influence degree of clinical significance.	Separate intake of mineral oil from meals and beta-carotene administration. Avoid extended use of mineral oil internally.
Neomycin ≈≈≈/◈	Oral neomycin, particularly high doses over extended periods, may impair absorption and increase elimination of beta-carotene through adverse effects on digestive tract; this could potentially contribute to depletion pattern. Preliminary evidence suggests further research warranted to assess degree of and factors influencing clinical significance.	Coadminister beta-carotene and/or vitamin A with oral neomycin use of 2 days or longer.
Omeprazole Proton pump inhibitors (PPIs) ≈≈≈	Inhibition of gastric acid production may reduce absorption of beta-carotene. Dose response to beta-carotene administration observed after gastric acid inhibition by omeprazole. Further research warranted to assess degree of and factors influencing clinical significance, especially with extended suppression of gastric parietal cell function by antacid therapy.	Encourage increased dietary consumption of carotenoid-rich fruits and vegetables, possibly with beta-carotene or mixed carotenoid supplementation, during extended PPI therapy. Monitoring of blood carotenoid levels may be appropriate.

Continued

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Orlistat ≈≈≈	Orlistat may interfere with absorption of beta-carotene and other fat-soluble nutrients. Mixed evidence suggests degree of impact on various nutrients may vary, with findings ranging from no observed effect to depletion despite concurrent supplementation. Further research warranted; timing, dosage, duration, diet, and other factors likely to influence degree of clinical significance.	Coadministration of a multivitamin formulation providing modest levels of carotenoids, along with vitamins A, D, E, and K and mixed tocopherols, may counter possible depletion patterns with little risk and minimal expense.
Probucol ◇≈≈/≈≈/X/◇	Preliminary research indicates that probucol may interfere with absorption and activity of beta-carotene and other carotenoids, by competing for incorporation into VLDL. Conversely, beta-carotene might potentially interfere with probucol absorption, but evidence is lacking. Further research warranted.	Supplementation with beta-carotene and increased consumption of carotenoid-rich foods may be appropriate. Monitoring may be advisable to ensure drug efficacy.

HRT, Hormone replacement therapy; *VLDL*, very-low-density lipoprotein.
Note: See also monograph for Vitamin A (Retinol).

NUTRIENT DESCRIPTION

This monograph reviews interactions issues relating to and deriving from intake of beta-carotene and other forms of provitamin A, as dietary components and supplements, and the metabolic processes of these substances within physiological/healthy, dysfunctional, and pathological processes and states. The related monograph for Vitamin A (Retinol) focuses on interactions issues involving intake, assimilation, and metabolic processes of the class of compounds that exhibit the biological activity of retinol. Inherently, interactions with some pharmaceutical agents involve both substances and their respective class of related substances.

Chemistry and Forms

Beta-carotene is the most well-known carotenoid, a class of related compounds found exclusively in plants (fruit and vegetable), where they are recognizable as brightly colored red, orange, and yellow pigments. Approximately 600 carotenoids have been identified, and about 50 are known to exert provitamin A activity; that is, they can serve as a naturally occurring precursor to vitamin A. Thus, "provitamin A" is the name of beta-carotene (and related compounds) that most directly describes its primary function in human physiology as viewed by conventional medicine. Alpha-carotene, lutein, lycopene, cryptoxanthin, and zeaxanthin are the most frequently occurring members of the group classified as "provitamin A carotenoids," as is all-*trans* (i.e., synthetic) beta-carotene, which is actually the most active in terms of potential for conversion to vitamin A on a weight basis.

Beta-carotene consists of two retinol molecules. Bonds within beta-carotene are cleaved to form all-*trans* retinol (and possibly *retinal*, the aldehyde form of vitamin A); divergent theories exist regarding the site of this cleavage, the product(s) and their proportion, though molecular structures suggest that one molecule of beta-carotene would result in two molecules of retinol. It is not reasonable, however, to equate the predicted retinol yield of the various provitamin A carotenoids, then add these to provide units of "vitamin A equivalents," because in non–vitamin A–deficient humans, only a small proportion of provitamin A carotenoids are actually converted to retinol or retinal. The supplement labeling convention of stating provitamin A carotenoid content in units of "retinol equivalents" has led to a widespread misperception among the lay public and many medical professionals alike, that such products contain potentially toxic levels of vitamin A. Potential toxicity of carotenoids, such as synthetic beta-carotene supplements in smokers, derives from the bimodal antioxidant/pro-oxidant phenomenon demonstrated by beta-carotene and is unrelated to issues of vitamin A toxicity.

Physiology and Function

In 1913, vitamin A was the first fat-soluble vitamin to be isolated. In 1929, Moore demonstrated that beta-carotene was converted into vitamin A, and 2 years later the chemical structures of both vitamin A and beta-carotene were determined. In 1932, beta-carotene (provitamin A) was discovered to be the precursor to vitamin A. Initially beta-carotene was considered to have the exclusive function in human physiology of serving as a source compound for conversion into vitamin A. The primary physiological functions of carotenoids include exerting antioxidant activity and deoxyribonucleic acid (DNA) protection, enabling both cell-mediated and humoral immunity, and feeding into the metabolic pathways of retinol, which is required for maintenance of all epithelial tissues.

The issue of bioavailability and conversion of beta-carotene and other provitamin A carotenoids to retinol remains contentious, evolving and often confusing because of uncertainty about the functional meaning of "bioavailability" and the inadequacy of the indicators used in its determination. Animal studies of the mechanism of carotenoid conversion to vitamin A indicate that before absorption, the two linked retinol molecules constituting beta-carotene can be converted to vitamin A in the wall of the small intestine. They are hydrolyzed in the gastrointestinal (GI) tract and absorbed into the mucosal cells of the small intestine, where they can be oxidized to retinoic acid and retinol in the presence of fat and bile acids. Carotenoids alpha, gamma, and beta are converted to vitamin A primarily in the intestinal mucosa. Theoretically, beta-carotene should be twice as active as the alpha and gamma carotenoids because it is composed of two potential molecules of retinol, and the others contain only one potential molecule of retinol. Both thyroxine and vitamin E enhance the conversion of carotene to retinol. Diabetes and hypothyroidism are two conditions that may impair conversion of carotenes to vitamin A. In non–vitamin A–deficient humans, it appears that the bulk of provitamin A carotenoids are absorbed intact and are not converted to vitamin A in significant quantities.

Absorption of beta-carotene and other carotenoids is influenced significantly by dietary intake, nutritional status, and storage levels, with efficiency of assimilation and utilization increasing in deficiency states and dropping with saturation of retinol and its metabolites. Beta-carotene and the other primary carotenoids with provitamin A activity demonstrate less bioavailability than retinol, also known as *preformed vitamin A*.

Retinol itself is absorbed two to four times as efficiently as beta-carotene. Carotene relies much more on bile salts for absorption than retinol. Although retinol can also be absorbed from a micelle in the presence of any nonionic detergent, carotenoids can only be absorbed from a micelle in the presence of bile salts. Furthermore, carotenoids are absorbed by passive absorption regardless of their concentration, whereas retinol is absorbed by diffusion when present in high doses but is carrier mediated at low doses.

For all these reasons, only one third of ingested beta-carotene is absorbed, as much as 75% of which can be converted into retinyl esters and retinol, with 25% remaining intact as beta-carotene. Small amounts are then stored in the liver as active retinol. Beta-carotene is approximately one-sixth as biologically active as pure retinol. The resulting convention of 6 micrograms (μg) of beta-carotene being equivalent to 1 μg of retinol is generally accepted, but absorption, conversion, and utilization of carotenoids are highly variable. As the daily intake of carotene rises above 5000 international units (IU; on the basis of theoretical conversion to retinol), the percentage absorption rate decreases significantly. Ultimately, absorption is typically 20% to 50% but can be as low as 10% when intake is elevated.

Storage of beta-carotene and most carotenoids occurs primarily in adipose tissue, the adrenals, epidermal and dermal layers, and the corpus luteum, in contrast to vitamin A, which is predominantly stored in the liver. Minor amounts of beta-carotene are conjugated with glucuronic acid and converted to retinol in the liver; small amounts are also stored in the lungs. Colostrum also contains relatively high levels of carotenoids. Very-low-density lipoprotein (VLDL) or low-density lipoprotein (LDL) cholesterol transports intact beta-carotene in the blood, with blood levels varying according to intake levels. Serum levels of beta-carotene directly reflect daily consumption, not storage. Elimination of beta-carotene is primarily through the feces, but conjugated water-soluble forms are also excreted through the urine.

In plants the antioxidant effects of carotenoids enable these compounds to play a crucial role in protecting plant organisms against damage during photosynthesis. Beta-carotene functions as a chain-breaking antioxidant; rather than preventing initiation of lipid peroxidation, it stops the chain reaction by trapping free radicals, which halts the progression of free-radical activity. Many consider beta-carotene to be the most effective natural agent for quenching single-oxygen free radicals in humans. However, beta-carotene and other carotenoids exhibit a bimodal functionality characteristic of many "antioxidant" agents in that it can act either as an antioxidant or a pro-oxidant, depending on availability of other antioxidant compounds, and the level of oxidative stress present in the compartment in which it is acting.

The *cis* isomers of beta-carotene, which occur only in natural source, as opposed to synthetic all-*trans* beta-carotene, are the most potent scavengers of singlet-oxygen radicals. Under high-oxidative-stress conditions, such as in the lungs of smokers who have a poor dietary intake of other antioxidants, large quantities of beta-carotene, particularly of the all-*trans* isomer, can generate long-lived all-*trans* beta-carotene free radicals, which set in motion their own cell-damaging chain reactions, thus functioning as pro-oxidants rather than antioxidants. The presence of multiple antioxidant substances appearing together in their natural context emphasizes the interdependent network effect of diet-derived antioxidants and suggests that they provide optimal benefit when consumed together rather than as individual, isolated nutrients.

Both beta-carotene and retinyl esters from the diet are converted to retinal (11 *cis* isomer). Retinal is combined with the protein *opsin* to form rhodopsin in the rods of the retina and iodopsin in the cones. Light hitting the retina causes visual excitation and changes the *cis* configuration into the all-*trans* form of retinaldehyde. The rods are particularly sensitive to vitamin A deficiency. When retinol is in low supply, the all-*trans* form generated during the light reaction cannot be converted back to the active rhodopsin, which is why natural sources of carotenes and preformed vitamin A, which provide *cis* isomers, are needed in some cases to prevent or correct night blindness.

The roles and effects of retinol and the various metabolites of vitamin A are reviewed in the Vitamin A (Retinol) monograph and derive, at least in part, from the presence of beta-carotene and the other provitamin A carotenoids.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Until recently, conventional medicine has largely treated beta-carotene as simply a precursor of vitamin A (and assigned similar subsidiary roles to the other carotenoids). Over the past decade, beta-carotene and related carotenoids have been increasingly recognized as independent nutrients of physiological significance with parallel development of recommended intake levels. A small amount of beta-carotene is converted into vitamin A in the body, but beta-carotene and other carotenoids act independently from vitamin A as antioxidants as well as in other roles. Preliminary and experimental studies, as well as significant epidemiological data, suggest that a higher dietary intake of carotenes offers protection against developing certain malignancies (e.g., GI tract, lung, skin, cervix, uterus), macular degeneration, cataracts, and other health conditions linked to oxidative or free-radical damage.

Historical/Ethnomedicine Precedent

Some Western medical traditions, particularly naturopathic medicine, and many indigenous folk and professional traditions of plant medicine (i.e., food and herbs) have emphasized the importance of foods containing carotenoids, readily identifiable through their signature pigments, as important to supporting health and beneficial in treating disease. Mothers and grandmothers have long advocated the consumption of carrots, collards, spinach, and sweet potatoes as "good for you"; they may not have known the mechanisms involved, but they paid attention to outcomes. Modern research into the manifold benefits of the Mediterranean diet increasingly points to the significant contributions of colorful vegetables and fruits and healthy oils from olives and fish toward its salubrious effects.

Possible Uses

Alcohol withdrawal support, asthma, atherosclerosis, cancer (risk reduction), cataracts, cervical dysplasia, cognitive decline (protective; APOE 4 allele), coronary heart disease (risk reduction; in combination), gastritis, heart attack, human immunodeficiency virus (HIV) support, immune support, leukoplakia, lung cancer, macular degeneration, night blindness, osteoarthritis, photoprotection (erythropoietic protoporphyria), photosensitivity, pancreatic insufficiency, scleroderma, sickle cell anemia.

Deficiency Symptoms

Deficiencies of beta-carotene are associated with increased free-radical activity and a weakened immune system. However, comprehensive analysis of deficiency patterns is limited by a narrow conception of its physiological function and subsequent inadequacies in available research data. Scientific research into the deficiency patterns associated with compromised beta-carotene intake has largely been lacking, and specific symptoms attributable to deficiency have not been characterized. Much of the conventional medical literature has focused almost exclusively on beta-carotene's role as a dietary precursor of vitamin A, and as a result, framed deficiencies of this nutrient as largely synonymous with the symptoms of vitamin A deficiency. Inadequate dietary intake of fruits and vegetables rich in carotenoids, signaled by their bright orange, red, and yellow pigments, constitutes the primary cause of beta-carotene deficiency.

Dietary Sources

Beta-carotene occurs exclusively in plant foods (vegetables and fruits). Foods containing high amounts of beta-carotene are yellow and dark leafy green vegetables, especially carrots, collards, sweet potatoes, squash, spinach, and green, yellow, and red peppers, and yellow fruit such as apricot, cantaloupe, and peach.

Mild cooking of food sources (e.g., carrot) for short periods can significantly increase bioavailability compared with raw forms. However, beta-carotene is quite unstable, and exposure to oxygen reduces its potency. Frying, freezing, microwaving, and canning can reduce stable beta-carotene content of foods, whereas overcooking can significantly reduce bioavailability.

Continued uncertainty about the meaning of bioavailability of carotenoids, shortcomings in methods for determining bioavailability and absorption, and emerging knowledge of numerous factors in individual variability reveal fundamental inadequacies and inaccuracy in current systems for evaluating and comparing various forms of vitamin A, particularly those from dietary intake of carotenoid-containing foods. Given the wide range of reported conversion ratios of beta-carotene to vitamin A in humans, including the ratio of 6:1 for beta-carotene and 12:1 for alpha-carotene and cryptoxanthin devised by the World Health Organization (WHO), it appears prudent to consider all such approaches as, at best, providing only an estimate that is not applicable to all diets or individuals.

Dosage Forms Available

Capsule, liquid, tablet.

Source Materials for Nutrient Preparations

Naturally occurring beta-carotene contains 40% of the nutrient as the all-*trans* isomer and 38% in a form designated 9-*cis*. In contrast, synthetic beta-carotene is 97% "all-*trans*" with virtually none of the "9-*cis*" isomer. Absorption of 9-*cis* molecule from food sources may be less than the *trans* isomers, and it can be converted to all-*trans* beta-carotene quickly after assimilation, although actual in vivo fates of the various isomers are complex and uncertain.

Natural beta-carotene supplements can be derived from a variety of sources, such as the sea algae *Dunaliella salina*, and usually contains small amounts of other carotenoids, such as alpha-carotene, lycopene, and cryptoxanthins. However, most commercial products contain synthetic beta-carotene. Many supplements provide a combination of retinol and beta-carotene to increase carotenoid benefits and mitigate risks associated with vitamin A excess. Combinations of mixed carotenoids, along with other naturally occurring antioxidants, are favored by some health care professionals experienced in nutritional therapeutics.

Dosage Range

Dietary: 2 to 6 mg/day.
Supplemental/Maintenance: No recommended dietary allowance (RDA) has been established for beta-carotene. The most common supplemental dose range of beta-carotene is 5000 to 25,000 IU (3-15 mg).
Pharmacological/Therapeutic: 25,000 to 75,000 IU (15-45 mg).
Toxic: No toxic dose has been established.

One IU of beta-carotene is equivalent to one IU of vitamin A; 1 mg of beta-carotene is equivalent to 500 µg of vitamin A, although, as noted previously, these equivalencies are on a theoretical basis only.

1000 retinol equivalents (RE)
= 1 mg retinol
6 mg beta-carotene
12 mg other provitamin A carotenoids
3330 international units (IU) vitamin A

Note: Further discussion of dosage issues and retinol equivalents is provided in the Vitamin A (Retinol) monograph.

Laboratory Values

Plasma beta-carotene: Normal: 0.3 to 0.6 mmol/L

SAFETY PROFILE

Overview

In general, carotenoids are nontoxic, even when consumed in large amounts. Beta-carotene has a high safety profile, and documented reports of serious adverse effects are generally lacking. Absorption and assimilation are self-regulating, and beta-carotene is not stored to a significant degree. Conversion to retinol is tightly regulated.

Nutrient Adverse Effects

Supplemental intake of beta-carotene is not normally associated with adverse effects. However, excessive intake of beta-carotene or other carotenoids in very high amounts (> 100,000 IU, or 60 mg, per day) may result in hypercarotenemia and reversible yellow-orange discoloration of the skin. This can be distinguished from jaundice by the absence of scleral pigmentation.

Beta-carotene may have antagonistic effects on vitamin E status. Thus, it may be advisable to supplement vitamin E if large doses of beta-carotene are given for prolonged periods. In fact, it may be judicious to coadminister the entire range of fat-soluble nutrients to an individual who is taking large doses of beta-carotene for prolonged periods.[1] There have been some reports of women who consume large amounts of carotenoids from foods becoming amenorrheic.

Hypercarotenemia can be associated with hypothyroidism, diabetes mellitus, liver/hepatic disease, and renal disease. It can

also result from a rare genetic variation that reduces the ability to convert beta-carotene to vitamin A.

The most well-known, controversial, and misunderstood concern with potential adverse effects associated with beta-carotene intake derives from its bimodal relationship to oxidative stress. This paradoxical effect was highlighted in the Finnish Alpha Tocopherol Beta Carotene (ATBC) trial, conducted between 1985 and 1993. In this study, more than 29,000 middle-aged men in Finland, who smoked over a pack of cigarettes daily for an average of 36 years each, were divided into four groups and followed for 5 to 8 years. One group received 20 mg (or 33,000 units) of synthetic beta-carotene daily. A second group received 50 mg of synthetic vitamin E, in the form of D,L-alpha tocopherol acetate. A third group received both these vitamins, and a fourth group received a placebo. The results of the study indicated a statistically significant 18% increase in incidence of lung cancer in the group receiving only beta-carotene,[2] which may have been due to the beta-carotene functioning as a pro-oxidant under these conditions. Average consumption of fruits and vegetables in Finland is low, and average consumption of alcohol (another source of oxidative stress) is high. The soil (and thus food produced from it) is very low in selenium, an important antioxidant trace mineral that cofunctions with vitamin E.

In another large study, the U.S. Carotene and Retinol Efficacy Trial (CARET), investigators administered 30 mg of synthetic beta-carotene and 25,000 IU of vitamin A daily to half of a group of 18,000 participants, a fourth of whom were asbestos-exposed men, while the rest were either former or present smokers. The other half of the group received placebo. In this trial, the beta-carotene and vitamin A group had 28% more lung cancers and 17% more deaths than the placebo group.[3] That study was discontinued early because of this trend. Notably, there was no evidence of increased incidence of other forms of cancer related to beta-carotene administration. Beta-carotene may decrease levels of other carotenes, such as lycopene, lutein, and canthaxanthin, in the body. In smokers and people exposed to asbestos, these carotene levels may already be low. Some clinicians have suggested clinical trials with multiple carotenes as well as vitamin E and with vitamin E alone to differentiate the effects of these nutrients, which should prove beneficial; comparisons between supplements from natural sources versus those from synthetic sources and between food sources and supplements are also warranted.[4]

In addition to the pro-oxidant effect associated with using high doses of synthetic beta-carotene in a population likely depleted of antioxidant reserves and under high oxidative stress, *synthetic* versus natural beta-carotene is also an issue. A 1989 Israeli study showed a 10-fold higher accumulation of natural beta-carotene versus synthetic beta-carotene in the livers of laboratory animals. The researchers stated, "Attention should be paid to the different sources of beta-carotene when testing their efficacy . . . such as in their possible role in the prevention of some types of cancer."[5] Even more significantly, natural beta-carotene has shown the ability to reverse premalignant gastric lesions, whereas synthetic beta-carotene had no activity of this sort.[6]

General Adverse Effects

Hypercarotenemia caused by excessive intake is nonthreatening and reflects high concentrations of carotenoids in the plasma and characteristic tissues. The yellowish discoloration of the skin, often most noticeable on the palms and soles, and without yellowing of the whites of the eyes (in contrast to jaundice), is harmless and will gradually recede after excess intake has been halted.

Hypervitaminosis A is not associated with intake of beta-carotene or other carotenoids alone because efficiency of absorption decreases rapidly as intake dose rises, and because the relatively slow rate of conversion to vitamin A is usually inadequate to induce vitamin A accumulation and toxicity.

Diarrhea, dizziness, and arthralgia have been associated with high intake of carotenoid supplements on rare occasions. Reports of allergic reactions, amenorrhea, and leukopenia also appear in the literature, but their incidence appears to be rare.

Adverse Effects Among Specific Populations

Individuals with *erythropoietic protoporphyria* and related disorders may develop canthaxanthin retinopathy with extended intake of 50 to 100 mg of canthaxanthin, a relative of beta-carotene used therapeutically in such patients because it reduces the severe skin photosensitivity.

Hypercarotenemia can also result from a rare genetic variation that reduces the ability to convert beta-carotene to vitamin A.

Synthetic beta-carotene has been associated with increased risk of lung cancer in smokers. This pattern of risk also extends to those with high alcohol intake and increases further when both lifestyle stressors are combined.[5,7,8]

Pregnancy and Nursing

Beta-carotene is not known to increase the risk of birth defects. Animal studies indicate beta-carotene is not toxic to a fetus or a newborn; evidence of adverse effects from human trials or case reports is lacking.

Excretion in breast milk is unconfirmed but probable, given the fat-soluble nature of carotenoids. Caution and professional supervision may be appropriate with high-dose administration during lactation.

Infants and Children

No particular adverse effects or toxicity related to beta-carotene has been indicated for infants or children.

Contraindications

Smokers and other individuals with high oxidative stress, especially involving respiratory exposure, are strongly advised to avoid consumption of synthetic beta-carotene. Similar cautions may be appropriate for individuals with high alcohol intake. Ethanol can interact with beta-carotene and interfere with its conversion to retinol. Furthermore, ethanol can promote a deficiency of vitamin A while also increasing toxicity of both vitamin A and beta-carotene. Some evidence indicates that combining beta-carotene and ethanol may increase the risk of hepatotoxicity.[8] Moreover, in smokers who also consume alcohol, beta-carotene supplementation may further exacerbate oxidative stress to promote pulmonary cancer and, possibly, cardiovascular complications. This narrowed therapeutic window for beta-carotene (and retinol) needs to be considered when formulating treatments for vitamin A deficiency in populations with high ethanol consumption.

Caution may be appropriate in individuals with renal or hepatic impairment.

Although preformed vitamin A intake in excess of 1500 µg/day (5000 IU/day) has been associated with increased risk of osteoporotic fracture and decreased bone mineral density

(BMD) in older men and women, no evidence or underlying pattern indicates that beta-carotene might induce such adverse effects on bone health.

INTERACTIONS REVIEW

Strategic Considerations

Interactions issues involving beta-carotene focus on three primary themes: antioxidant activity, decreased absorption and potential depletion, and purposeful coadministration. Patterns of clinical evidence are emerging in each of these areas, but scientific knowledge and clinical understanding are still limited, and further research is warranted through well-designed trials based on a clear understanding of the physiologic function of beta-carotene and related carotenoids and their roles in clinical practice.

Evidence suggests that mixed carotenes found in food can protect against cancer, cataracts, osteoarthritis, and heart disease.[9-15] Food rich in carotenoids (i.e., colorful vegetables and fruits) are generally considered more beneficial than isolated beta-carotene supplements. Furthermore, products containing only purified beta-carotene, especially of synthetic origin, may actually increase risk for or counter therapeutic measures against these conditions.[2,7,16-19] Thus, for physiological support, disease prevention, and therapeutic application, administration of a group of antioxidant nutrients, including carotenoids, is safer and more efficacious than administration of a single one, thus paralleling the natural pattern of diverse nutrient intake from nutritious food sources. Furthermore, although the body can convert beta-carotene into retinoids, the extent of that conversion is limited. Consequently, consumption of high doses of beta-carotene does not provide the same effect as intake of vitamin A itself.

NUTRIENT-DRUG INTERACTIONS

Note: Some interactions described in the Vitamin A (Retinol) monograph are relevant to the subject of beta-carotene but are presented there without replication here. Although interactions issues for retinoids and beta-carotene usually diverge when examining administration and its effects, directly or concomitantly with pharmaceutical agents, the interactions issues characterized by nutrient depletion are inherently synonymous in most cases. Issues of absorption and assimilation may coincide for these two primary forms of vitamin A, within food or administered as nutritional supplements or therapeutic agents.

Anthelmintic Drugs

Albendazole (Zentel), levamisole (Ergamisol), praziquantel (Biltricide).

Effect and Mechanism of Action

Helminth infections, particularly roundworms, can interfere with vitamin A absorption, partly through their effect on intestinal epithelial cells, and thereby deplete bodily stores of vitamin A. Vitamin A deficiencies are also associated with increased risk of parasitic infections. Increased intake of vitamin A sources, whether through diet or supplementation, can counter this adverse effect of intestinal parasites and can be further enhanced by coadministration of antihelminthic (anthelmintic) agents. Enhanced vitamin A status may then help prevent or reduce symptoms associated with intestinal worms, especially roundworm. Furthermore, beta-carotene and vitamin A supplementation has often been suggested for its physiological role in maintaining epithelial integrity, its ability to stimulate specific and nonspecific immune functions, and its beneficial effects on diarrhea. Absorption of beta-carotene and vitamin A can also be supported by increasing levels of dietary fat intake because both beta-carotene and retinoids are fat soluble.

Research

Depressed iron status and serum retinol have been associated with infections involving intestinal helminths, particularly *Ascaris lumbricoides* and hookworm, in South Asian and African children.[20] Deworming can contribute significantly to the prevention of morbidity and mortality associated with vitamin A deficiency among children in rural communities where intestinal helminth infection is prevalent.[21]

Jalal et al.[22] conducted a study of the effect of food sources of beta-carotene, increased dietary fat, and *A. lumbricoides* infection on serum retinol concentrations in children, 3 to 6 years of age, in Sumatra, Indonesia. Some children were administered levamisole for deworming before the feeding period, and others were untreated and remained infected. These researchers found that the incorporation of beta-carotene sources (primarily as red sweet potatoes) into the diet significantly increased serum retinol concentrations, with the greatest rise occurring when meals contained both additional beta-carotene sources and extra fat and the children had been dewormed. Adding more fat to the meal and deworming caused a rise in serum retinol similar to that observed when the diet included additional beta-carotene. Furthermore, the combined effects of dietary fat and deworming were additive to the effects of dietary additional beta-carotene sources. When the meal contained additional beta-carotene sources, added fat caused a further improvement in serum retinol concentrations, but only if *A. lumbricoides* infection was low.

In a study involving 977 Kenyan children, Mwaniki et al.[23] found that the combination of multi-micronutrient supplementation, including 1000 µg (3300 IU) vitamin A, and multihelminth chemotherapy, using albendazole and praziquantel, reduced egg output of *Schistosoma mansoni*, a species of trematode blood flukes, and increased serum retinol, regardless of initial serum retinol.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Increasing vitamin A or beta-carotene intake through beta-carotene–rich dietary sources and administration of supplements, especially with additional dietary fat intake, can reduce susceptibility to and adverse outcomes from intestinal helminth infections and work synergistically with anthelmintics to eradicate such infections. Health care professionals treating such infections or supporting preventive measures in at-risk populations can improve clinical outcomes by increasing dietary sources of vitamin A, through plant foods rich in beta-carotene and other nutrients, or through administration of broad-based nutritional supplements. Dosing levels for supplements should be based on intake needs and safety restrictions, as determined by age, weight, and other relevant factors.

Chemotherapy (Cytotoxic Agents)

Evidence: Cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox), docetaxel (Taxotere), fluorouracil (5-FU; Adrucil, Efudex, Efudix, Fluoroplex), methotrexate (Folex, Maxtrex, Rheumatrex), paclitaxel (Paxene, Taxol).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**
✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**
⊕✗ **Bimodal or Variable Interaction, with Professional Management**

Antioxidant Activity

Probability: **3. Possible** and **2. Probable**
Evidence Base: ◉◉ **Emerging** and ▽ **Mixed**

Oral Mucositis

Probability: **2. Probable** to **1. Certain**
Evidence Base: ●●● **Consensus**

Effect and Mechanism of Action

Beta-carotene can reduce adverse effects of chemotherapy, particularly oral mucositis (i.e., mouth sores), by reducing drug-induced oxidative stress and free-radical damage. Similarly, beta-carotene may reduce oral mucositis caused by radiotherapy. Such antioxidant activity carries the potential risk of interfering with the free-radical–based mechanism of action of radiotherapy, as well as of drugs such as docetaxel and methotrexate, which require oxidation for activation, particularly when administered within 24 hours of such therapies.

Research

Kennedy et al.[24] conducted a 6-month observational study of 103 children with acute lymphoblastic leukemia treated with chemotherapy. They reported that a large percentage of children undergoing treatment for acute lymphoblastic leukemia (ALL) have inadequate intakes of antioxidants and vitamin A, and lower intakes of antioxidants are associated with increases in the adverse side effects of chemotherapy. In particular, greater beta-carotene intakes at 6 months after beginning therapy were associated with a decreased risk of toxicity.

Mills[25] gave chemotherapy patients approximately 400,000 IU of beta-carotene per day for 3 weeks and then 125,000 IU/day for an additional 4 weeks. Those taking beta-carotene still had mouth sores, but these developed later and tended to be less severe than the sores in patients receiving the same chemotherapy without beta-carotene.

In animal tumor models, beta-carotene has been associated with reduction of 5-fluorouracil (5-FU) activity, but an increase in cytotoxic activity of alkylating chemotherapy agents, etoposide and doxorubicin.

Teicher et al.[26] compared the effect of treatment with beta-carotene alone and in combination with minocycline (a tetracycline antibiotic), as chemotherapy modulators, along with several different chemotherapeutic agents in two murine solid tumors, the FSaII fibrosarcoma and the SCC VII carcinoma. Administration of the modulators alone or in combination did not alter the growth of either tumor. Whereas increases in tumor growth delay (indicative of increased chemotherapy effect) occurred with the antitumor alkylating agents and beta-carotene as well as with minocycline and beta-carotene, a diminution in tumor growth delay (indicative of decreased chemotherapy effect) produced by 5-FU in the presence of these modulators. The modulator combination also resulted in increased tumor growth delay with doxorubicin and etoposide. Tumor-cell survival assay showed increased killing of FSaII tumor cells with the modulator combination and melphalan or cyclophosphamide, compared with the drugs alone. In vitro experiments can be used only as hypothesis generators to test in clinical trials; the results cannot be reliably extrapolated to in vivo effects in human patients.

Beta-Carotene, Antioxidants in General, and Chemotherapy/Radiotherapy

Oxygen radicals have increasingly come under investigation as highly toxic stressors contributing to the causes of many diseases, including many forms of cancer. Beta-carotene is among the nutrients well known as antioxidant agents. Antioxidants protect the body against cellular oxidative damage and thus some of the adverse effects induced by cisplatin and other cytotoxic drugs. Many nutritionally oriented health care professionals regard the oxidative damage caused by chemotherapy as a particularly troublesome adverse effect because evidence increasingly indicates that oxidative damage is a contributing factor in many cancers. Some oncologists consider antioxidants as potentially contraindicated with some agents or during some phases of chemotherapy based on the premise that many chemotherapeutic agents attack cancer cells by inducing oxidative damage, mediated by free radicals. No substantial clinical research in humans has emerged to support this speculation or to warrant considering antioxidants as inherently contraindicated during chemotherapy, and the trend in reviews and meta-analyses increasingly suggests a lack of adverse effect and possible evidence of benefit in some circumstances.[27]

The interactions between chemotherapeutic agents and antioxidant nutrients display some patterns of similarity, but also other aspects of diversity in usage, action, and attention by researchers. The issue of antioxidants in oncology remains controversial, with a small but slowly growing body of clinically based evidence. In general, clinicians and researchers most familiar with antioxidants consistently emphasize the importance of using antioxidant agents in clusters capable of creating an antioxidant network to avert the potential for individual nutrients to act as pro-oxidants under conditions of high oxidative stress, particularly in individuals with multiple biochemical stressors and compromised physiology. Furthermore, high-quality randomized trials that control for the antioxidant contribution of diet, which may well confound the contribution of antioxidant supplements, have not been performed, and this key issue of study design has not been adequately addressed by those presenting their findings as conclusive.

See also Vitamin E or Melatonin monograph for further discussion of antioxidants in relation to radiotherapy.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The coordinated use of beta-carotene and some chemotherapeutic agents may play a valuable role in an integrative approach to oncology care. Consistent evidence supports benefit from beta-carotene in preventing or remediating treatment-induced oral mucositis. Broader use of beta-carotene, alone or with other antioxidants, requires close supervision and regular monitoring and is most appropriate in the context of collaborative care involving health care

professionals trained and experienced in both conventional oncology and nutritional therapeutics. In many cases the timing of such nutritional interventions in the therapeutic sequence is critical to its safety, effectiveness, and synergy. In particular, practitioners who judiciously use antioxidants during chemotherapy or other conventional cancer treatments are advised to question patients about self-prescribing of antioxidants. Such concomitant use could be problematic and contraindicated, beneficial and appropriate, or both, for certain patients with individualized dosage at coordinated intervals. In almost all cases the administration of multiple antioxidant agents, such as mixed tocopherols, vitamin C, *N*-acetylcysteine, parenteral glutathione, coenzyme Q10, and proanthocyanadins, is more likely to be appropriate, safe, and effective than the use of single agents in high doses. Further research through well-designed human trials is necessary to inform this evolving debate.

Cholestyramine, Colestipol, and Related Bile Acid Sequestrants

Evidence: Cholestyramine (Locholest, Prevalite, Questran), colestipol (Colestid).
Extrapolated, based on similar properties: Colesevelam (WelChol).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:
3. Possible

Evidence Base:
◉◉ **Emerging** and/or
▽ **Mixed**

Effect and Mechanism of Action

Absorption of dietary sources of beta-carotene requires bile. Bile acid sequestrants, such as cholestyramine and colestipol, can decrease lipid digestion and absorption, as well as absorption of beta-carotene and other fat-soluble nutrients.[28-33] Furthermore, VLDL or LDL cholesterol transport intact beta-carotene in the blood, with blood levels varying according to intake levels; consequently, decreased lipid levels may impair beta-carotene transport. Conversely, both beta-carotene and vitamin A may increase triglycerides.

Carotenes rely on bile salts for absorption much more than retinol. Retinol can also be absorbed from a micelle in the presence of a nonionic detergent, but carotenoids can only be absorbed from a micelle in the presence of bile salts. Furthermore, carotenoids are absorbed by passive absorption regardless of the concentration, whereas retinol is absorbed by diffusion when present in high doses, but is carrier mediated at low doses.

Research

A general consensus has emerged over the past 40 years: Drugs that alter fat absorption and bile function will disrupt absorption and assimilation of fat-soluble nutrients. However, the evidence on the degree of such impairment, the nutrients affected, and the clinical significance of the phenomena is mixed, inconclusive, and still emerging. Using early research by Longnecker and Basu[28] and later by West and Lloyd,[29] reviews posited a general impairment of absorption of vitamin A and the range of fat-soluble nutrient caused by bile acid sequestrants and other antilipidemic agents. Subsequent human trials have investigated the significance of these effects on various nutrients for different medications used in various patient populations.

West and Lloyd[29] studied the effects cholestyramine (mean dosage, 0·6 g/kg/day) on 18 children with familial hypercholesterolemia over 1 to 2½ years. In addition to a major reduction in serum folate concentration and red blood cell folate, these researchers also noted "a significant decrease in the mean serum concentrations of vitamins A and E and of inorganic phosphorus over the first two years of treatment, although values remain within the normal range." They concluded that "routine administration of fat-soluble vitamins appears unnecessary, but it is prudent to measure prothrombin time [to assess vitamin K status] and serum vitamins A and E at intervals."

Knodel and Talbert[33] reported that large doses of cholestyramine (>32 g/day) may be associated with malabsorption of fat-soluble vitamins but concluded that impaired absorption of vitamins D and K presented the most significant clinical risk with long-term therapy, with bone loss and bleeding disorders being the potential adverse outcomes. However, in a 3-year, double-blind randomized trial involving 303 hypercholesterolemic subjects, Elinder et al.[34] demonstrated that cholestyramine lowered serum concentrations of beta-carotene by 40% "due to impairment of gastrointestinal absorption and to serum cholesterol lowering"; likewise, vitamin E and lycopene were reduced by 7% and 30%, respectively.

In a study involving type IIa hyperlipoproteinemic patients, Probstfield et al.[35] observed that serum total carotenoid levels fell by 30% after administration of colestipol (30 g/day) for 6 months, most likely as a result of decreased absorption of carotenoids induced by bile acid sequestrant administration, but that serum vitamin A levels were not significantly altered. Tonstad et al.[36] investigated the effects of colestipol granules (10 g/day), along with a low-fat diet, in an 8-week, double blind placebo-controlled trial, followed by open treatment for 44 to 52 weeks, on LDL cholesterol levels in 37 boys and 29 girls, age 10 to 16 years, with familial hypercholesterolemia. Serum concentrations of vitamins A and D, as well as other relevant nutrient parameters, were not affected significantly in the colestipol group even though levels of serum folate, vitamin E, and carotenoids were significantly reduced. Thus, although these researchers did not suggest a need for compensatory enhancement of fat-soluble nutrients in general or vitamin A in particular, they did recommended supplementation with folate and "possibly vitamin D." They also noted the high degree of noncompliance among the adolescents in the study.[36]

This trend toward a significant interaction raises serious questions given the ongoing debate regarding the correlation between nutrient status, particularly dietary antioxidants, and long-term risk of coronary heart disease. Most importantly, the limited scope of the research available and lack of follow-through investigation of long-term effects (i.e., decades) of such drug-induced nutrient depletion patterns on nutrient status, healthy cardiovascular function, and ultimate outcomes render the data suggestive but inconclusive in answering the fundamental questions of benefit and risk.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although not always necessary, supplementation with beta-carotene, as well as other affected nutrients, in the form of a multivitamin-mineral formulation can provide a safe and inexpensive means of avoiding adverse effects from these medications without interfering with (and perhaps enhancing) the therapeutic goal of supporting healthy cardiovascular function and reducing risk. Beta-carotene and other fat-soluble nutrients (as well as folic acid and many medications) should be taken

1 hour before or 4 to 6 hours after bile acid sequestrants for optimal absorption. Characteristics of the individual being treated will influence the need for compensatory nutrient administration, particularly age, typical diet, digestive function, comorbid conditions, and pharmacogenomic response to the medication being used. Increased consumption of red, orange, and yellow fruits and vegetables, which may also contribute to cholesterol lowering, as well as providing increased dietary intake of carotenoids, should be encouraged.

Colchicine

Colchicine

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **4. Plausible** or **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Oral colchicine may impair absorption of beta-carotene and other nutrients.[37,38] Colchicine also blocks hepatic release of retinol and retinol-binding protein (RBP) and thereby impairs upregulation of serum retinol and interferes with its homeostasis.

Research

Race et al.[37] reported that oral colchicine can induce intestinal malabsorption, affecting beta-carotene and other nutrients.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing colchicine for extended regular use should suggest the likely benefit of using a high-potency multivitamin/mineral supplement to compensate for potential drug-induced depletion of beta-carotene and other nutrients. Further research through well-designed human trials is warranted to determine the severity, frequency, and clinical implications of this probable interaction and to identify characteristics of individuals most susceptible to clinically significant adverse effects and the circumstances involved.

Medroxyprogesterone

Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); medroxyprogesterone, oral (Cycrin, Provera); medroxyprogesterone, injection (Depot medroxyprogesterone acetate, DMPA; Depo-Provera, Depo-subQ Provera 104); progestin and estrogen injectable: estradiol cypionate and medroxyprogesterone acetate (Cyclofem, Lunelle).

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **3. Possible** or **2. Probable**

Evidence Base: ◉◉ **Emerging**

Effect and Mechanism of Action

Medroxyprogesterone acetate (MPA) use is associated with elevations in serum retinol levels. Exogenous estrogen and progestin increase hepatic synthesis of RBP, thus increasing the export of RBP-retinol complex in the blood.

Research

Numerous clinical trials have investigated the effect of medroxyprogesterone administration, whether for contraception or as a component of menopausal hormone replacement therapy (HRT), on blood levels of vitamin A and its metabolites as well as other nutrients. Elevations in serum retinol levels have been observed in most studies, with 40% mean increases in some trials; RBP elevations were also noted in one study.[39-43] In a trial involving 12 healthy, nonlactating Thai women, Amatayakul et al.[39] found no significant changes in serum levels of several nutrients, including vitamin A, before and with daily coadministration of a vitamin-mineral supplement, including beta-carotene and vitamin A, in association with 1 year's continual use of MPA as an injectable contraceptive (150 mg intramuscularly every 90 days). In a subsequent study focusing on the effect of 1 year of oral contraceptive (OC) use on liver vitamin A storage, as assessed by the relative dose response (RDR) test, daily (one capsule) or periodic (two capsules 7 days per month) multivitamin supplementation, including 1700 µg vitamin A per capsule, did not significantly influence vitamin A serum values. After 13 cycles, however, the RDR test was elevated in one individual who had taken OCs and the periodic multivitamin supplement, returning to normal after supplementation with vitamin A.[41]

Given the inadequate nutritional intake or compromised nutrient status of the women in some of these studies, the researchers have interpreted the phenomena of elevated serum retinol as beneficial. However, in the study of Nigerian women, whose diet is typically high in carotenoids, Wien and Ojo[44] reported that serum carotene was lower in OC users (combination estrogen-progestogen) than in groups using intrauterine devices (IUDs) or injectable progestogen. These researchers concluded that "more detailed study of plasma transport forms of vitamin A is needed to determine if the very high serum vitamin A levels seen in some OC users in this population are potentially harmful." The role of dietary and supplemental beta-carotene in this interaction pattern deserves further research through well-designed human trials to determine the severity, frequency, and clinical implications of this probable interaction and to identify characteristics of individuals most susceptible to clinically significant adverse effects and the circumstances involved. Studies of tissue levels of retinol and carotenoids in these populations would also be useful.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing medroxyprogesterone, for contraception or as a component of menopausal HRT, are advised to consider monitoring blood levels of vitamin A in patients, particularly those with compromised liver function. Enhanced carotenoid intake may be beneficial, through diet and supplementation, and is unlikely to contribute significantly to further elevation of vitamin A levels, given the body's limited ability to convert carotenoids to vitamin A. In some individuals, vitamin A supplementation may need to be avoided; in others it might be indicated, depending on individual patient characteristics and response to the medication. Dietary intake of provitamin A carotenoids and preformed vitamin A, nutritional status, age and menstrual status, dose, form, and therapeutic intent are all important factors that appear to influence the degree to which medroxyprogesterone administration alters beta-carotene and

vitamin A levels and functions and whether that effect is beneficial, adverse, or insignificant.

Methyltestosterone

Methyltestosterone (Android, Methitest, Testred, Virilon).
Related but evidence lacking for extrapolation: Methyltestosterone combination drug: methyltestosterone and esterified estrogens (Estratest, Estratest HS); testolactone (testolacton, HSDB 3255, SQ 9538; Fludestrin, Teolit, Teslac, Teslak).

Interaction Type and Significance

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **6. Unknown**

Evidence Base: ☐ **Inadequate**

Effect and Mechanism of Action

The mechanisms involved in the report examined are not established, and research has not specifically focused on this potential interaction, its mechanisms, susceptibility factors, or clinical implications.

Report

Nisbett et al.[45] reported the case of a 59-year-old man who presented with a 3-month history of night blindness and a 9-month history of steatorrhea after initiating therapy with methyltestosterone. Low serum levels of carotene (0.1 mmol/L) and vitamin A were accompanied by numerous changes in visual function. The symptoms and the biochemical and electrophysiological abnormalities resolved within 9 months of the discontinuation of methyltestosterone.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although this report may represent an anomalous phenomenon, resulting from pharmacogenomic variability and/or other factors, it still suggests a need for further research. Physicians prescribing methyltestosterone (an anabolic steroid, not testosterone replacement) may find it prudent to assess patients for beta-carotene and vitamin A status and recommend concomitant supplementation with beta-carotene and/or vitamin A as indicated.

Mineral Oil

Mineral Oil (Agoral, Kondremul Plain, Liquid Parafin, Milkinol, Neo-Cultol, Petrogalar Plain).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **4. Plausible** or **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Mineral oil, as a lipid solvent, may absorb many substances and interfere with normal absorption of beta-carotene, retinol, and other nutrients.

Research

Some disagreement exists, but most research has found that mineral oil can interfere with the absorption of, and thus contribute to a depletion of, many nutrients, including beta-carotene, calcium, phosphorus, potassium, and vitamins A, D, K, and E. One study involving 25 children with chronic constipation found that a short course of mineral oil can reduce serum levels of beta-carotene while elevating serum retinol levels modestly.[46]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

As a preventive and protective measure, health care professionals are advised to recommend regular use of a multivitamin supplement to individuals using mineral oil for an extended period. Malabsorption of fat-soluble vitamins from ingestion of mineral oil can be minimized by administering mineral oil on an empty stomach or administering vitamin or mineral supplements at least 2 hours before or after the mineral oil. In general it is advisable to limit the internal use of mineral oil to less than 1 week.

Neomycin

Neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin).
Combination drugs: Adcortyl with Graneodin, Betnovate-N, Dermovate-NN, Gregoderm, Synalar N, Tri-Adcortyl, Trimovate.

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable**

Evidence Base: ●●● **Consensus** or ○ **Preliminary**

See also Vitamin A (Retinol) monograph.

Effect and Mechanism of Action

Neomycin may damage the structure and adversely affect the function of the lining of the digestive tract. In many individuals this reduces the absorption and increases the elimination of beta-carotene from the body.[30,38] Neomycin may also reduce the bioavailability of vitamin A.

Research

Orally administered neomycin can impair absorption of beta-carotene (and vitamin A).[47-50]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing neomycin internally for more than 2 or 3 days can advise patients of the probable benefit of supplementing with beta-carotene (25,000 IU or 15 mg daily) or vitamin A (25,000 IU or 7.5 mg daily). Individuals using neomycin topically will not experience problems related to malabsorption; likewise, adverse effects are unlikely to result from a single dose of oral neomycin as part of surgery preparation.

Omeprazole and Related Proton Pump Inhibitors

Evidence: Omeprazole (Losec, Prilosec).
Extrapolated, based on similar properties: Esomeprazole (Nexium), lansoprazole (Prevacid, Zoton), pantoprazole (Protium, Protonix, Somac), rabeprazole (AcipHex, Pariet).

Interaction Type and Significance
≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action
Proton pump inhibitors (PPIs) impair production of stomach acid by inhibiting the hydrogen-potassium–adenosine triphosphate (ATP) enzyme system in gastric parietal cells. This change in the gastric environment and its effect on subsequent digestive chemistry may adversely affect absorption of beta-carotene, as well as other nutrients.

Research
In a crossover trial involving 12 normal adults, Tang et al.[51] administered omeprazole for 7 days to block gastric acid secretion and raise gastric pH from the normal postprandial level of between 1 and 2 to greater than 4.5. They then measured blood levels of beta-carotene after a single dose of 120 mg beta-carotene before starting omeprazole (low gastric pH phase), then again after administering omeprazole for 9 or 26 days (high gastric pH phase). Increases in serum concentrations of both *trans* and *cis* beta-carotene at 6 and 24 hours after the beta-carotene dose were significantly greater at a low gastric pH phase (i.e., without omeprazole) than at a high gastric pH phase (i.e., with omeprazole). Likewise, 24 hours after beta-carotene administration, the area under the blood beta-carotene response curve (*trans* plus *cis* beta-carotene) was significantly greater at a low gastric pH than at a high gastric pH. Results after 9 days of omeprazole were the same as those after 26 days. Although expressing uncertainty as to the mechanisms underlying the observed phenomenon, the researchers concluded that "suppressed blood response of beta-carotene at a high intraluminal pH may have been due to the slower movement of negatively charged micelles through the unstirred water layer and cell membrane."[51]

This test demonstrated that almost complete loss of stomach acid in healthy subjects can interfere with the digestive absorption of single-dose beta-carotene. However, its limited design did not address the response to repeated administration of supplemental beta-carotene or carotenoids from food sources in determining whether continued use of PPIs might induce beta-carotene depletion. The results do suggest that testing blood carotenoid levels in patients receiving extended PPI therapy might be useful and, if low, dietary or supplemental therapy instituted.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Physicians prescribing PPIs for extended periods are advised to recommend that these patients increase their dietary intake of fruits and vegetables rich in carotenoids and consider supplementation with naturally occurring forms of beta-carotene. Monitoring of blood levels of carotenoids could be used to detect and forestall nutrient depletion, if suspected. Further research through well-designed human trials is warranted to determine the severity, frequency, and clinical implications of this plausible nutrient depletion pattern and to develop guidelines for protecting nutrient status.

Orlistat

Orlistat (alli, Xenical).

Interaction Type and Significance
≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability:
3. Possible (short term) or
2. Probable (long term)

Evidence Base:
○ **Preliminary** or
◉◉ **Emerging**

Effect and Mechanism of Action
As a GI lipase inhibitor, and thus an inhibitor of dietary fat absorption, orlistat may also decrease absorption of beta-carotene and other fat-soluble nutrients. Carotenes rely on bile salts for absorption to a much greater extent than retinol does. Furthermore, in contrast to retinol, carotenoids are absorbed by passive absorption and are not stored to the extent of retinol.

Research
Clinical trials investigating the short-term pharmacokinetic effects of orlistat on beta-carotene, vitamin A, and other nutrients have shown reductions in nutrient absorption but no significant depletion in the time frame studied. In an open-label, parallel, placebo-controlled, randomized, two-way crossover study involving 48 healthy subjects in 1996, Zhi et al.[52] demonstrated that simultaneous intake of orlistat and beta-carotene can reduce beta-carotene by approximately one-third. They concluded that two thirds of a dose of beta-carotene will still be absorbed during orlistat treatment, and that such intake levels would generally be sufficient to achieve physiological levels of beta-carotene with an appropriate dose, when coadministered to prevent or respond to orlistat-induced beta-carotene deficiency. Also in 1996, in a small, open-label, placebo-controlled, randomized, two-way crossover trial, Melia et al.[53] investigated the effect of orlistat on the absorption of sequential single oral doses of vitamins A (25,000 IU) and E (400 IU) in 12 healthy volunteers. Based on subsequent analysis of serum concentrations of retinol, they found no significant effect on absorption of vitamin A during oral administration of 120 mg orlistat or placebo three times daily for 9 days, although absorption of vitamin E was reduced significantly (about 43% according to maximum concentration and 60% according to area under the concentration-time curve). Beta-carotene was not directly studied in this experiment, but general pharmacological principles suggest that its absorption would be more susceptible to impairment than that of vitamin A.

Longer trials indicate that regular use of orlistat can exert a continued effect on nutrient absorption, but the cumulative effects of this pharmacokinetic phenomenon have not been studied for more than 1 year. In a multicenter, randomized, double-blind, parallel-group clinical trial involving 676 obese male and female subjects, van Gaal et al.[54] demonstrated reduced blood levels of vitamin A (and vitamin D) after administration of orlistat for 6 months in conjunction with a mildly hypocaloric diet. However, mean levels of beta-carotene, as well as of vitamins A, D, and E, remained within the clinical reference ranges in all treatment groups. A small percentage of patients developed levels deemed low enough to require supplementation. However, at the end of a 1-year, randomized, double-blind, placebo-controlled, multicenter trial involving 228 obese adult patients, Finer et al.[55] also reported that orlistat decreased plasma levels of beta-carotene (and vitamin E) compared with placebo.

They concluded, "Fat-soluble vitamin supplements may be required during chronic therapy."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Research into the efficacy and tolerability of orlistat indicates that it can be an effective tool in treating obesity. However, further research is warranted to investigate the probable risk of long-term nutrient depletion as a result of known adverse effects on absorption of beta-carotene and other fat-soluble nutrients. Pending conclusive evidence of a lack of cumulative effect, physicians prescribing orlistat for longer than 3 months can recommend to their patients that they take a multivitamin supplement containing naturally occurring forms of beta-carotene, alpha-tocopherol, and other potentially affected nutrients, at least 2 hours after orlistat or at bedtime.

Further research through long-term, well-designed human trials can determine the severity, frequency, and clinical implications of this probable nutrient depletion pattern and identify characteristics of individuals most susceptible to clinically significant adverse effects and the circumstances involved.

Probucol

Probucol (Bifenabid, Lesterol, Lorelco, Lurselle, Panesclerina, Superlipid).

Interaction Type and Significance

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary;** possibly ◉◉ **Emerging**

Effect and Mechanism of Action

Probucol is lipid soluble and can interfere with absorption and activity of beta-carotene and other carotenoids, at least in part, through competition for incorporation into VLDL during hepatic synthesis.

Research

In a 3-year, double-blind randomized trial involving 303 hypercholesterolemic subjects, Elinder et al.[54] demonstrated that probucol reduced serum carotenoids by 30% to 40%, "most probably due to reductions in lipoprotein particle size and to competition with these substances for incorporation into VLDL during its assembly in the liver." Similarly, serum vitamin E decreased 14% secondary to cholesterol and triglyceride lowering.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The available research, although limited, provides strong preliminary evidence that use of probucol, a lipid-soluble antioxidant and cholesterol-lowering drug, may have adverse effects on blood levels of beta-carotene and other diet-derived antioxidants. Supplementation with affected nutrients may be judicious to prevent or reverse depletion, and regular monitoring is appropriate to confirm that such increased nutrient intake does not interfere with drug efficacy by the same apparent mechanism of competition that contributes to the decrease in nutrient levels. Further research through well-designed human trials is warranted to determine the severity, frequency, and clinical implications of this probable nutrient depletion pattern and to develop guidelines for protecting nutrient status while maintaining drug efficacy.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

HMG-CoA Reductase Inhibitors (Statins)

Atorvastatin (Lipitor), fluvastatin (Lescol, Lescol XL), lovastatin (Altocor, Altoprev, Mevacor), combination drug: lovastatin and niacin (Advicor), pravastatin (Pravachol), rosuvastatin (Crestor), simvastatin (Zocor); combination drug: simvastatin and extended-release nicotinic acid (Niaspan).

It is known that 3-hydroxy-3-methylglutaryl–coenzyme A (HMG-CoA) reductase inhibitors may increase serum retinol levels.[56] However, the question of how HMG-CoA reductase inhibition might influence beta-carotene metabolism or alter liver regulation of vitamin A has not been investigated.

Very-low-density lipoprotein cholesterol or LDL cholesterol transports intact beta-carotene in the blood, with blood levels varying according to intake levels; consequently, decreased lipid levels may impair beta-carotene transport. Conversely, both beta-carotene and vitamin A may increase triglycerides.

Further research through well-designed human trials is warranted to determine the severity, frequency, and clinical implications of this potential interaction and to identify characteristics of individuals most susceptible to clinically significant adverse effects and the circumstances involved.

Retinoids: Isotretinoin, Tretinoin

Acitretin (Soriatane), bexarotene (Targretin), etretinate (Tegison), isotretinoin (Accutane), tretinoin (all-*trans* retinoic acid, ATRA; Atragen, Avita, Renova, Retin-A, Vesanoid, Vitinoin).

The concomitant use of retinoids and supplemental vitamin A is generally considered contraindicated based on additive toxicity of the two structurally similar substances. However, no such risk pertains to coadministration of pharmaceutical retinoids and beta-carotene. Some retinol is metabolized into retinoic acid, but in the absence of retinol deficiency, very little beta-carotene (or other provitamin A carotenoid) is metabolized into retinol.

Quinidine

Quinidine (Quinaglute, Quinidex, Quinora).

Quinidine therapy is associated with the development of sensitivity to ultraviolet radiation from the sun (photosensitivity) in certain individuals. Preliminary research by Fisher[57] involving three subjects indicates that patients with skin inflammation caused by quinidine may experience greater tolerance of intense sun exposure without recurrence of the rash when supplemented with 90 to 180 mg beta-carotene daily.

Although data are promising, further research is necessary to confirm that individuals taking quinidine can prevent adverse effects by supplementing with beta-carotene.

NUTRIENT-NUTRIENT INTERACTIONS

Carotenoids

Antheraxanthin, astaxanthin, canthaxanthin, alpha-carotene, beta-carotene, epsilon-carotene, gamma-carotene, zeta-carotene, alpha-cryptoxanthin, diatoxanthin, 7,8-didehydroastaxanthin, fucoxanthin, fucoxanthinol, lactucaxanthin, lutein, lycopene, neoxanthin, neurosporene, peridinin, phytoene, rhodopin, rhodopin glucoside, siphonaxanthin, spheroidene, spheroidenone, spirilloxanthin, uriolide, uriolide acetate, violaxanthin, zeaxanthin.

Large doses of beta-carotene could theoretically reduce bioavailability, assimilation, and utilization of other carotenoids. In one small study with two healthy subjects, White et al.[16] observed that ingestion of beta-carotene concurrently with the carotenoid canthaxanthin reduced the peak serum canthaxanthin concentration by 38.8% and the 72-hour area under the serum canthaxanthin concentration-time curve by 34.4%. These results suggest that administration of beta-carotene inhibits the bioavailability of canthaxanthin. Although canthaxanthin had no effect on the bioavailability of beta-carotene, these findings suggest that administration of beta-carotene alone might promote deficiencies of other carotenoids. Further research is necessary to draw any reliable conclusions regarding bioavailability interactions between provitamin A carotenoids.

Vitamin E (Alpha-Tocopherol)

A competitive relationship between beta-carotene and alpha-tocopherol has been suggested, but evidence is lacking. Generally, health care professionals experienced with antioxidant nutrients recommend that multiple antioxidant agents be coadministered to achieve a network effect that would enhance beneficial effects and prevent the agents from exerting pro-oxidant activity.

The 57 citations for this monograph, as well as additional reference literature, are located under Beta-Carotene on the CD at the back of the book.

Folic Acid

Nutrient Name: Folic acid; folate, folinic acid.
Synonyms: Folacin; folate triglutamate, folicin, pteroyltriglutamate, pteroylglutamic acid, vitamin B_9, vitamin Bc, vitamin M; 5-formyltetrahydrofolate (5-FTHF), 5-methyltetrahydrofolate (5-MTHF), 6(S) 5-MTHF, L-methylfolate; calcium folinate, calcium levofolinate, citrovorum factor, sodium folinate.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Acetylsalicylic acid (ASA, aspirin) Salsalate ≈≈/≈≈≈/☼/⊕⊕⊕	Aspirin and salicylic acid can inhibit folate-dependent enzymes, interfere with folate metabolism, and increase urinary excretion of folate. Drug-induced impairment well-documented, but degree of adverse effects variable depending on dose, duration, and patient characteristics. Evidence lacking that coadministration of folic acid might interfere with drug activity. Synergy probable with low-dose ASA in stroke prevention.	Supplement folic acid with chronic and high-dose ASA or salsalate.
Antacids Histamine (H_2) antagonists Gastric acid–suppressive medications ≈≈≈/≈≈/☼/◇	Agents that interfere with normal acidic-alkaline balance in gastrointestinal environment, particularly alkalinization of jejunum, can impair folic acid absorption and availability. Mineral-containing antacids can reduce absorption by binding folate. Adverse effects on vitamin B_{12} assimilation may also impair folate function. Possible clinically significant folate deficiency (and B_{12} depletion), which may not parallel degree of change in pH, especially in compromised patients. MTHFR and CYP2C19 polymorphisms, compromised gut ecology, Zollinger-Ellison syndrome, and atrophic gastritis.	Coadminister folic acid, as well as a cobalamin intramuscularly or orally (>500 µg/day), during extended antacid therapy.
Anticonvulsant medications Antiepileptic drugs (AEDs) ☼/◇≈≈≈/≈≈/◇◇/ ≈◇◇/⊕✗/✗✗/✗✗✗	Adverse effects of anticonvulsants on folate are documented and well known, especially with multiple agents. AEDs decrease absorption of folate (and cobalamin); all except valproic acid induce CYP450. Anemia common from drug-induced folic acid and B_{12} deficiency, also elevated homocysteine. Teratogenic effects may be particularly severe, even months before pregnancy. Evidence conclusive, but variable probability of clinically significant effect. Folic acid may decrease phenytoin levels and increase risk of seizure activity; unlikely with <1 mg/day folic acid. Folate mouthwash protects against gingival hyperplasia.	Supplement folic acid and B_{12} during extended or multidrug anticonvulsant therapy. Monitor folate, homocysteine, and cobalamin status and medication levels. Avoid pregnancy; otherwise, supplement or change medication. Genomic testing may be warranted.
Antifolates, antimetabolites Lometrexol, methotrexate, pemetrexed ✗✗✗/⊕⊕/◇≈≈/☼/ ⊕✗/◇◇	Antifolates competitively inhibit folate and interfere with folate-related enzyme systems; thus they inherently carry significant risk of folate deficiency and attendant toxicity. Folic acid or 5-MTHF may impair antineoplastic activity but is often appropriate for reducing adverse effects and sometimes critical against toxicity. Significant effect axiomatic, and coherent pattern of evidence emerging as to coadministration.	Pharmacogenomic assessment helpful in predicting drug efficacy and tolerance. Folic acid or 5-MTHF generally warranted in treating inflammatory conditions; only with close supervision and active management in integrative oncology setting. Monitor folate status and medication levels.
Bile acid sequestrants ≈≈≈/◇/⊕⊕	Bile acid sequestrants likely to impair absorption and reduce bioavailability of folic acid and B_{12}, as well as fat-soluble nutrients. Coadministration suggested for comprehensive cardiovascular support strategy. Further research warranted. Cholestyramine and folinic acid may be used together to reduce methotrexate toxicity.	Folic acid recommended as prudent and proactive, especially in children and with MTHFR C677T mutation. Fat-soluble nutrients warranted. Separate intake of drug and nutrients.
Chloramphenicol ◇≈≈/☼/⊕⊕⊕/◇	Chloramphenicol interferes with hematopoietic processes and may cause aplastic anemia. Folic acid may prevent or reduce such adverse effects. Drug activity may impair therapeutic action of folic acid. Significant effect probable but specific evidence lacking; broad agreement on mechanisms.	Coadministration of folic acid prudent with extended chloramphenicol. Monitor hematological parameters.
Colchicine ◇≈≈/☼/⊕⊕⊕/◇	Colchicine may decrease folate levels. Minimal evidence. Significant effect plausible. Evidence lacking to confirm benefit of concomitant folic acid. Research may be warranted.	Coadminister folic acid during extended colchicine therapy. Monitor folate and homocysteine levels.
Fibrates Fenofibrate, bezafibrate ≈≈/☼/⊕⊕⊕	Fenofibrate, bezafibrate, and to lesser degree other fibrates are known to elevate total plasma homocysteine (Hcy), but primarily nonatherogenic protein-bound Hcy. Observed effect most likely from mechanisms other than folate depletion. Concomitant folic acid may lower Hcy and enhance therapeutic strategy, but evidence mixed as to whether drug-induced effects on Hcy are clinically significant.	Administration of folic acid, B_6, and B_{12} may be appropriate, if only for strategic considerations. Monitor folate, Hcy, and lipid levels.
Fluoxetine Selective serotonin reuptake inhibitor and serotonin-norepinephrine reuptake inhibitor (SSRI and SSRI/SNRI) antidepressants ⊕⊕	Folate plays important roles in synthesis of S-adenosylmethionine (SAMe) and tetrahydrobiopterin; deficiency may be associated with depressive disorders and lack of response to SSRIs. Concomitant folic acid may enhance response to fluoxetine therapy by improving tryptophan, phenylalanine, and serotonin status; improvements in Hcy levels may also support strategic outcomes.	Coadminister folic acid with SSRI therapy. Monitor tissue folate and plasma Hcy levels. Genetic assessment often relevant.
Isoniazid (INH), rifampin Antitubercular agents ☼/◇≈≈	Generally accepted that isoniazid and related antitubercular medications adversely affect action of folate and potentially induce depletion. Multiple mechanisms likely, including interference with B_6 and B_{12}, but knowledge incomplete.	Broad nutrient support, including folic acid, B_3, B_6, and B_{12}, judicious during antitubercular therapy. Supervise closely and monitor regularly.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
	Numerous reports of adverse effects, but evidence inconclusive and further research needed.	
Levodopa Antiparkinsonian medications ☼/⊕⊕/◈≈≈	Levodopa can elevate Hcy in Parkinson's patients, particularly in the context of compromised B-vitamin status, caused by competition at site of methylation. Folic acid, with B_6 and B_{12}, may help prevent Parkinson's, maintain healthy Hcy levels, and reduce adverse effects of levodopa therapy. Evidence of folate's effects on Hcy is well-established. However, evidence of benefit from folate during levodopa therapy limited. Genomic factors may significantly influence pathology, folate levels, nutrient activity, and drug response.	Supplement folic acid (and B_{12}) during levodopa therapy. Monitor folate, Hcy, and L-dopa levels. Caution appropriate regarding high-dose B_6 use with carbidopa or benserazide.
Lithium ⊕⊕	Higher folate levels may be associated with better clinical response to lithium. Coadministration of folic acid may enhance therapeutic efficacy of lithium therapy. Evidence lacking to suggest that lithium depletes folate or folic acid reduces lithium adverse effects.	Concomitant folic acid may be beneficial, but drug dose may need to be modified. Monitor folate status and lithium levels.
Mercaptopurine, azathioprine, and thioguanine Thiopurines ✗/⊕✗/⊕	Thiopurines are cytotoxic antimetabolites used predominantly in cancer and autoimmune disease therapies where they act as purine antagonists and tend to induce myelosuppression and macrocytic normegaloblastic anemia. Genetic variation in folate handling may influence drug efficacy and toxicity. Limited evidence indicates that concomitant folate may protect bone marrow, moderate drug adverse effects, and enhance tolerance.	Consider folic acid or 5-MTHF coadministration. Monitor folate and hematological status. Pharmacogenomic evaluation may be warranted.
Metformin Biguanides ≈≈/☼/⊕⊕/◈	Metformin is known to elevate Hcy, but evidence not conclusive as to degree to which biguanides deplete folate. Metformin impairs vitamin B_{12} absorption through calcium-dependent mechanism, which may be corrected with concomitant calcium. Maintaining low Hcy levels important to therapeutic strategy of reducing cardiovascular risk.	Coadminister folic acid B_{12}, B_6, and calcium, especially in women with PCOS. Encourage exercise and folate-rich diet. Monitor folate, Hcy, serum holotranscobalamin II, and glucose levels.
Neomycin ≈≈≈/☼	Neomycin can decrease absorption and increase elimination of folate and numerous other nutrients. Interaction accepted as consensus but evidence limited. Extended use or high dosage can further disrupt gut ecology and impair synthesis of folate and B_{12} by eliminating probiotic flora.	Daily multivitamin and mineral formulation, and probiotic flora, recommended during extended neomycin therapy. Separate nutrient intake from neomycin.
Nitroglycerin Nitrates ⊕⊕	Folate-dependent activities involving NADPH, tetrahydrobiopterin, and nitric oxide synthase appear to play key roles in tolerance to nitroglycerin, although mechanisms not yet fully elucidated. Coadministration of folic acid can attenuate tolerance by enhancing regeneration and bioavailability of tetrahydrobiopterin; it also supports therapeutic strategy of reducing cardiovascular risk.	Coadminister folic acid during nitrate therapy. Monitor folate and cobalamin status and medication levels.
Nitrous oxide (N_2O) ☼/⊕⊕	Nitrous oxide can interfere with activity of folate and vitamin B_{12}, potentially depleting both; in particular, resultant methyl trap can decrease mitochondrial folates. Significant effect plausible but remains controversial. Duration and extent of exposure, as well as individual patient characteristics, may determine degree of effect and attendant risk.	Prudence suggests supplementation with acid or 5-MTHF (and B_{12}) starting 1 week before major N_2O anesthesia. Medical and dental personnel may also benefit from prophylactic nutrient support; consider periodic B_{12} assessment.
Nonsteroidal anti-inflammatory drugs (NSAIDs) ≈≈≈/≈≈/◈/☼	Many NSAIDs exert antifolate activity by impairing or competitively interfering with folate absorption, metabolism, and transport. Chronic use, especially at high doses, could potentially decrease serum folate concentrations and cause deficiency. Limited evidence suggests need for further human research. Evidence lacking to confirm benefits of folate coadministration or to suggest interference with drug activity.	Concomitant folic acid may be prudent during extended high-dose NSAID therapy.
Oral contraceptives (OCs) ≈≈≈/≈≈/☼	Birth control pills, especially with higher estrogen doses, can impair folate metabolism and may cause depletion, especially in women with compromised folate status; these effects may play a role in known OC risks. Evidence is mixed and controversy continues regarding probability of occurrence and clinical significance of adverse effects. Folic acid particularly important with cervical dysplasia and possibility of pregnancy after OC termination.	Concomitant folic acid and vitamin B_6 recommended as prudent, especially in smokers. Consider assessing folate, platelets, and Hcy, initially and periodically.
Pancreatic enzyme Proteolytic enzymes ≈≈≈	Simultaneous intake of pancreatin and other proteolytic enzymes may impair folic acid absorption. Research involving patients with pancreatic insufficiency indicates higher serum folate levels before treatment. Significant effect plausible; evidence inconclusive.	Consider supplementing folic acid with extended use of pancreatic extracts, especially with history of insufficiency.
Pyrimethamine ◈≈≈/≈≈/⊕✗/✗	Pyrimethamine is competitive inhibitor of dihydrofolate reductase that acts as folic acid antagonist and inhibits biosynthesis of tetrahydrofolic acid; it depletes serum folic acid levels and interferes with hematopoiesis, especially in combination with other antifolates (sulfadiazine, sulfadoxine, methotrexate). Bone marrow suppression, neutropenia, thrombocytopenia, and megaloblastic anemia are among clinically significant adverse effects resulting from drug-induced folate deficiency.	Coadminister folic acid acid or 5-MTHF, as well as oral or intramuscular cobalamin. Monitor cobalamin and folate levels, as well as hematological parameters. Extra caution with G6PD deficiency or hepatic or renal impairment.
Sulfasalazine ≈≈≈/≈≈/◈/☼	Sulfasalazine and other sulfonamides interfere with absorption, bioavailability, and activity of folic acid, most likely acting as competitive inhibitor and impairing activity of folate-dependent enzymes. Adverse effects of sulfasalazine on	Encourage diet rich in high-folate foods. Coadminister folic acid acid or 5-MTHF. Monitor red blood cell (RBC)/tissue folate and Hcy levels.

Continued

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
	folate are generally recognized. However, no evidence-based consensus as to influence of various factors, including drug dosage, polymorphisms, nutritional deficiencies, and comorbid conditions. Tissue depletion and elevated Hcy more likely than frank deficiency with maintenance sulfasalazine. Increased risk of colon cancer in patients with irritable bowel and colitis.	
Tetracycline antibiotics ⊕⊕/⊕✗/◇◇/◇≈≈	Folic acid and tetracyclines may bind and inhibit absorption and availability of both agents when ingested simultaneously. These antibiotics can also interfere with activity of and potentially induce depletion of folic acid and other nutrients. Extended use or high dosage can further disrupt gut ecology and impair synthesis of folate and B_{12} by eliminating probiotic flora. Coadministration of tetracycline and folate, often with B_{12}, is recommended treatment for tropical sprue.	Daily multivitamin formulation, and probiotic flora, recommended during repeated or extended tetracycline therapy. Separate intake. Monitor cobalamin and folate status.
Triamterene Potassium-sparing diuretics ◇≈≈/≈≈≈/◇/⊕⊕	Triamterene impairs folate absorption and bioavailability, possibly by acting as competitive inhibitor of folate intestinal absorption. It may contribute to folate depletion and thereby contribute to teratogenesis and hyperhomocysteinemia. Triamterene may decrease biologically active folates by acting as relatively weak folate antagonist through dose-related inhibitory effect on dihydrofolic reductase. Evidence indicates variable risk of clinically significant adverse effect, but concomitant folic acid may mitigate such effects. Also contributes to strategic goal of reducing cardiovascular and stroke risk by lowering Hcy level.	Encourage diet rich in high-folate foods. Coadminister folic acid or 5-MTHF. Monitor RBC/tissue folate and Hcy levels.
Trimethoprim-sulfamethoxazole Sulfonamide antibiotics ≈≈/◇≈≈/☼/⊕✗/✗	Trimethoprim and sulfamethoxazole inhibit dihydrofolic reductase to block conversion of unreduced dietary folates into tetrahydrofolate. Co-trimoxazole–induced folate deficiency possible, especially with underlying folate deficiency, and teratogenicity and macrocytic anemia are known adverse effects, particularly with high dose and prolonged use. However, clinically significant anemia is considered rare. Folic acid coadministration could theoretically interfere with drug activity, but evidence indicates that interference is unlikely with low-dose intake.	Concomitant folic acid or 5-MTHF, with probiotic flora, may be prudent during extended therapy.
Zidovudine/AZT Reverse-transcriptase inhibitor (nucleoside) antiretroviral agents ◇≈≈/≈≈/☼	Macrocytosis, anemia, and granulocytopenia are common adverse effects associated with AZT therapy. However, coadministration of vitamin B_{12} and folinic acid may not prevent or reduce drug-induced myelotoxicity. Modification of drug regimen often necessary to reverse toxic effects.	Coadminister folic acid acid or 5-MTHF as well as oral or intramuscular cobalamin. Closely monitor cobalamin and folate status.

5-MTHF, 5-Methyltetrahydrofolate; *MTHFR*, methylenetetrahydrofolate reductase; *CYP*, cytochrome P450; *NADPH*, reduced nicotinamide-adenine dinucleotide phosphate; *IM*, intramuscular; *PCOS*, polycystic ovary syndrome; *G6PD*, glucose-6-phosphate dehydrogenase; *RBC*, red blood cell.

NUTRIENT DESCRIPTION

Chemistry and Forms

The Latin word for leaf, *folium*, was chosen to designate the nutrient present in green leafy vegetables and originally isolated from four tons of spinach leaves in 1946. The terms "folic acid" and "folate" are often used interchangeably for this water-soluble B-complex vitamin. However, *folate* is the preferred term for the mixture of related compounds occurring naturally in foods, whereas *folic acid* is the more stable form and is used in supplements and added to fortified foods, but rarely occurs in foods or the human body. Thus, forms are preferentially referred to on this basis in most usages within this monograph, with deference to nomenclature of original sources.

Folic acid may be more specifically identified as pteroylmonoglutamate or pteroylglutamic acid (PGA). Described chemically as *N*-[4-[[(2-amino-1,4-dihydro-4-oxo-6-pteridinyl)methyl]amino]benzoyl]-L-glutamic acid, it is comprised of *para*-aminobenzoic acid (PABA) linked at one end to a pteridine ring and at the other end to glutamic acid. Its molecular formula is $C_{19}H_{19}N_7O_6$, and its molecular weight is 441.40 daltons. Folic acid forms yellowish orange crystals. The color is imparted by the pteridine ring of folic acid. Pteridine also imparts color to the wings of certain butterflies.

Pteroylmonoglutamate (PGA) is the parent compound for many structurally related, derivative compounds that exhibit the biological activity of folic acid and are collectively referred to by the generic term *folate*. Most naturally occurring folates are pteroylpolyglutamate derivatives, containing two to seven glutamates joined in amide (peptide) linkages to the gamma-carboxyl of glutamate, with folylpoly-γ-glutamates being the predominant, naturally occurring form of dietary folates. Naturally occurring folates include 5-methyltetrahydrofolate (5-MTHF), 5-formyltetrahydrofolate (5-formyl-THF), 10-formyltetrahydrofolate (10-formyl-THF), 5,10-methylenetetrahydrofolate (5,10-methylene-THF), 5,10-methenyltetrahydrofolate (5,10-methenyl-THF), 5-formiminotetrahydrofolate (5-formimino-THF), 5,6,7,8-tetrahydrofolate (THF), and dihydrofolate (DHF). The term *folate* is also used specifically to designate the anionic form of folic acid.

Physiology and Function

Folate, usually present as pteroylpolyglutamate derivatives in food, is hydrolyzed to pteroylmonoglutamate forms by folyl conjugase (also known as folate conjugase or γ-glutamylhydrolase) from the pancreas and mucosal conjugase from the intestinal wall before absorption from the small intestine. The monoglutamate forms of folate, including folic acid, are transported across the proximal small intestine, primarily the jejunum, by both active transport and diffusion. This is a saturable pH-dependent process, so absorption is decreased in an alkali

medium and in the presence of added zinc. When ingested on an empty stomach, folic acid is generally twice as available as dietary sources of folate; folic acid consumed with food is 1.7 times as available as folate in food.

Following absorption of physiological amounts of folic acid into the enterocytes, a certain percentage undergoes reduction. Folic acid (PGA) is the inactive precursor of tetrahydrofolic acid (THFA) and methyltetrahydrofolate; it is converted to THFA, its biologically active form, with the participation of niacin and vitamin C, as well as several coenzymes and other nutrients. However, a functional methionine synthase deficiency can develop within the context of vitamin B_{12} deficiency so that essentially all the folate becomes trapped as the N5-methyl THF derivative, thus preventing the synthesis of other THF derivatives required for the purine and thymidine nucleotide biosynthesis pathways. Reduced folate is transported to the liver via the portal circulation, where it is metabolized to polyglutamate derivatives by the action of folylpolyglutamate synthase. These pteroylpolyglutamate forms are the active cellular cofactor forms of folate.

The total body store of folate is about 12 to 28 mg. All tissue forms of folate are polyglutamates, with pteroylpentaglutamates being the principal type of intracellular folates. Approximately two thirds of folate in plasma is protein bound. Circulating forms of folate are monoglutamates, with pteroylmonoglutamates as the principal extracellular folates and 5-MTHF in its monoglutamate form being the principal folate in the plasma. The liver contains approximately 50% of the body stores of folate, or about 6 to 14 mg. Folate is excreted in the bile, and much of it is reabsorbed through the enterohepatic circulation. This enterohepatic recycling is important for modulating serum levels. Folate is also synthesized by the gut microflora, and as a result, some folates may be eliminated in the feces. However, the kidneys provide the predominant route for folate excretion. Folate enters the glomerulus intact and is reabsorbed into the proximal renal tubule. It is excreted in the urine primarily as folate cleavage products, with only a small amount of intact folate. The excretion of folates found through the breast milk represents a critical pathway for folate activity by providing availability for infant development.

The functions of folate in human physiology are relatively simple, but the implications of their activity (and dysfunction) can be profound and far-reaching. Through its coenzymes, folate plays an essential role in synthesis of nucleic acids, interconversion of amino acids, and single-carbon metabolism. Mediation of single-carbon transfer reactions is considered the primary and possibly exclusive function of folate coenzymes involved in a variety of reactions critical to the metabolism of nucleic acids and amino acids, especially the synthesis of purines and pyrimidines, glycine, and methionine. Thus, through its role in the synthesis of nucleotides from guanine, adenine/pyrimidine, and thymine, folate is required for the synthesis, methylation, and repair of deoxyribonucleic acid (DNA) and is involved in the synthesis of transfer ribonucleic acid (tRNA). This role in cell division is critical in cellular development and maturation, including tissue regeneration, but especially fetal growth and development in general and healthy formation of the nervous system in particular.

Folate plays a fundamental role in synthesis and interconversion of amino acids and the formation and utilization of formate. Folate is involved in the synthesis of glutamic acid, norepinephrine, and serotonin and the detoxification of homocysteine (Hcy) to methionine. Notably, several genetic mutations, including the 677CT polymorphism, influence Hcy metabolism by their effect on the activity of 5,10-methylenetetrahydrofolate reductase, the gene that provides instructions for making *methylenetetrahydrofolate reductase* (MTHFR), a critical enzyme (requiring flavin adenine dinucleotide [FAD] as a cofactor) that converts 5,10-methylenetetrahydrofolate to 5-methyltetrahydrofolate, which is required for the conversion of Hcy to methionine. Consequently, individuals who are homozygous (TT) for the abnormal gene have lower levels of the MTHFR enzyme and a marked tendency to hyperhomocysteinemia. Improved folate nutriture appears to stabilize the MTHFR enzyme, as does adequate riboflavin nutriture (the source of FAD), resulting in improved enzyme levels and lower Hcy levels. Methionine synthase (another enzyme requiring folate and B_{12} as cofactors) combines Hcy with the 5-MTHF produced in the reaction catalyzed by MTHFR so that the Hcy becomes methionine and the 5-MTHF becomes MTHF. Thus, this folate coenzyme plays a critical role in the synthesis of methionine, which is required for the synthesis of *S*-adenosylmethionine (SAMe), the universal methyl donor essential to many biological methylation reactions.

Folate is also essential for the formation and maturation of red blood cells (RBCs) and white blood cells (WBCs). Folic acid is required for nucleoprotein synthesis and maintenance in erythropoiesis and is the single carbon carrier in the formation of heme; it also stimulates WBC and platelet production. Folate deficiency anemia is one of the megaloblastic anemias and is clinically and pathologically indistinguishable from vitamin B_{12} deficiency anemia (pernicious anemia).

Impairment of any of these activities of folate, whether caused by genetic mutations, dietary deficiency, or drug-induced depletion, can produce a cascade of adverse effects directly influencing fetal development, DNA replication, healthy cellular and system function, and development of atherosclerosis, heart disease, and cancer.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Within conventional practice, supplemental folic acid and dietary folate are used exclusively for the prevention of neural tube defects (NTDs; e.g., spina bifida, anencephaly) during in utero development and the treatment of demonstrated folate deficiency, primarily manifesting as megaloblastic and macrocytic anemias. However, epidemiological and clinical evidence continues to emerge regarding the preventive and therapeutic efficacy of enhanced folate intake in reducing atherogenic Hcy levels and improving endothelial function to modify cardiovascular risks, supporting neurotransmitter levels in relation to mood disorders and neurodegenerative processes, and preventing cancers, particularly breast, pancreatic, and colon cancers.

Broad efforts at preventing NTDs through dietary fortification have produced mixed benefits. Thus, although largely successful, these programs have exhibited varied penetration of key susceptible populations, and controversy as to their adequacy continues regarding both NTDs and other epidemiological patterns.[1-9] For example, a 2006 survey showed that, even after mandatory fortification of U.S. cereals and grains with folic acid in 1998, women in racial and ethnic minority groups had lower serum folate levels than non-Hispanic white women.[10] Thus, pregnant women who do not regularly take folic acid–containing supplements are eight times more likely to have low serum folate values, despite eating folate-fortified foods.[11] Additionally, expanding knowledge of the

multiple polymorphisms affecting folate metabolism is providing a working understanding of susceptibilities to folate-related pathologies and is highlighting the influence of individual genomic variability in the effectiveness of preventive measures and therapeutic applications.

Historical/Ethnomedicine Precedent

The long-standing adages declaring the value of leafy green vegetables in health maintenance and disease prevention may be a result, at least in part, of their being rich in folates.

Possible Uses

Acquired immunodeficiency syndrome and human immunodeficiency virus (AIDS/HIV) support, age-related hearing loss (reduction), Alzheimer's disease, anemia (thalassemia, if deficient), anger (hyperhomocysteinemia associated with MTHFR mutations), atherosclerosis, bipolar disorder, breast cancer prevention (risk reduction in women who consume alcohol), canker sores (with deficiency), cardiac events and death (risk reduction after first stroke), celiac disease (deficiency only), cervical cancer prevention, cervical dysplasia (abnormal Pap test), Crohn's disease, colon cancer prevention, depression, dermatitis herpetiformis (deficiency), diarrhea, Down syndrome, epilepsy, folate metabolism polymorphisms, gingivitis (as rinse), gout, hemorrhagic stroke (risk reduction), hypercholesterolemia, hyperhomocysteinemia, hypertension (risk reduction), laryngeal leukoplakia (risk reduction), lung cancer (risk reduction), malabsorption and gastrointestinal inflammation, megaloblastic anemia, migraine headaches, myocardial infarction, neural tube defect (prevention), osteoarthritis (with vitamin B_{12}), osteoporosis, periodontal disease, peripheral vascular disease, postpartum support, preeclampsia, pregnancy (potential or known), psoriasis, restless legs syndrome, rheumatoid arthritis, schizophrenia (deficiency or hyperhomocysteinemia associated with MTHFR mutations), seborrheic dermatitis, second stroke (risk reduction), seizure disorders, sickle cell anemia (hyperhomocysteinemia), skin ulcers, ulcerative colitis, vitiligo.

Deficiency Symptoms

Folate deficiency results in reduction of DNA synthesis and thus in reduction of cell division. Because the main metabolic consequences of folic acid deficiency are changes in cellular nuclear morphology, rapidly multiplying cells are most affected, such as fetal tissue, erythrocytes, and the epithelial cells of the stomach, intestines, vagina, and cervix. Thus, folate deficiencies result in neural tube and other birth defects, impaired infant development, poor growth, megaloblastic (macrocytic) anemia and other blood disorders, fatigue, weakness, frequent infections, insomnia, irritability, paranoid behavior, mental confusion, hostility, forgetfulness, depression, syncope, headache, palpitations, elevated Hcy level, atherosclerosis, dyspnea, anorexia, glossitis, nausea, dyspepsia, constipation, diarrhea, cervical dysplasia, and hair loss. Gastrointestinal (GI) disturbances are common, resulting from atrophy of digestive tract epithelium. Reduced production of platelets can increase risk of abnormal bleeding. Likewise, impairments in WBC development reduce immune response and increase susceptibility to infections.

Folate deficiency is common, and folate activity is subject to many stressors. Intake of dietary folate and supplemental folic acid is inadequate for a significant proportion of the population, and mild folic acid deficiencies are often undetected. Populations particularly at risk for compromised folate nutriture include alcoholics, the elderly, impoverished people, women using birth control pills, and individuals with malabsorption disorders. Some conditions, such as chronic alcohol consumption and celiac disease, are associated with both low dietary intake and diminished absorption. Tobacco decreases the absorption of folic acid. Certain conditions, such as pregnancy, lactation, hemolytic anemia, leukemia, and other cancers, result in increased rates of cell division and metabolism, leading to an increase in the body's demand for folate. In 1975, folate deficiency during pregnancy was estimated as high as 60%; programs of folate fortification of grains have not been consistently effective in eliminating this significant risk factor. Finally, numerous medications can interfere with folate metabolism, deplete folate (especially with long-term use), or exacerbate folate deficiency in those with other factors adversely influencing folate status.

Several genetic mutations may directly impair folate activity, with profound implications only beginning to be understood. Most prominently, the C677T MTHFR polymorphism, a common variation involving the gene for methylenetetrahydrofolate reductase (MTHFR), can adversely affect folate metabolism and function, particularly the conversion of 5,10-methylene-THF to 5-methyl-THF. Elevated Hcy levels and increased risk for vascular disease are strongly associated with these MTHFR mutations because methyl-THF is the predominant circulatory form of folate and the main carbon donor for the remethylation of homocysteine to methionine. A mutation in the MTHFR gene leading to mild to moderate hyperhomocysteinemia has been found in 15% of patients with premature cerebrovascular disease. Individuals with severe MTHFR deficiency (0%-20% residual activity) present in infancy or adolescence with developmental delay, motor and gait dysfunction, seizures, schizophrenic disturbances, and other neurological abnormalities; they are also at risk of vascular complications.

Homocysteic acid, the oxidation product of Hcy, exerts potent excitatory effects and may be associated with anger, hostility, schizophrenia-like psychosis, depression, and bipolar disorder, particularly in individuals with the homozygous TT genotype of the thermolabile C677T MTHFR polymorphism. The risk of elevated serum levels of total homocysteine (tHcy) is increased in individuals with the combination of the MTHFR 677TT and RFC1 80GG genotypes. Devlin et al.[12] conducted a study of interactions among polymorphisms in folate-metabolizing genes and serum tHcy concentrations in a healthy elderly population. They found that folate and tHcy concentrations were not affected individually by the MTHFR 1298AC, RFC1 80GA, or GCPII 1561CT polymorphisms or by combinations of the MTHFR 677CT and MTHFR 1298AC genotypes. However, individuals with the combination of MTHFR 677TT and RFC1 80GG genotypes exhibited higher serum tHcy.

Inherited defects in methionine synthase, dihydrofolate reductase, and glutamate formiminotransferase, as well as congenital conditions affecting folate absorption and membrane transport, can also influence vascular and mental health through their impact on folate metabolism.

Administration of folic acid will produce marked alleviation of pernicious anemia (the megaloblastic anemia related to vitamin B_{12} deficiency), but the GI signs and symptoms and the neurological lesions continue to progress. For this reason, supplements of 1000 µg (1 mg) or greater of folic acid require a prescription in the United States and some other Western countries. Combining 1 mg or more of oral vitamin B_{12} with

1 mg or more of folic acid would obviate this problem; 1 mg or more of vitamin B_{12} will reliably correct B_{12} deficiency, even in the presence of pernicious anemia, atrophic gastritis, chronic proton pump inhibitor therapy, or other B_{12} malabsorption syndromes.

Dietary Sources

Foods rich in folates include dark-green leafy vegetables (spinach, kale, mustard greens, turnip greens, escarole, chard, arugula, beet greens, bok choy, dandelion green, mache, radicchio, rapini or broccoli de rabe, Swiss chard), liver (beef or chicken) and other organ meats, egg yolk, and brewer's yeast. Folylpoly-γ-glutamates are the predominant form of folates occurring naturally in foods. Other good sources are beets, broccoli, brussel sprouts, cabbage, cauliflower, asparagus, orange juice, cantaloupe, kidney and lima beans, pinto beans, garbanzo beans, black-eyed peas, lentils, soybeans, soy flour, potato, wheat germ, and whole-grain cereals and breads. Fortified cereals made from processed grains can also serve as sources of folic acid. The symbiotic flora comprising the intestinal microbiota, if intact, also synthesize a significant amount of folate.

Folic acid is water soluble, with some forms stable to heat and others heat sensitive. Some forms are stable to acid and others destroyed. Vegetables stored at room temperature undergo considerable loss of folic acid. Virtually all the folate in dried milk has been destroyed.

The absorption efficiency of natural folates is approximately 50% that of folic acid in supplements or fortified foods. The model of *dietary folate equivalents* (DFEs) has been introduced to account for the difference in absorption efficiency between natural food folate and folic acid. Thus, DFEs can be calculated as follows:

1 microgram (μg) of DFEs = 1μg food folate
= 0.5 μg folic acid taken on empty stomach
= 0.6 μg folic acid taken with meals

Nutrient Preparations Available

The principal form of supplemental folate is folic acid, as a single ingredient or in combination products such as B-complex formulations. Folate triglutamate (pteroyltriglutamate) is also used. 5-Methyl folate and 5-formyl folate are commercially available reduced folates.

5-formyltetrahydrofolate (5-FTHF) and 5-methyltetrahydrofolate (5-MTHF) are the reduced and metabolically active forms of folic acid. Folinic acid, the free acid of calcium folinate, is the more frequently used form and is also known as calcium folinate (Leucovorin Calcium, Leukovorin, Wellcovorin), calcium levofolinate (Isovorin), citrovorum factor (Citrovorum), and sodium folinate (Sodiofolin). Folinic acid is a racemic mixture of levorotatory and dextrorotatory isomers. The levo-isomer is the metabolically active moiety. These calcium or sodium salts are used for parenteral or oral administration.

Metafolin, Merck's patented synthetic form of 6(S) 5-MTHF, or L-methylfolate, is the only form available (for the duration of Merck's patent) of the levorotatory (L) chiral isomer of 5-MTHF, which is the chiral isomer made by human metabolism from folic acid, and also the chiral form found in foods which contain 5-MTHF. It is derived from commercially available B-complex vitamin folic acid, which is reduced to tetrahydrofolate in a process that leads to the formation of a new chiral center and two diastereoisomers in an equimolar ratio. The L isomer (6S-isomer) of methylfolate is then isolated by selective crystallization. Metafolin is promoted as a form of folate that requires no reduction steps once absorbed and that is immediately bioavailable and thus unaffected by the MTHFR C→T polymorphism.[14] L-Methylfolate also bypasses most folate-interfering compounds, such as those that inhibit dihydrofolate reductase (e.g., methotrexate, pemetrexed, EGCG).

Dosage Forms Available

Oral: Capsule, liposomal spray, liquid, tablet, tablet (effervescent).
Injection: Deep intramuscular, subcutaneous, or intravenous; sodium folate solution (0.1 mg folic acid per 1 mL), usually 5 mg/mL (10 mL), contains benzyl alcohol.

Source of Materials for Nutrient Preparations

Folic acid used in supplements, prescriptions, and food fortification (e.g., wheat flour) is synthesized from guanidine and glutamic acid as starting materials. The chemical synthesis of L-5-MTHF (Metafolin) starts from the commercially available vitamin folic acid, which is chemically reduced to tetrahydrofolate (THF). This reduction step leads to the formation of a new chiral center and two diastereoisomers in an equimolar ratio. In nature, reduced folates consist only of the pure levo (L) isomer (corresponding to the 6S isomer for methylfolate); thus, processes were developed allowing the isolation of the natural L form by selective crystallization.[13]

Dosage Range

Adult

Dietary: 300 μg folic acid daily for adults. In United Kingdom, average adult daily diet for women provides 224 μg, and for men, 322 μg.
Supplemental/Maintenance: 400 μg daily for adults.

The U.S. Food and Drug Administration (FDA) recommends 600 μg folic acid for pregnant women and 500 μg for nursing women. Based on survey data published in 1996, Lawrence et al.[10] recommend, "Until the optimal folate level is identified that confers maximum protection against neural tube defects, health care providers and women's health advocates should continue to encourage women who can become pregnant to take a vitamin containing 400 micrograms of folic acid every day." Women who could become pregnant are advised to take 400 to 800 μg of folic acid per day in anticipation of the possibility of conceiving because folic acid deficiency is most critical during the initial stages of pregnancy, when many women are not yet aware of their being pregnant.

The folic acid dose in over-the-counter (OTC) nutritional supplements is limited to 900 μg. Doses of 1 mg or greater require a prescription. Folic acid is best taken between or with meals, preferably with the dose divided throughout the day.
Pharmacological/Therapeutic:
500 to 800 μg/day is common.
Pregnant and lactating women: 0.8 mg/day
Pharmacological dosages in scientific literature: 400 to 4000 μg

Administration of 5 to 10 mg daily may occur in research or other specialized settings, including treatment of severe deficiency. Men show a smaller increase in folate and decrease in Hcy to a given dose of folic acid than women.[15]

Toxic: Folic acid is essentially nontoxic, even at very high doses. The tolerable upper intake level (UL) established by the U.S. Institute of Medicine's Food and Nutrition Board is 1000 µg/day (based on synthetic folic acid). This UL is based on folic acid doses of 1 mg or more masking an undiagnosed vitamin B_{12} deficiency (by correcting the anemia that occurs with B_{12} deficiency, which is often the sole sign that alerts health care providers to the presence of an underlying B_{12} deficiency).

Pediatric (<18 Years)
Dietary:
Infants, birth to 6 months: 25 µg/day
Infants, 7 to 12 months: 35 µg/day
Children, 1 to 3 years: 150 µg/day
Children, 4 to 8 years: 200 µg/day
Children, 9 to 13 years: 300 µg/day
Adolescents, 14 to 18 years: 300 µg/day
Supplemental/Maintenance:
Infants, birth to 12 months: 0.1 mg/day
Children, 1 to 3 years: up to 0.3 mg/day
Children, 4 years and older: 0.4 mg/day
Pharmacological/Therapeutic: None specifically established at this time.
Toxic: None specifically established at this time.

Laboratory Values

Serum Folate
Serum folate reflects recent dietary intake and is most useful when combined with assays of vitamin B_{12} and red blood cell (RBC) folic acid. However, serum folate and serum vitamin B_{12} can be normal in mild folate and vitamin B_{12} deficiencies. Homocysteine (folate and B_{12}) and methylmalonic acid (B_{12} only) are more sensitive indicators of mild folate and vitamin B_{12} deficiencies.
Normal levels: 4.5 to 30 nmol/L or 5.4 to 24 µg/mL.

Red Blood Cell Folate (Erythrocyte Folate)
The RBC folate levels reflect body folate stores. RBCs are generally macrocytic when folate and/or B_{12} deficiency states are present except in combined deficiencies of both folate and iron, common in malnourished individuals.
Normal levels: 280 to 790 ng/mL RBCs.
Levels < 312 nmol/L can indicate deficiency.

Note: Different laboratories use different reference ranges for serum folate and RBC folate because their analytical assays vary. Many antibiotics may interfere with the microbiological assay for serum and erythrocyte folic acid and can produce falsely low results.

Neutrophilic Hypersegmentation Index (NHI)
The *neutrophilic hypersegmentation index* (NHI) can identify the earliest stages of folate insufficiency. Deficiency indicated when the ratio of neutrophils with five or more lobes to those with four or fewer lobes is greater than 30%. Hypersegmentation can also result from vitamin B_{12} deficiency and is not reliable during pregnancy.

Serum Methylmalonic Acid
Methylmalonic acid (MMA) is useful in differentiating folate and cobalamin deficiency. L-Methylmalonyl coenzyme A (CoA mutase is a vitamin B_{12}–dependent enzyme; therefore a B_{12} deficiency, but not a folate deficiency, will lead to an increase in MMA.

Total Homocysteine
Total homocysteine (tHcy) concentration indicates folate and/or cobalamin deficiency and serves as predictor of risk for arterial stiffness, ischemic stroke, and myocardial infarction. Homocysteine levels can also be elevated by genetic polymorphisms that result in greater requirements of pyridoxine (vitamin B_6), as well as deficiencies of pyridoxine and methyl donor nutrients in general.

A plasma tHcy concentration exceeding 15 µmol/L indicates hyperhomocysteinemia, although many investigators propose that achieving much lower levels (7-10 µmol/L) is necessary for decreasing vascular disease risk.

If anticoagulated blood tubes are allowed to sit longer than 10 minutes before spinning, the tHcy level can be falsely elevated. Pharmacological doses of niacin also falsely elevate tHcy levels and should be held for 24 hours before drawing blood to determine tHcy levels.

Serum Homocysteine
Serum Hcy indicates folate or cobalamin deficiency and serves as predictor of risk for ischemic stroke and myocardial infarction. It is used to assess homocystinuria.
Normal levels: Male: 4.3-11.4 micromol/L
Female: 3.3-10.4 micromol/L

Emerging and Related Tests
- Tetrahydrofolate (THF) concentrations.
- Whole-blood folate may also be valuable in some settings, but standards have only recently been established.
- Fluorescence polarization immunoassay (FPIA) can be performed for the quantitation of total human L-homocysteine in serum or plasma.
- Methylene-THFR identifies normal, heterozygous, and homozygous genotypes.
- 5,10-Methylene-THFR C677T polymorphism identifies the mutation and provides preliminary evaluation of associated increased thrombotic risk and obstetrical risk.

Emerging research indicates the need to test for MTHFR 1298AC, RFC1 80GA, and GCPII 1561CT polymorphisms in establishing cardiovascular risk.[12]

Analysis of both the C677T mutation and the A1298C mutation is recommended for evaluation of obstetrical risk in patients with recurrent fetal loss. Patients who are heterozygous for the C677T mutation are reflex-tested for the A1298C mutation. Only C677T homozygotes and C677T/A1298C compound heterozygotes are at increased risk for thrombotic events.

Note: *S*-adenosylmethionine (SAMe) has a similar molecular form to *S*-adenosylhomocysteine, and exogenous intake, at therapeutic levels, may interfere with this assay.

SAFETY PROFILE

Overview

Supplemental folic acid is essentially nontoxic, even at high doses, and extremely safe at nutritional doses. Folic acid doses up to 1 mg daily are well tolerated. Substantive and consistent evidence of adverse effects attributable to folic acid supplementation is lacking. Adverse effects attributed to folic acid primarily derive from issues of diagnosis and clinical management.

Health care professionals are advised to counsel patients to avoid supplementing with 800 µg or more of folic acid daily unless they have been evaluated for vitamin B_{12} deficiency or they coadminister 1 mg or more of B_{12}. Inappropriate use of folic acid in large doses could precipitate neuropathy in

individuals with undiagnosed B_{12} deficiency (usually from pernicious anemia). More than 100 cases have been reported in which vitamin B_{12}–deficient subjects receiving oral folic acid at 5 mg or more daily experienced progression of neurological symptoms and signs. Reports are rare of such complications in individuals receiving doses of folic acid less than 5 mg daily. Consequently, the U.S. Food and Nutrition Board advises that all adults limit their intake of folic acid to 1000 µg daily. The concerns regarding safety underlying dose restrictions are limited to synthetic folic acid intake through supplements and fortification. Folate from food sources is generally considered highly unlikely to mask vitamin B_{12} deficiency.

Aggravations of seizure disorders have been reported in patients who initiated folic acid supplementation while undergoing anticonvulsant therapy. Such reactions may result from folic acid interfering with the activity of antiepileptic drugs.

Nutrient Adverse Effects

General Adverse Effects

Sleep disturbances, mental changes, and GI effects have been associated with high-dose folic acid intake, greater than 10 mg daily. Doses greater than 5 mg (5000 µg) daily may cause digestive upset in some individuals. Wheezing, dyspnea, fever, erythema, skin rash, itching, and other symptoms of allergic reactions have been reported on rare occasions.

Some secondary sources suggest that extended intake of high doses may cause uricosuria or produce folacin crystals in the kidney. Dialysis patients have increased requirements for folic acid and vitamin B_6, needing at least 800 µg to 1 mg or more of folic acid and 10 mg or more of B_6 each day.

Adverse Effects Among Specific Populations

Folic acid supplementation, without vitamin B_{12}, is contraindicated in patients with B_{12} deficiency, especially pernicious anemia.

The effects of folate on cognitive function have generally been considered salubrious, particularly in elderly persons. However, a single study in 2005 produced the unexpected finding that high folate intake was associated with more rapid cognitive decline in older adults, particularly men and women taking supplemental folic acid at levels greater than 400 µg/day. Subjects in the top quintile of folate intake (> 700 µg/day) exhibited twice the rate of mental decline over 6 years as those who with the lowest folate intake. Although suggesting caution in routine use of folic acid supplements (without vitamin B_{12}), the authors emphasized that evidence was lacking to confirm that folate itself caused the cognitive deterioration seen in some study participants and noted that high folate intake might be masking a vitamin B_{12} deficiency in some individuals.[16] No other research has pointed to similar patterns. An intervention trial administering folate supplements, B_{12} supplements (in equivalent doses to the folate), and both folate and B_{12} together, with single and double placebo control groups, to elderly subjects over 5 years would be required to address the issues conclusively. Notably, in the subsequent Veterans Affairs Normative Aging Study, Tucker et al.[17] found that high Hcy and low B-vitamin plasma levels predicted cognitive decline in aging men. Moreover, folate (plasma and dietary) "remained independently protective against a decline in spatial copying score after adjustment for other vitamins and for plasma homocysteine."

Preschool children administered folic acid (and iron) may be at higher risk of severe illness and death in a high-malaria-transmission setting. Routine prophylactic supplementation should be avoided pending further research. However, within the context of an active program "to detect and treat malaria and other infections, iron-deficient and [anemic] children can benefit from supplementation."[18]

Haggarty et al.[19] reported that high levels of serum folate appear to increase the risk of a dizygotic twin birth after women are impregnated through in vitro fertilization (IVF) or intracytoplasmic sperm injection (ICSI). In particular, the rate of twins was associated with elevated levels of plasma and RBC folate (odds ratio [OR] 1.27 for each 100-g change in folate intake). However, the authors noted that "there was no significant association between folate and vitamin B_{12} intake, or blood levels, and pregnancy or rate of live births or pregnancy loss after IVF."

Pregnancy and Nursing

Enhancement of dietary folates and supplemental folic acid is recommended for any woman of childbearing age who might become pregnant, and this is specifically required during pregnancy. Folate enters breast milk and is beneficial. Folic acid and folate are specifically recommended to prevent developmental birth defects, particularly neural tube defects. Specific maximum safe dosages have not been established for pregnant or nursing women. (See, however, previous discussion on possible effects of high folate levels in relation to assisted reproduction.)

Infants and Children

No adverse effects have been reported in children or would be predicted.

Contraindications

Folic acid at doses greater than 800 µg/day is contraindicated when vitamin B_{12} status is uncertain. Doses greater than 1 mg/day may obscure pernicious anemia, with irreversible progression of neuropathy, unless the B_{12} deficiency is corrected with high-dose (1-2 mg/day) oral or parenteral B_{12}.

Prophylactic folic acid (and iron) may be contraindicated for children in malarial environments.[18]

Some clinicians have suggested that individuals with elevated blood levels of histamine (i.e., histadelia) should avoid supplemental folic acid because it can produce further histamine excess and aggravate a tendency to depression, schizophrenia, or other adverse effects purported to be associated with elevated histamine levels.

Precautions and Warnings

Self-administration of folic acid at levels greater than 400 µg/day is inadvisable in individuals being treated with anticonvulsants, antifolates, and other medications with a mechanism of action based on interfering with folate activity.

INTERACTIONS REVIEW

Strategic Considerations

Folate is a vital nutrient for everyone, as evidenced by universal recommendation to eat bountiful amounts of dark-green leafy vegetables and other folate-rich foods. Overwhelming evidence indicates that folate deficiency is widespread, even among those presumed to have adequate diets, but particularly among the elderly population, malnourished individuals, tobacco smokers, and those who excessively consume alcohol or processed foods. Furthermore, the folate that is consumed in the diet, produced endogenously, and ingested as a supplement is fragile, or at

least vulnerable to a wide range of stressors, most notably pharmacological agents.

Healthy levels of folate in the blood and target tissues enable many key physiological functions, such as normal DNA synthesis and healthy cell division, homocysteine regulation, and endothelial function, and thus play a key role in preventing many pathological processes, including carcinogenesis and atherogenesis. However, polymorphisms in the genes coding for key folate metabolism enzymes, such as MTHFR, thiopurine methyltransferase (TPMT), and inosine triphosphate pyrophosphatase (ITPase), play a key role in folate status, susceptibility to folate-related pathologies, response to folate administration, and tolerance of and therapeutic response to medications affecting folate.

Conventional medicine does not generally employ laboratory tests adequately sensitive for detecting compromised folate status, particularly depletion patterns and deficiency states at the tissue and mitochondrial level, before they reach pathological proportions at a system-wide level. Unless specifically contraindicated, folic acid supplementation could reasonably be recommended for everyone as basic nutritional support for health maintenance and prevention of many pathological and degenerative processes, especially if the person is taking one of the medications discussed later. The supervising caregiver then focuses on carefully monitoring the patient in specific situations requiring closer clinical management. The implications of folate deficiency can be profound and severe, from teratogenesis during pregnancy to stroke later in life, and constitute the primary clinically significant influence of drug interactions involving folate and folic acid for both short-term medical management and long-term strategies of wellness and prevention.

The main caution against folic acid administration is that vitamin B_{12} deficiency, especially severe deficiencies such as those associated with pernicious anemia, might be masked. This warning, however, seems misplaced or at least uninformed because almost every folic acid product on the market is formulated with vitamin B_{12}, at a minimum, or a comprehensive range of synergistic nutrients, as in a multivitamin or B-complex formulation. All health care providers experienced in nutritional therapeutics routinely coadminister folic acid and vitamin B_{12} as a matter of safety, synergy, and efficacy. The more significant (and sometimes controversial) question centers on appropriate dosage levels, and emerging evidence is clarifying this clinical picture. Generous quantities of B_{12} may be critical to effectiveness much more often than previously thought, especially in older people. Generally, conventional nutritional education has framed folate dosing in hundreds of micrograms and B_{12} in single-digit micrograms because of the difference in quantity that prevents serious deficiency states. However, a pivotal clinical trial by Eussen et al.[20] showed that once deficient (by MMA levels), at least 500 to 600 µg of oral vitamin B_{12} is required to correct an established pattern of "mild" depletion. Thus it is advisable always to give equivalent amounts of B_{12} with folate.

Folic acid interacts with and is depleted by a wide range of medications. Some agents incidentally impair folate absorption and transport, but others rely on competitive inhibition and other means of directly interfering with folate activation and folate-dependent enzymes as central to their mechanism of action. In most cases, coadministration of folic acid offers a safe, easy, and inexpensive means of preventing, reducing, or reversing drug-induced adverse reactions, particularly folate deficiency at blood, tissue, and cellular levels, and interference with physiological activities of folate and related enzymes. Folate coadministration is contraindicated only in patients being treated with antifolate medications for tumors, and then primarily in doses greater than 1000 µg/day. Moreover, when the toxic effects of these medications exceed tolerance or safety limits, folic acid, or more often folinic acid, the activated form, is applied "to pull the situation back from the brink" (so-called rescue). Such contraindications are generally not applicable when the same medications, particularly methotrexate, are used for reasons other than antineoplastic activity.

Research and clinical experience increasingly indicate significant clinical benefits from use of 5-FTHF (folinic acid) and 5-MTHF as sources of activated folate in light of impaired enzyme activity, especially MTHFR, as a result of drug interference and genetic polymorphisms. For many years the use of folinic acid (5-FTHF) has largely been restricted to rescue use with methotrexate and other antifolate medications. The therapeutic significance of this and other forms of folate administration that bypass enzymatic inhibition (e.g., 5-MTHF) becomes more apparent, with growing awareness of the potential adverse implications of unintended decreases in functional folate levels.

Along with the major risk of neural tube defects from folate deficiency during early gestation, homocysteine (Hcy) regulation appears as the most recurrent theme in reviewing the strategic significance of drug interactions with dietary folate and supplemental folic acid. The pervasive and destructive effects of elevated Hcy levels are well documented and widely known. Methionine synthase, the enzyme that metabolizes Hcy to methionine, uses 5-MTHF and vitamin B_{12} as cofactors. Folic acid may have antiatherogenic mechanisms independent of lowering Hcy levels. Besides effects on the vascular system, plasma tHcy level and low serum folate concentrations are independent risk factors for dementia as well as low bone mineral density, particularly among women.[17,21-26] In a randomized, placebo-controlled trial involving 46 Taiwanese subjects (42 men, average age 73), Lin et al.[27] demonstrated that low-dose folic acid (400 µg daily) supplementation reduces Hcy concentration in hyperhomocysteinemic coronary artery disease (CAD) patients and could also reduce CAD risk. Compliance was assessed over 8 weeks by 24-hour diet recalls at week 0 and week 8. Notably, although the low-dose folic acid supplements had no significant effect on Hcy concentrations in the general study population, levels did significantly decrease in hyperhomocysteinemic subjects, by 1.8 µmol/L, especially for carriers of the T-allele.

The evolving debate as to whether Hcy represents a causal or coincident factor in heart disease, cerebrovascular accident (stroke), and related conditions shifted to a new level with publication of the Vitamin Intervention for Stroke Prevention (VISP) trial. When the VISP intention-to-treat analysis failed to show efficacy of combined vitamin therapy for recurrent vascular events in patients with nondisabling stroke, Spence et al.[27a] conducted an "efficacy analysis limited to patients most likely to benefit from the treatment, based on hypotheses arising from evidence developed since VISP was initiated." After excluding "patients with low and very high B_{12} levels at baseline," they found "a 21% reduction in the risk of events in the high-dose group compared with the low-dose group." Also, "patients with a baseline B_{12} level at the median or higher randomized to high-dose vitamin had the best overall outcome, and those with B_{12} less than the median assigned to low-dose vitamin had the worst." They concluded: "In the era of folate fortification, B_{12} plays a key role in vitamin therapy for total homocysteine. Higher doses of B_{12}, and other treatments to lower total homocysteine, may be needed for some patients."

Subsequently, the Women's Antioxidant and Folic Acid Cardiovascular Study (WAFACS), NORVIT, and HOPE-2 trials supported research demonstrating that these nutrients help lower Hcy levels. However, these trials failed to support the hypothesis that lowering Hcy levels alone will provide protection against a future cardiovascular event in high-risk patients with established cardiovascular disease. For example, in the Norwegian study of post–myocardial infarction (MI) patients randomized to a folate-B_{12}-B_6 formulation or placebo, Bønaa et al.[28,29] observed a pattern of increased risk of a second MI in the intervention group, despite a lowering of Hcy. Although relevant to certain patient populations, the findings from these trials suggest that such a study of secondary prevention (patients with previous MI) have limited applicability to primary prevention (individuals without previous vascular events) in healthy individuals and in those with elevated risk. Notably, the HOPE-2 study demonstrated a statistically significant 25% reduction in nonfatal strokes.[30]

Nevertheless, the current data are incomplete because all patients were taking standard post-MI medications (e.g., beta blockers, ACE inhibitors, aspirin). Also, investigators did not monitor drug levels to see if the B vitamins were depleted by the medications or, conversely, if the medications were impaired or levels lowered by the nutrients, as may occur if the nutrients (e.g., vitamin E) induce the pregnane X receptor (PXR). Such potentially significant variables, which were not assessed or factored in, might explain the unexpected "increased risk" associated with the B vitamins, which would actually be analogous to poor compliance with medication. Research into PXR is in preliminary stages, and a focus on its relevance to B vitamins may be warranted and could clarify these and other findings. More broadly, such findings do not detract from other potential benefits derived from lowering Hcy levels, or at least reversing processes associated with elevated Hcy.

An ongoing dialectic between reviews and meta-analyses continues and is unlikely to produce definitive conclusions and more precise recommendations until large-scale, long-term, and well-designed prospective interventional clinical trials are conducted. In reviewing the data from numerous cohort studies, Wald et al.[31] (2006) determined that despite controversy and apparently conflicting evidence in reports of the benefits of folate consumption on cardiovascular disease risk, the weight of evidence supports recommending folic acid for cardiovascular health. Their meta-analysis showed that a 3-μmol/L decrease in serum Hcy levels, considered achievable with a daily folic acid intake with 0.8 mg, lowers the risk of heart attack and stroke by 15% and 24%, respectively. Furthermore, in studies focusing on MTHFR genotypes, the investigators reported that high Hcy levels were associated as "causal" for the risk of stroke and that the "dose-response relation in the genetic studies is particularly relevant in suggesting a causal effect." Overall, the estimate from the trials was consistent with a short-term protective effect of 12% on ischemic heart disease episodes and 22% on stroke, or a greater long-term effect. The degree that folic acid reduces Hcy concentration depends on background folate levels, so increasing folic acid consumption should reduce the risk of heart attack and stroke to a degree related to the Hcy reduction. The authors concluded "that the evidence is now sufficient to justify action on lowering homocysteine concentrations, although the position should be reviewed as evidence from ongoing trials emerges."[31]

Conversely, in a meta-analysis, Bazzano et al.[32] evaluated the effects of folic acid supplementation on risk of cardiovascular diseases and mortality in randomized controlled trials among persons with preexisting cardiovascular or renal disease. They concluded that folic acid supplementation "has not been shown to reduce risk of cardiovascular diseases or all-cause mortality among participants with prior history of vascular disease," but noted that "ongoing trials with large sample sizes might provide a definitive answer to this important clinical and public health question."

The issue of whether the potential benefits of folic acid and related nutrients that affect Hcy derive from other functions and effects, beyond lowering Hcy, appears increasingly important given the controversial findings and disappointed expectations of Hcy-centered interventional trials and meta-analyses. The role of folic acid in reversing endothelial dysfunction may be central to these protective effects. In a small but potentially pivotal study involving 128 patients with CAD, Moat et al.[33] found that high-dose folic acid (5 mg/day) for 6 weeks significantly improved endothelial function, independent of its effect on lowering plasma Hcy levels. Notably, these investigators observed that subjects administered folate at either 400 μg/day or 5 mg/day had significant increases in plasma folate and significant decreases in plasma Hcy, whereas only subjects who received 5 mg/day exhibited significant improvements in flow-mediated dilation. Another subgroup of subjects, administered betaine (3 g twice daily), showed significant impairment in flow-mediated dilation, despite a reduction in plasma Hcy. The authors' conclusion that their findings suggest that folic acid "dose-dependently improves endothelial function in CAD via a mechanism independently of Hcy lowering" may portend a significant evolution in this body of research.

In a related experiment focused on the mechanism(s) underlying such observed phenomena, Moat et al.[34] demonstrated that folic acid can reverse "both the endothelial dysfunction and increased production of superoxide following depletion of rabbit aortic ring tetrahydrobiopterin (BH4) levels with 2,4-diamino-6-hydroxy-pyrimidine (DAHP) and *N*-acetyl-5-hydroxy-tryptamine (NAS)." Thus, they concluded that "folic acid reverses the endothelial dysfunction induced by BH4 depletion independently of either the regeneration or stabilization of BH4 or an antioxidant effect."

Emerging evidence indicates that the influence of elevated Hcy levels extends beyond risk of stroke and heart disease, and that folate and other B vitamins have an important role in preventing or reducing other degenerative processes, especially those associated with aging. The literature associating hyperhomocysteinemia with dementia is well known and suggests a broader focus for future research and preventive nutritional support. For example, in a 3-year, randomized, placebo-controlled trial involving 728 subjects age 50 to 72, Durga et al.[35] found that folate (800 μg/day) may reduce age-associated hearing loss, particularly in individuals with elevated Hcy levels. The interconnections between Hcy, folate nutriture, and degenerative processes will undoubtedly be the subject of continued investigation.

The causes of hyperhomocysteinemia are broadly categorized as "inherited" and "acquired." Many causes involve folate nutriture, metabolism, and function. The inherited causes include MTHFR deficiency or defect, methionine synthase defect, vitamin B_{12} transport defect, vitamin B_{12} coenzyme synthesis defect, and cystathionine-β-synthase deficiency. The acquired causes can be grouped as vitamin deficiencies, chronic diseases, and medication effects. Nutritional deficits of folic acid, vitamin B_{12}, and vitamin B_6 can usually be remedied by ensuring adequate dietary sources and administering supplements that provide these synergistic nutrients. Enhanced folate intake may be of direct and indirect benefit for patients with chronic renal failure, hypothyroidism, psoriasis, and

malignancies (including acute lymphoblastic leukemia). Notably, conventional treatment of these conditions often involves drug therapies that deplete or interfere with folate. Also, medications that adversely affect folate status and function constitute one of the primary risk factors for hyperhomocysteinemia. Fortunately, this last factor may be the most amenable to clinician intervention, with this monograph being a tool in providing safe and effective medical management by employing an evidence-based, integrative approach to health care delivery.

NUTRIENT-DRUG INTERACTIONS

Acetylsalicylic Acid (Aspirin) and Salsalate

Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine), ASA, codeine, butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin). Salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab).

Effect and Mechanism of Action

Aspirin and salicylic acid, its metabolite, can inhibit folate-dependent enzymes and interfere with folate metabolism. Increased urinary excretion of folate has been associated with chronic ASA use in patients with rheumatoid arthritis (RA).[36] Administration of exogenous folic acid may compensate for and reverse these adverse effects on endogenous folate metabolism.

Research

In 1971, Alter et al.[37] initiated the discussion of reduced blood levels of folate among individuals with rheumatoid arthritis taking aspirin chronically.[37] Lawrence et al.[38] conducted in vivo and in vitro studies of serum binding and urinary excretion of endogenous folate caused by aspirin ingestion. They analyzed serum and blood samples during two series of experiments involving one healthy woman following a fixed diet for 11 days and taking 650 mg aspirin orally every 4 hours during the middle 3 days. They found that "aspirin induced a brisk, significant but reversible fall in total and bound serum folate and a small but insignificant rise in urinary folate excretion." Furthermore, aspirin in vitro also displaced significant amounts of bound serum folate. The authors concluded that "aspirin in therapeutic doses can contribute to subnormal serum folate values, and if it increases urinary folate excretion even slightly, may impair folate balance."[38]

Baggott et al.[39] found that salicylic acid was a competitive inhibitor (with respect to folate) of avian liver phosphoribosylaminoimidazolecarboxamide formyltransferase (AICAR transformylase, EC 2.1.2.3) and bovine liver dihydrofolate reductase (EC 1.5.1.3), whereas aspirin (as well as the antipyretic-analgesic drugs acetaminophen and antipyrine) were weak inhibitors of these enzymes. Their research suggests that, based on a structure-activity correlation, an aromatic ring with a side chain containing a carboxylic acid is a requirement for competitive inhibition of the transformylase. Thus, "aspirin exerts its anti-inflammatory effects after its conversion into salicylic acid, which possesses greater antifolate activity than its parent compound."[39] They also noted that sulindac, sulphasalazine, naproxen, and ibuprofen are the NSAIDs possessing more potent antifolate activity.

The evidence demonstrating interference with folate metabolism by aspirin is direct and incontrovertible, but the clinical significance of such interference and subsequent folate depletion appears to depend on dosage, duration of intake, and individual variability and susceptibility. High aspirin dosage levels over extended periods can produce adverse effects that are potentially significant and can increase the metabolic needs for folic acid. Further research is warranted given the broad use of ASA, especially over long periods.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians and other health care providers are advised to ask patients regarding their patterns of aspirin use, prescribed and self-administered, and to counsel folate supplementation as a prudent protective measure against potential adverse effects from long-term intake. The body of evidence indicates that although interference with folate metabolism is probable and cumulative depletion of folate possible, the effects of such processes will vary among individuals depending on other factors, such as age, gender, nutritional intake, supplement use, genomic variability, and drug depletion. Supplementation with a minimum of 400 µg folate daily represents a judicious intervention, given the multiple stressors affecting folate status and the low cost and strong safety profile of folic acid. The necessary amount of daily folic acid support can usually be obtained in a multivitamin formula. However, 800 µg/day is probably appropriate in some individuals, such as pregnant women and those with other risk factors. Low-dosage, chronic ASA intake, as in stroke prevention, is unlikely to contribute to significant compromise of folate status and function, barring other major influences. However, given its potential beneficial impact on homocysteine, supplementation with folic acid and allied nutrients is generally warranted in such patients to reduce risk of atherosclerosis and stroke.

Antacids, Histamine (H_2) Antagonists, and Related Gastric Acid–Suppressive Medications

Antacids

Evidence: Aluminum hydroxide (Alternagel, Amphojel). Extrapolated, based on similar properties: Aluminum carbonate gel (Basajel), aluminum hydroxide combination

drugs: aluminum hydroxide, magnesium carbonate, alginic acid, and sodium bicarbonate (Gaviscon Extra Strength Tablets, Gaviscon Regular Strength Liquid, Gaviscon Extra Strength Liquid); aluminum hydroxide and magnesium hydroxide (Advanced Formula Di-Gel Tablets, Co-Magaldrox, Di-Gel, Gelusil, Maalox, Maalox Plus, Mylanta, Wingel); aluminum hydroxide, magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets), calcium carbonate (Titralac, Tums); magnesium hydroxide (Phillips' Milk of Magnesia MOM); combination drugs: magnesium hydroxide and calcium carbonate (Calcium Rich Rolaids); magnesium hydroxide, aluminum hydroxide, calcium carbonate, and simethicone (Tempo Tablets); magnesium trisilicate and aluminum hydroxide (Adcomag trisil, Foamicon); magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); combination drug: sodium bicarbonate, aspirin, and citric acid (Alka-Seltzer).

Cimetidine and Related Histamine (H_2) Receptor Antagonists

Evidence: Cimetidine (Tagamet; Tagamet HB).
Extrapolated: Famotidine (Pepcid RPD, Pepcid, Pepcid AC), nizatidine (Axid, Axid AR), ranitidine (Zantac), combination drug: ranitidine, bismuth, and citrate (Tritec).

Proton Pump Inhibitors

Similar properties but evidence lacking for extrapolation: Esomeprazole (Nexium), lansoprazole (Prevacid, Zoton), omeprazole (Losec, Prilosec), pantoprazole (Protium, Protonix, Somac), rabeprazole (AcipHex, Pariet).

Effect and Mechanism of Action

The influence of gastric acid sets the stage for folate absorption, which is maximal in the jejunum. Thus, medications that interfere with the normal pH of the gastrointestinal (GI) environment, particularly alkalinization of the proximal small intestine, can impair folic acid absorption and may cause low or deficient plasma and erythrocyte folate.[40] However, some evidence indicates the degree to which a medication alters pH does not always parallel the degree to which it adversely affects folic acid absorption.[40,41] Additionally, antacids containing aluminum hydroxide, magnesium hydroxide, or other minerals may bind to folate and reduce its absorption.[41,42] These pharmacokinetic interactions may produce secondary metabolic effects because folic acid is required for proper metabolic function of vitamin B_{12}.

Research

A review of the available literature indicates medications that suppress gastric acidity can reduce folate bioavailability and absorption to a degree that might not affect most individuals but are of increased clinical significance in populations who use such medications frequently for extended periods and who also have compromised folate nutriture or increased metabolic demands, both of which are relatively common situations.

Cimetidine and ranitidine are H_2 antagonists known to reduce folate absorption because of their effect on pH in the GI tract, although this is generally minor and unlikely to be of clinical significance in most individuals. Russell et al.[41] conducted two experiments investigating these issues. First, in vitro studies showed that neither cimetidine nor ranitidine physically bound folate or interfered with its metabolism (as indicated by a lack of inhibition of dihydrofolate reductase at concentrations of 5 and 50 μmol/L). Subsequently, 30 participants followed a standard regimen of either cimetidine or ranitidine and then were fed a specially formulated liquid meal containing 200 μg of folate. Monitoring of pH values at the ligament of Treitz showed that the slight acidity existing before consumption of the liquid meal was generally maintained during the 2-hour period after food intake. Folate absorption was 50% with the formula meal alone versus 45.8% with the formula meal plus cimetidine. The decrease in folate absorption with ranitidine did not attain statistical significance. Although drug-induced effect on intestinal pH was the focus, the observation that cimetidine reduced folate absorption more than ranitidine suggests a more complex interaction because ranitidine increased intestinal pH to a greater degree.

Russell et al.[41] also observed that aluminum with magnesium hydroxide reduces folate absorption to a small extent, apparently by adsorbing the nutrient, rather than through its effect on gastric acid. These researchers tested dietary folate absorption in 30 subjects by administering the antacid 1 hour and 3 hours after a specially formulated liquid meal containing 200 μg of folate. Folate absorption was 50.6% with the formula meal alone versus 43.1% when the antacid was administered after the formula meal. Acidity actually increased slightly during the 2-hour period after the liquid meal, as indicated by monitoring of pH values at the ligament of Treitz, despite the activity of the antacid.

Further research indicates that the aluminum hydroxide component of the antacid adsorbs folate onto its surface, as gel particles agglomerate and hydroxide begins to precipitate from the gel state (characteristic at pH range of ~3.7-10), and removes it from contact with the aqueous phase.[42]

Evidence regarding the effects of proton pump inhibitors (PPIs) on folate and folic acid is lacking, but these agents might be expected to have a similar effect. This possible interaction poses significant risk because such medications are often prescribed for patients in populations most susceptible to folate deficiency, such as the elderly. The PPIs have clearly been shown to interfere with vitamin B_{12} absorption.

Reports

Ruscin et al.[42a] reported on a 78-year-old, nonvegetarian Caucasian woman with symptomatic gastroesophageal reflux who had vitamin B_{12} deficiency associated with long-term use (~4½ years) of cimetidine and a PPI; serum folate was within the normal range at 4.9 ng/mL. The patient responded to oral B_{12} replacement, thus demonstrating that she could adequately absorb non–protein-bound vitamin B_{12} from the GI tract and suggesting her deficiency was a result of food-cobalamin malabsorption. This case report suggests that long-term H_2/PPI antagonist therapy (≥4 years) may adversely impact vitamin B_{12} status but is unlikely to influence folate.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Most medications that suppress gastric acid appear to impact folate (and vitamin B_{12}) absorption to some degree by at least one mechanism. The severity of such effect may vary based on individual physiological characteristics, diet, pathophysiology, and specific factors relating to particular drug agents or classes. Although the effects on folate absorption and nutriture are often dismissed as "marginal," they may produce significant adverse effects, especially in undernourished populations and individuals with increased metabolic needs (e.g., pregnancy). Prudence suggests that physicians prescribing such medications advise patients to supplement with a folic acid/B_{12} combination. Increasing folate intake without accompanying B_{12} can stimulate systems that also use B_{12} and can result in lower B_{12} levels. Such preventive measures should also be communicated to patients who may be self-administering antacids on a chronic basis, especially if they are at risk of folate deficiency from dietary factors or depletion from medications.

Anticonvulsant Medications, Including Phenobarbital, Phenytoin, and Valproic Acid

Evidence: Carbamazepine (Carbatrol, Tegretol), divalproex semisodium, divalproex sodium (Depakote), fosphenytoin (Cerebyx, Mesantoin), phenobarbital (phenobarbitone; Luminol, Solfoton), phenytoin (diphenylhydantoin; Dilantin, Phenytek), primidone (Mysoline), sodium valproate (Depacon), valproate semisodium, valproic acid (Depakene, Depakene Syrup).

Extrapolated, based on similar properties: Ethosuximide (Zarontin), ethotoin (Peganone), felbamate (Felbatol), levetiracetam (Keppra), mephenytoin, mephobarbital (Mebaral), methsuximide (Celontin), phensuximide (Milontin), tiagabine (Gabitril), topiramate (Topamax), trimethadione (Tridione), zonisamide (Zonegran).

Similar properties but evidence lacking for extrapolation: Acetazolamide (Diamox, Diamox Sequels), gabapentin (Neurontin), pheneturide (ethylphenacemide), piracetam (Nootropyl), vigabatrin (Sabril).

Similar properties but evidence indicating no or reduced interaction effects: Clonazepam (Klonopin), clorazepate (Tranxene), diazepam (Valium), lamotrigine (Lamictal), lorazepam (Ativan), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal).

Effect and Mechanism of Action

Antiepileptic drugs (AEDs) and related medications interact with supplemental folic acid and dietary folate through several mechanisms to produce varied, complex, reinforcing, and sometimes countervailing effects. Most drugs in this broad class interfere with folate function and cause folate depletion by inhibiting nutrient absorption, inducing microsomal oxidase enzymes (cytochrome P450) to increase hepatic folate metabolism, and adversely impacting the microbiota of symbiotic flora in the gut.[43-45] Furthermore, the recycling of folate cofactors depends on vitamin B_6 and riboflavin, and riboflavin is necessary for activating vitamin B_6 to pyridoxal 5′-phosphate (PLP).[46] Thus, induction of enzymes by anticonvulsants may strain available folate resources and limit synthesis of the cytochromic enzymes responsible for AED metabolism.

Numerous factors can adversely influence folate metabolism in individuals being treated with anticonvulsant medications. Decreased MTHFR activity in some individuals reduces conversion of folate to active forms. Primidone and phenobarbital, its metabolite, may both decrease folate absorption and increase its hepatic metabolism while also inhibiting the growth of folate-dependent symbiotic microflora.[47] Valproic acid may interfere with folate absorption but may not induce enzymes; decreased folate levels are found after long-term valproate therapy. Carbamazepine can reduce folate absorption, but evidence is conflicting as to whether this enzyme inducer (CYP450) actually produces any significant effect on hepatic metabolism of folate.[48,49] Many AEDs are metabolized through arene oxides, which are highly reactive intermediates and generally considered to be teratogenic.[50] By impairing the action of epoxide hydrolase (the enzyme system responsible for detoxifying arene oxides), inadequate folate levels could result in incomplete metabolism of anticonvulsants and the accumulation of highly reactive epoxides and thus could contribute to fetal abnormalities.[43,51] For example, the teratogenicity of carbamazepine appears to derive, at least in part, from the formation of the 10,11-epoxide metabolite, which may act as a free radical, binding to proteins and nucleic acids and disrupting DNA, RNA, and protein synthesis.[52] In contrast to carbamazepine, oxcarbazepine undergoes reduction of the carbonyl group to form MHD, which subsequently undergoes glucuronidation, and thus does not form the epoxide.[53] However, such effects constitute only one of several factors in the significant rate of major malformations in offspring exposed to these medications during pregnancy.[54-58] Anticonvulsant-induced low serum folate levels can also elevate homocysteine (Hcy) levels and thereby increase risk of cardiovascular disease, particularly atherosclerosis.[59-61] Elevated Hcy levels are associated with pregnancy complications, neural tube defects (NTDs), and other birth defects. Notably, Hcy has been used as an experimental convulsant.

Conversely, folate may decrease serum levels of some medications (e.g., phenytoin), possibly by acting as a cofactor for the enzyme epoxide hydrolase, or otherwise increasing metabolism of the anticonvulsants and reducing serum drug levels, possibly to subtherapeutic levels. Thus, increased intake of supplemental folic acid, and/or theoretically of dietary folate, could impair the therapeutic activity of AEDs and could increase the incidence of seizure activity. In particular, folate in doses greater than 1 mg daily can compromise phenytoin seizure control by creating a "pseudo–steady state" in which phenytoin appears to be at steady state but actually is not; this

effect may be due to competition for brain-cell surface receptors.[43]

Research

Although the issues of folate deficiency and depletion may have significant effects on the health and disease susceptibility of broad sections of the general population, their impact is perhaps most dramatic among individuals being treated with AEDs for seizure disorders and related conditions. Decades of research have demonstrated low folate levels (and increased Hcy levels) in patients treated with AEDs, particularly as polypharmacy.[45,59-67] Nevertheless, although the interaction between AEDs and folates is well documented and potentially clinically important, its clinically significant incidence is uncertain and subject to many variables.

In their landmark 1966 study, Reynolds et al.[68] examined folate status in 62 patients with epilepsy, 54 of whom were taking phenobarbital, primidone, or phenytoin singly or in various combinations, with eight serving as untreated controls. Serum folate concentrations in 76% of treated patients were below the range found in control subjects, and average folate concentration for the treated patients was 3.7 ng/mL, versus 6.4 ng/mL for the controls. Of 45 with bone marrow examination, 17 exhibited megaloblastic hematopoiesis, even though none of the treated patients was anemic, and only 7 of the 54 treated patients showed macrocytosis.

In a survey of the red blood cell (RBC) folate status of 200 patients with epilepsy and 72 controls, Goggin et al.[69] found that median RBC folate levels were reduced significantly in patients treated with phenytoin or carbamazepine alone. Also, patients administered AED polypharmacy had reduced levels, with 22% in the group taking more than one drug showing reduced levels of RBC folate compared with 17% of those receiving carbamazepine monotherapy, 13% taking phenytoin only, and 9% taking sodium valproate only. Notably, patients treated with sodium valproate alone exhibited no significant decrease in RBC folate levels (compared to controls). Dietary folate intake was significantly reduced in all the patient groups compared with controls, but there was no significant correlation between RBC folate levels and dietary folate. The investigators concluded that "all anticonvulsant drugs interfere with folate metabolism."[69]

Kishi et al.[45] measured serum folate concentrations in epileptic outpatients treated with a single anticonvulsant drug, including carbamazepine, phenobarbital, and valproate, and in age-matched controls without anemia. They used a protein-binding radioassay to demonstrate that reduced serum folate was associated with hepatic CYP450 enzyme induction by carbamazepine and phenobarbital, but not valproate, compared with controls.

The influences of AEDs and the MTHFR genotype further complicate the research exploring the powerful relationship between folate status and homocysteine and its profound implications for health and disease. The methylenetetrahydrofolate reductase (MTHFR) genotype appears to modulate depletion of active folate and contribute directly to an increased incidence of hyperhomocysteinemia. Elevated Hcy levels have been documented after anticonvulsant treatment with phenytoin, carbamazepine, phenobarbital, and primidone, agents that induce CYP450.[59-61,66,67,70-72] Likewise, in addition to impairing folate status, long-term treatment with valproate also increases Hcy levels.[67,72] Yoo and Hong[73] demonstrated that the TT allele of the MTHFR C677T polymorphism, a common mutation in the MTHFR gene, is a significant determinant of hyperhomocysteinemia in epileptic patients receiving anticonvulsants.

The concerns raised by high Hcy levels extend beyond cardiovascular risk. In their study of 130 epileptic patients taking anticonvulsant monotherapy or multidrug polytherapy (including carbamazepine and/or phenytoin), Ono et al.[59] noted that individuals diagnosed with megaloblastic anemia as a result of folate deficiency exhibit a high incidence of neuropsychiatric illness and elevated plasma total homocysteine (tHcy) levels. The four folate-deficient patients had received long-term treatment (>7 years) with multiple anticonvulsants. Their tHcy levels were higher than the 90th percentile of those in control subjects. Folate therapy normalized their Hcy and folate levels. Notably, disturbances of the remethylation pathway of Hcy can significantly impact numerous physiological activities, thereby influencing fetal development and contributing to malformations such as NTDs, spontaneous abortions, and other pregnancy complications. Dean et al.[74] found that the MTHFR C677T polymorphism is associated with fetal anticonvulsant syndrome in the offspring of mothers administered AEDs during pregnancy.

The impact of anticonvulsant medications on folate status has been a concern since the introduction of AEDs, and thus research has focused most on the consequences of drug-induced folate deficiency, especially during pregnancy, and the clinical implications of compensatory folic acid coadministration. The strong association between increased risk of birth defects and treatment with AEDs is well established by a consistent body of epidemiological evidence.[75-79] Hydantoins such as phenytoin are most frequently associated with teratogenesis.[55,80] Valproic acid (VPA), divalproex, and valproate sodium have all been reported to cause birth defects when administered during the first 3 months of pregnancy. Specifically, VPA use during early pregnancy can result in a 1% to 2% incidence of spina bifida aperta in humans, a closure defect of the posterior neural tube.

Hendel et al.[48] conducted research on the effect of carbamazepine and valproate treatment on folate metabolism in 11 epileptic patients and interpreted their findings as an inhibition of intestinal folic acid absorption caused by the antiepileptic therapy. However, Kishi et al.[45] examined the role of induction of liver enzymes by AEDs in folate depletion and determined that patients treated with valproate, a non–enzyme inducer, exhibited serum folate levels that did not differ significantly from values in controls. Furthermore, NTDs in humans and rodents associated with VPA do not seem to be related to folate deficiency, and NTD incidence has not changed with administration of folic acid or its activated form, folinic acid.[80] Several other studies have indicated that VPA has the least antifolate action of the major AEDs, and that folate is probably not involved in the mechanism of VPA-induced embryotoxicity. One study found that the consumption of ethanol potentiated VPA-induced NTDs in mice resulting from toxicokinetic interactions.[81] Subsequently, however, findings from a Finnish population-based study by Artama et al.[82] confirmed the teratogenicity of valproate. "The offspring of women with epilepsy on valproate [at doses >1500 mg/day] during the first trimester of pregnancy have a substantially increased risk for congenital malformations." They also reported that the risk for teratogenic malformations is not elevated in offspring of mothers using carbamazepine, oxcarbazepine, or phenytoin (as monotherapy or polytherapy without valproate). This study is notable in being one of the few large studies on the teratogenic effects of AEDs to include a reference group of untreated women with epilepsy.

The incidence of NTDs, such as spina bifida and anencephaly, may dominate broad awareness of adverse effects,

but cardiovascular defects, oral clefts, and urinary tract defects are also reported. Likewise, a Danish study by Fonager et al.[77] found that the risks of low birth weight and preterm delivery were increased by 50% and 60%, respectively, in women exposed to anticonvulsant drugs. In another Danish study, Hvas et al.[78] observed that the infants of women with drug-treated epilepsy exhibited a lower birth weight, shorter length, and a smaller head circumference than infants of untreated subjects.

For years clinicians and investigators were unsure as to whether the incidence of fetal abnormalities in mothers with seizure disorders was a result of the condition itself or of their medications. Kaneko et al.[83] prospectively analyzed 983 offspring born in Japan, Italy, and Canada to identify the major risk factors for the increased incidence of congenital malformations in offspring of mothers being treated for epilepsy with AEDs during pregnancy and to determine the relative teratogenic risk of AEDs. The incidence of congenital malformations in offspring with drug exposure was 9.0%, versus an incidence without drug exposure of 3.1%. The highest incidence among offspring exposed to a single AED occurred with primidone (14.3%), followed by valproate (11.1%), phenytoin (9.1%), carbamazepine (5.7%), and phenobarbital (5.1%). The incidence of malformations was positively associated with the total daily dose and number of drugs, with specific combinations of AEDs (e.g., valproate and carbamazepine; phenytoin, primidone, and phenobarbital) producing a higher incidence of congenital malformations. Moreover, the presence of malformations in siblings was the only background factor associated with the incidence of malformations. These authors concluded that "the increased incidence of congenital malformations was caused primarily by AEDs, suggesting that malformations can be prevented by improvements in drug regimen, and by avoiding polypharmacy and high levels of VPA (more than 70 μg/mL) in the treatment of epileptic women of childbearing age."[83]

In a multicenter study, Holmes et al.[56] screened 128,049 pregnant women at delivery to investigate the frequency of anticonvulsant embryopathy (i.e., major malformations, growth retardation, hypoplasia of midface and fingers) and determine whether the abnormalities are caused by the maternal epilepsy itself or by exposure to anticonvulsant drugs in utero. They reported that the combined frequency of anticonvulsant embryopathy was higher in 223 infants exposed to one anticonvulsant drug than in 508 control infants (20.6% vs. 8.5%) and that the frequency was higher in 93 infants exposed to two or more anticonvulsant drugs than in the controls (28.0% vs. 8.5%). Moreover, the 98 infants born to the mothers with a history of epilepsy but no use of anticonvulsants during pregnancy did not exhibit a higher frequency of abnormalities than control infants.[56]

In 2003, Kaaja et al.[84] prospectively followed up 970 pregnancies in women with epilepsy at a single maternity clinic from 1980 through 1998. Of the 979 total offspring, 740 were exposed to maternal AEDs during the first trimester, and 239 were not exposed. Serum folate concentrations were measured at the end of the first trimester, as were maternal AED levels (to minimize exposure). Major malformations were detected in 28 fetuses (3.8%) exposed to maternal AED and in two (0.8%) not exposed. Eight of the 28 cases had NTDs, which is fourteenfold the national rate. Seven had oral clefts, six had cardiovascular malformations, four had visceral malformations, and three exhibited miscellaneous malformations. Logistical regression analysis revealed that the occurrence of major malformations was independently associated with use of carbamazepine (odds ratio [OR] 2.5), valproate (OR 4.1), and oxcarbazepine (OR 10.8); low serum folate concentration; and low maternal level of education. Also, the authors found no association between major malformations and seizures during the first trimester. None of these women reported preconception use of folate, but all were advised to take multivitamins containing 0.1 to 0.8 mg of folate at the first antenatal visit, usually between the eighth and twelfth week of gestation.[84]

The risks of AED-induced folate deficiency on fetal development also involve the effect of AEDs on the efficacy of birth control. The most common AEDs induce the CYP450 enzymes that metabolize estrogens (e.g., ethinyl estradiol, mestranol), causing up to a 40% reduction in serum levels.[85-88] Oral contraceptives (OCs) can also interfere with folate cofactor interactions, causing impaired DNA synthesis. Thus the use of OCs or Norplant does not reduce the need for folic acid coadministration in women of childbearing age and may actually increase such need because increased clearance of the contraceptive agents may impair their efficacy.

Compared with older anticonvulsants, particularly hydantoin derivatives, newer AEDs may exert less adverse effect on fetal development because of lesser adverse influence on vitamin status, among other reasons.[89] Such probabilities, their implications, and clinical responses have yet to be adequately researched and supported by conclusive evidence.

The coadministration of folic acid to counterbalance the adverse effects of AEDs on folate nutriture has been investigated and refined to a point where broad parameters of efficacy and guidelines for clinical implementation now have general consensus. In a long-term study, Reynolds[90] investigated the effects of 1 to 3 years of folate coadministration on the "mental state and fit-frequency" in 26 chronic epileptic patients with AED-induced folic-acid deficiency treated with one or more anticonvulsants. Mental state improved in 22 patients, but seizure frequency or severity was aggravated in 13 patients (50%). Reynolds concluded that "folic acid partially reverses both the therapeutic (antiepileptic) and retarding effects of phenobarbitone, phenytoin, and primidone."[90] Baylis et al.[91] assessed the effects of folic acid administration in 50 folate-deficient epileptic patients taking phenytoin, primidone, and phenobarbital in various combinations. Serum phenytoin levels fell from 20 to 10 μg/mL in a group of 10 patients after 1 month's treatment with folic acid, 5 mg/day. Likewise, serum phenytoin levels fell from 14 to 11 μg/mL in a second group of 40 patients administered 15 mg/day of folic acid. "In one patient the fall was to below the therapeutic range and was associated with deterioration in fit control."[91] Phenobarbital levels were unchanged in the presence of folate supplementation.

In a randomized, double-blind trial, Gibberd et al.[92] tested the effects of folic acid coadministration on seizure frequency in a group of outpatients with epilepsy treated with phenytoin for at least 1 year. Although the group receiving folic acid in the treatment period showed a significant improvement in seizure frequency, the authors suggested that "subjective well-being of patients was not influenced by folic acid therapy" and concluded that "the improvement while on folic acid was not due to the folic acid treatment alone."[92] Biale and Lewenthal[93] conducted a study to determine the frequency of malformations among newborn infants of mothers receiving anticonvulsive therapy with and without folate supplementation. In the retrospective portion of the study involving 24 women not receiving folate, 10 children among the 66 newborns (15% frequency) exhibited congenital malformations, including congenital heart disease, cleft lip and palate, NTDs, and skeletal abnormalities; 3 of the 10 were stillborn or

died immediately after delivery. In the prospective portion of the study, involving 22 women receiving folate, all 33 infants were born alive, and no congenital malformations occurred. The authors concluded that the "teratogenic activity of anticonvulsant drugs seems to be mediated by interference with folic acid metabolism, and such activity might be influenced by hereditary and environmental factors."[93] They recommended folic acid coadministration to epileptic women intending to become pregnant.

Berg et al.[43] (1995) demonstrated the interdependence of the phenytoin-folate interaction by showing that the addition of folic acid to phenytoin therapy improved phenytoin pharmacokinetics and produced changes in blood levels of phenytoin. In a randomized crossover study involving six women of childbearing age, they compared outcomes of two groups of women, both receiving 300 mg phenytoin daily. Both groups had essentially equivalent dietary folate intake, but the subjects in the second treatment group also received 1 mg folic acid daily. The no–folic acid group exhibited a 38% reduction in serum folate level, with a serum phenytoin concentration in the low therapeutic range. The folic acid/phenytoin group showed a 26% increase in serum folate level, with a phenytoin level similar to that in phenytoin-only subjects. Notably, only one woman achieved phenytoin steady state during phenytoin-only treatment, but four women achieved steady state during treatment with both folic acid and phenytoin (PHT). The authors concluded that their findings suggest "an interdependence between PHT and folic acid and supports the observation that fertile women treated with PHT require folic acid supplementation to maintain a normal serum folate level."[43]

Later in 1995, in their review of the literature on phenytoin-folate interactions, Lewis et al.[44] proposed that folic acid should always be prescribed with phenytoin because of a synergistic effect. Folic acid supplementation in folate-deficient patients with epilepsy can change the pharmacokinetics of phenytoin and, without appropriate clinical management, may increase risk of possible seizure breakthrough by leading to lower serum phenytoin concentrations. Folate is hypothesized to be a cofactor in phenytoin metabolism and may be able to assist in obtaining a concentration where phenytoin appears to be at steady state but actually is not. Phenytoin and folic acid therapy initiated concomitantly with monitoring and titration can prevent decreased folate and obtain steady-state phenytoin concentrations sooner. The authors concluded that folic acid supplementation should be initiated concomitantly with phenytoin therapy because of the hypothesized cofactor mechanism, decreased adverse effects associated with folate deficiency, and better seizure control with no perturbation of phenytoin pharmacokinetics.

Subsequently, in a controlled trial, Eros et al.[94] reported that both healthy and epileptic women taking less than 1 mg of folic acid daily had no increased risk of seizures. Of 60 epileptic women with periconception multivitamin supplementation with 800 µg of folic acid, none developed epilepsy-related side effects during the periconception period. One epileptic woman delivered a newborn with cleft lip and palate. However, a 22-year-old epileptic woman receiving carbamazepine, as well as taking a daily multivitamin supplement with 1.0 mg of folic acid from the twentieth week of gestation, exhibited a cluster of seizures after the periconception period. Furthermore, she developed status epilepticus and symptoms of systemic lupus erythematosus; this pregnancy ended with stillbirth. The authors concluded that an autoimmune disease (probably drug-induced lupus) had emerged in this epileptic patient and damaged the blood-brain barrier, so the 1-mg (or greater) therapeutic dose of folic acid may have triggered a cluster of seizures. Overall, they noted that administration of a physiological dose (<1 mg) of folic acid to women without autoimmune disease did not increase the risk of epileptic seizures.

Evidence is mixed as to what dosage level and form of folic acid coadministration is necessary to reverse adverse AED effects on folate metabolism yet avoid interfering with the therapeutic activity of the medications. A review of the evidence generally indicates that the levels of folic acid in typical multivitamin formulations (e.g., 400 µg/day) may be adequate for folate nutriture during pregnancy in healthy, nonmedicated women. Some sources, such as Hiilesmaa et al.,[95] suggest that "low-dose" folic acid (100-1000 µg/day) is sufficient to prevent deficiency during pregnancy in women treated with AEDs. In contrast, most authorities now report that 800 to 1000 µg/day is required for effective protection within the context of folate-depleting medications. Nulman et al.[88] advise that "seizure control should be achieved at least six months prior to conception and, if clinically possible, by the lowest effective dose of a single anticonvulsant according to the type of epilepsy." Moreover, they recommend that women undergoing AED polytherapy supplement with 5 mg of folic acid daily, for 3 months before conception and during the first trimester, to prevent malformations caused by drug-induced folic acid deficiency.[88] Thus, based on individual variability and the medication involved, folate coadministration is simply not adequate for some women, and a change in AED regimen, such as eliminating valproate, may be necessary for a safe pregnancy. Furthermore, administration of 5-methyltetrahydrofolate (5-MTHF), such as folinic acid, may be required to counterbalance the adverse effects of folate-depleting medications as well as concurrent factors such as inadequate nutritional status, smoking, alcohol intake, and genetic variability.

Gingival hyperplasia is a common adverse effect associated with some AEDs, particularly phenytoin and valproic acid. The topical application of folate is generally helpful in the treatment of gingival overgrowth, especially in pregnant women, outside the context of anticonvulsants.[96-98] Folate mouthwash appears to have an influence on gum health through local rather than systemic influence. Most research on phenytoin-induced changes in the gums indicates that daily rinses with a folate-based mouthwash may also inhibit gum disease caused by phenytoin. Notably, the level of dietary folate did not correlate with changes in hyperplasia in experimental subjects.[99-101]

The broad context of diet, lifestyle, economic status, and education frames the more narrow clinical issues of folic acid coadministration, Hcy status, and genomics. Lower economic status and educational levels are both associated with increased risk of birth defects in general and AED-induced malformations in particular. Likewise, children of women with epilepsy who smoked had lower gestational age and were at 3.4-fold increased risk of preterm delivery compared with infants of nonepileptic women who smoked.[78] However, the findings of a 2002 British questionnaire-based survey of 795 women of childbearing age with epilepsy revealed significant shortcomings in education and awareness regarding pregnancy and childbearing. Of those women surveyed who considered the questions personally relevant, 38% to 48% recalled receiving information about contraception, pre-pregnancy planning, folic acid, and teratogenicity; overall, proportions were lower among adolescent women.[102]

Researchers and public health experts predict that the policies of dietary folate fortification and associated nutrition education programs adopted during the 1990s will have a significant, but not optimal, effect in preventing folate-related

birth defects among healthy women, even those eating foods fortified with folic acid.[1,5,10,11,103] However, these folate intake recommendations, typically a 400 μg daily dose before and during pregnancy, as adopted by the U.S. FDA in 1998, and folate fortification of grains and other foods, estimated to increase actual daily intake of folic acid by approximately 78 μg, do not provide adequately for woman with compromised folate metabolism, particularly those taking folate-depleting medications.[104]

Botto et al.[105] conducted an international retrospective cohort study of NTDs in relation to folic acid recommendations and found limited effect in Europe. After examining 13 birth defects registries, they reported that "the issuing of recommendations on folic acid was followed by no detectable improvement in the trends of incidence of neural tube defects" from 1988 to 1998. They concluded that dietary recommendations alone did not seem to influence trends in NTDs up to 6 years after clinical trials confirmed the effectiveness of folic acid, and that "cases of neural tube defects preventable by folic acid continue to accumulate."[105] Perhaps even more disturbing, evidence suggests that enrichment of foods with folic acid may not be circumventing widespread deficits in nutritional awareness and a related lack of proactive behavioral changes, to serve as an effective preventive measure.[11] However, in reviewing results from the National Health and Nutrition Examination Survey (1999–2000), Pfeiffer et al.[1] concluded: "Every segment of the US population appears to benefit from folic acid fortification." Some commentators have also raised troubling yet essential questions about strong genetic selection pressure and potential adverse effects on the human genome from such public policy.[106]

More immediately, the policy of food fortification with folic acid expands the long-standing issue of folic acid supplementation with vitamin B_{12} supplementation from clinical management to unsupervised mass intervention into nutrient interrelationships. Thus, researchers might find it worthwhile to study the real potential of introducing a relative excess of folate into well-nourished populations who do not necessarily need it, while failing to enhance the nutrient intake of less well-fed populations and failing to consider B_{12} deficiencies, both relative and absolute.

Reports

A long-standing body of literature in case reports and scientific reviews documents the relatively high incidence of megaloblastic anemia and other hematological disorders among individuals undergoing long-term, and sometimes even short-term, therapy with AEDs.[107–117]

Guidolin et al.[118] reported on a 26-year-old woman being treated with carbamazepine for symptomatic partial epilepsy with simple and complex seizures. She experienced an increase in seizure frequency and severity after initiation of folic acid prophylaxis at 800 μg/day in anticipation of pregnancy.

Torres et al.[119] reported three cases of neonates with seizures who were unresponsive to one or more anticonvulsant medications but demonstrated immediate relief after administration of folinic acid.

When viewed within the context of relevant research literature, these reports reflect the broad trends and illustrate the need for further research into the individual variations in folate coadministration requirements, permutations of clinical response, and close supervision and regular monitoring during such coadministration, particularly on initiation or modification.

However, coadministration of preconception folic acid may not be protective for women with epilepsy. Craig et al.[120] described a young woman whose seizures were controlled for 4 years by of valproic acid (2000 mg/day). Even though she supplemented with 4.0 mg of folic acid daily for 18 months before her pregnancy, she delivered a child with a lumbosacral NTD, a ventricular and atrial septal defect, cleft palate, and bilateral talipes. Likewise, two Canadian women delivered children with NTDs despite folate supplementation. One taking folic acid (3.5 mg/day) for 3 months before conception and valproic acid (1250 mg) aborted a child with lumbosacral spina bifida, Arnold Chiari malformation, and hydrocephalus. Another woman who supplemented with folic acid (5.0 mg/day) experienced one spontaneous abortion of a fetus with an encephalocele and two therapeutic abortions of fetuses with lumbosacral spina bifida.[121] It would be of interest to know if these women carried MTHFR genetic polymorphisms and might have been unable to properly metabolize and activate folic acid in its usual form.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing anticonvulsants and related medications are advised to educate their patients regarding implications of drug-induced depletion of folate and other nutrients and to assess their serum B_{12} and Hcy levels. The available evidence indicates that valproic acid, as monotherapy or a component of polytherapy, carries significantly greater risk of teratogenicity than other AEDs administered during pregnancy. Coadministration of folic acid and enhancement of dietary intake of folate-rich foods are almost always appropriate to prevent a drug-induced deficiency. Nevertheless, the data remain unclear and the benefits uncertain as to whether folate coadministration in women with epilepsy taking AEDs will reduce their risk. Further research using L-5-methyl folate is needed. Coadministration of folic acid (800 μg/day) and vitamin B_{12} (6 μg/day) may be sufficient in some cases, but levels typical of multivitamins have proved inadequate for many individuals. Dose titration enables reduction of adverse effects while minimizing the risk of interfering with the therapeutic activity of the AED(s). Special attention should be given to the possibility of decreased seizure control as folic acid supplementation is initiated, as well as to possible increased AED toxicity when administration of additional folic acid is halted.

The critical importance of ongoing supervision, nutritional assessment, and lifestyle education within the context of a frank and supportive therapeutic relationship cannot be overstated in the care of patients undergoing long-term therapy with AEDs. Close supervision and regular monitoring of serum levels of the medication(s) and clinical effects, as well as monitoring of folate and Hcy levels, are essential, especially with patients receiving long-term multidrug therapy. Although folate is generally considered nontoxic, large doses of folic acid may precipitate clinical B_{12} deficiency, especially if vitamin B_{12} status was already impaired. Spontaneously or iatrogenically hypochlorhydric patients may require much more than 6 μg of B_{12} for adequate function. Urinary and serum MMA levels may be the most reliable way of assessing functional B_{12} status. Beyond the concerns of folate deficiency and Hcy-associated risk in the general population, thrombosis from hyperhomocysteinemia in epileptic patients taking anticonvulsants represents a significant risk responsive to proactive clinical management. Genetic testing for folate polymorphisms may provide an especially valuable tool in risk assessment and clinical management of Hcy status in relation to folate nutriture during treatment with AEDs. Patients with a TT allele of the

MTHFR C677T polymorphism, particularly in combination with the RFC1 80GG genotype, may have an even higher folate requirement than other patients treated with AEDs because of their significantly increased risk of elevated Hcy from compromised folate metabolism.

The dosage and number of folate-lowering drugs should be minimized and folic acid coadministration initiated in women with epilepsy who are contemplating pregnancy.

Seizure control should be achieved at least 6 months before conception and, if clinically possible, by the lowest effective dose of a single anticonvulsant individualized according to the type of epilepsy. Substitution of another agent is strongly indicated in women being treated with valproic acid, as monotherapy or a component of polytherapy. Folic acid at 5 mg/day (along with vitamins B_6 and B_{12}) should be administered starting 3 months before conception and during the first trimester to prevent folic acid deficiency–induced malformations. Strong consideration should be given to using the activated form (L-5-methyl or 5-formyl) of folate in this setting, unless genetic testing has ruled out MTHFR genetic polymorphisms. The addition of folic acid to a prenatal regimen becomes even more imperative for women using OCs while undergoing anticonvulsant therapy when they choose to become pregnant, because OCs also tend to adversely affect folate status. Some clinicians consider benzodiazepines or phenytoin to be effective for seizure cessation during labor and delivery. Administration of vitamin K immediately after birth is prudent. Furthermore, the neonate should be thoroughly assessed for epilepsy and anticonvulsant-associated dysmorphology.

Antifolates and Related Antimetabolites, Including Lometrexol, Methotrexate, Pemetrexed

Evidence: Lometrexol (T64), methotrexate (Folex, Maxtrex, Rheumatrex), pemetrexed (Alimta), raltitrexed (ZD-1694; Tomudex).

Similar properties but evidence lacking for extrapolation: Agalsidase beta (Fabrazyme), capecitabine (Xeloda), cladribine (Leustatin), cytarabine (ara-C; Cytosar-U, DepoCyt, Tarabine PFS), floxuridine (FUDR), fludarabine (Fludara), fluorouracil (5-FU, Adrucil, Efudex, Efudix, Fluoroplex), gemcitabine (Gemzar), mercaptopurine (6-mercaptopurine, 6-MP, NSC 755; Purinethol), methotrexate (Folex, Maxtrex, Rheumatrex), pentostatin (Nipent), thioguanine (6-thioguanine, 6-TG, 2-amino-6-mercaptopurine; Lanvis, Tabloid), ZD9331, Trimetrexate (Neutrexin).

See also Mercaptopurine (and Thioguanine) later, as well as Raltitrexed under Theoretical, Speculative, and Preliminary Interactions Research.

Effect and Mechanism of Action

By definition, the agents in this drug class share the central mechanism of being "antifolate" as well as several key characteristics that influence folate metabolism and affect clinical implications of depletion. However, they differ in their pharmacological characteristics and mechanisms, therapeutic applications and effects, and characteristic patient populations, all of which influence their safety profile, adverse effects, and approaches to coadministration of folic acid.

Methotrexate is the prototype antifolate, used in oncology for decades before it was introduced to rheumatology, and still used in both specialties. The cancer chemotherapeutic agent lometrexol [(6R)-5,10-dideaza-5,6,7,8-tetrahydrofolate] is a representative later generation folate antimetabolite. Used mainly in treating solid tumors, lometrexol targets the de novo purine nucleotide biosynthesis pathway and limits DNA synthesis by inhibiting glycinamide ribonucleotide formyltransferase (GARFT), the first folate-dependent enzyme in de novo purine synthesis; it is avidly polyglutamated and retained in tissues expressing folylpolyglutamate synthetase.[122-125] Lometrexol pharmacokinetics are often described by a three-compartment model and are considered independent of either lometrexol or folic acid dose. The cumulative hematological toxicity of lometrexol is related to cellular pharmacokinetics and tissue concentration and not plasma pharmacokinetics.[126]

Methotrexate is a folic acid antagonist used in the treatment of several types of cancer, rheumatoid arthritis (RA), psoriasis, and other conditions. Many of the adverse effects associated with methotrexate are similar to those of severe folate deficiency. Methotrexate produces its immunosuppressant and antineoplastic effects by binding to and reversibly inhibiting the activity of dihydrofolate reductase, which reduces folate to active tetrahydrofolate.[127] By thus restricting levels of tetrahydrofolate, methotrexate decreases the availability of single-carbon fragments required for biosynthesis of purines, DNA, and cellular proteins. Perhaps the most widely used folate antagonist, methotrexate has varying patterns of use for different conditions, and the relationship of folic acid to the drug mechanism changes accordingly. This difference is especially important in individuals using methotrexate as a chemotherapeutic agent and those taking it for RA.

As with other antifolates, pemetrexed exerts its antineoplastic activity by inhibiting multiple tetrahydrofolate cofactor-requiring enzymes involved in the de novo biosynthesis of purine, thymidine, and pyrimidine nucleotides, thus interfering with folate-dependent metabolic processes critical to cell replication. Pemetrexed also inhibits dihydrofolate reductase. Its greater potency, compared with other antifolates, is related to its transport into cells by both the reduced–folate carrier system and the membrane folate-binding protein transport system. The enzyme folylpolyglutamate synthetase then intracellularly converts pemetrexed to polyglutamate forms, which are retained in cells and act as inhibitors of thymidylate synthase (TS) and GARFT. Thus, functionally, pemetrexed acts as a prodrug for its polyglutamate forms. Polyglutamation

occurs more rapidly and extensively in tumor cells than in healthy tissues, and polyglutamated metabolites exhibit a prolonged intracellular retention in malignant cells and a 60-fold increase in inhibition of TS compared with the monoglutamated form. Pemetrexed has demonstrated significant antineoplastic activity against a variety of tumor types, including lung, breast, colon, mesothelioma, pancreatic, gastric, bladder, head and neck, and cervix. Tumors with codeletion of the methylthioadenosine phosphorylase gene, as a consequence of p16 deletions, may be particularly sensitive to pemetrexed. Attention has also focused on its ability to enhance the cytotoxicity and tolerability of doxorubicin, paclitaxel, cisplatin, gemcitabine, and other important chemotherapeutic agents.[128-132]

Raltitrexed is a quinazoline folate analog that selectively inhibits TS and thereby causes DNA fragmentation and cell death. Raltitrexed is transported into cells through a reduced folate carrier, where it is extensively polyglutamated. As with pemetrexed, polyglutamation enhances potency and extends half-life to increase the duration of TS inhibition and raltitrexed's antitumor activity.

In summary, the finding that folate intake does not seem to interfere with efficacy of these drugs, both in autoimmune disease and cancer applications, is both intriguing and clinically significant, suggesting these agents may have other mechanisms besides folate antagonism or being "antifolate."

Research

Researchers and clinicians generally agree that impaired folate status plays a major role in the activity and toxicity of methotrexate and other antifolates.[127] The degree of folate depletion during methotrexate therapy for autoimmune disease depends primarily on the weekly administered dose. The risk of adverse effects from interference with folic acid utilization is particularly significant with high dose and prolonged use. Folic acid (or 5-MTHF) coadministration can usually mitigate adverse effects of antifolates, but their ability to do so without impairing drug efficacy may vary significantly in low-dose treatment (e.g., methotrexate for RA or psoriasis) versus high-dose administration (e.g., cancer therapy). Furthermore, emerging trends suggest research may be warranted to explore the clinical potential of antifolates whose pharmacodynamic effects are less affected by variations in folate status among different patients.

The coadministration of folinic acid (Leucovorin) is well established in conventional practice as an adjunctive therapy to mitigate toxic effects of methotrexate, lometrexol, and related agents, particularly in the context of high-dose antineoplastic chemotherapy. Folinic acid (5-FTHF) is the most well-known reduced form of folic acid, available as a calcium salt for parenteral or oral administration, which competes with methotrexate for entry into cells and repletes intracellular pools of tetrahydrofolate. Overall, findings from studies conducted in the late 1980s and early 1990s were mixed as to both the effects of folinic acid coadministration in reducing methotrexate toxicity and drug-induced adverse effects and the possible impairment of methotrexate efficacy and therapy outcomes.[133-140] Nevertheless, folinic acid has been used as a rescue agent throughout the history of clinical trials and has become part of conventional practice in the clinical application of antifolates, such as after high-dose methotrexate in the treatment of osteosarcoma.[141] For many years, folinic acid has been coadministered as part of a standard therapy using 5-fluorouracil for metastatic colorectal cancer (5-FU/leukovorin), at least in part because of its ability to increase the affinity of fluorouracil for TS. More recently, with raltitrexed, intravenous folinic acid, 25 mg/m^2 every 6 hours, can reduce intestinal damage and improve recovery of neutrophil and platelet levels.[142] As a form of 5-formyltetrahydrofolate (5-FTHF), folinic acid's ability to bypass dihydrofolate reductase contributes both to its rapid action and therapeutic efficacy and its potential to reduce drug activity.

In certain circumstances, folic acid may be capable of reducing the symptoms of antifolate toxicity without interfering with clinical effectiveness. Evidence consistently demonstrates the safety and efficacy of folate coadministration with methotrexate in the treatment of RA, psoriasis, and similar autoimmune conditions. In contrast to folinic acid or 5-MTHF, folic acid still requires reduction by dihydrofolate reductase, a factor that may reduce its potency and the probability of it interfering with antifolate drug efficacy.

As the use of methotrexate for the treatment of RA has evolved, so has the understanding of the use of folic acid by individuals undergoing therapy. Although use of methotrexate for RA treatment has grown in recent years, more than 30% of patients abandon treatment because of drug-related adverse effects. Initially, researchers assumed that methotrexate's effects on folic acid were the source of its presumed benefits in cases of rheumatoid arthritis, as in chemotherapeutic uses. However, with time and further research, practice has shifted to support the coadministration of folic acid to counter the adverse effects of methotrexate in these cases for several reasons: (1) its well-proven ability to reduce toxic effects of methotrexate; (2) methotrexate causes folate deficiency, and the folate status of patients taking even low-dose methotrexate declines precipitously without adjunctive folic acid; and (3) plasma Hcy levels can increase significantly in those taking methotrexate but not folate, thereby significantly increasing risk of cardiovascular disease. These and other benefits are gained with no apparent loss of antirheumatic effect. Most researchers have found that folic acid levels were not related to parameters of disease activity and concluded that methotrexate does not exert its action in RA primarily by inhibiting dihydrofolate reductase.[143-148]

In 1993, Duhra[149] studied 78 patients with psoriasis to determine the frequency, severity, and dose relationship of GI symptoms induced by low-dose, once-weekly oral methotrexate (MTX) therapy and the response to concomitant folic acid administration. After initiation of MTX, 32% of subjects reported GI symptoms, with nausea accounting for 80%. The author reported that the "onset and severity of symptoms were related to the weekly dose of methotrexate but not to the cumulative dose or to the duration of methotrexate therapy." Folic acid, 5 mg daily, eliminated these adverse effects without impairing the therapeutic effect of the medication. Likewise, Morgan et al.[138] found that "5 mg or 50 mg/week dose of folic acid supplementation does not alter the efficacy of methotrexate treated rheumatoid arthritis patients." In a double-blind, placebo-controlled trial of 79 patients over 1 year, Morgan et al.[148] demonstrated that folic acid coadministration (5 or 27.5 mg/week) prevents deficient blood folate levels and hyperhomocysteinemia, thus providing cardiovascular disease prevention, during long-term, low-dose MTX therapy for RA. Folate nutriture declined in patients administered low-dose MTX without adjunctive folic acid. The authors observed that "low blood folate levels and increased mean corpuscular volumes were associated with substantial methotrexate toxicity, whereas daily dietary intakes of more than 900 nmol (400 micrograms) of folic acid were associated with little methotrexate toxicity." Plasma Hcy levels increased significantly and hyperhomocysteinemia occurred more often in the placebo

group than in the folic acid–supplemented groups. The authors concluded that for long-term, low-dose MTX therapy, "there are now at least three reasons to consider supplementation with folic acid (a low cost prescription): (1) to prevent MTX toxicity, (2) to prevent or treat folate deficiency, and (3) to prevent hyperhomocysteinemia."[148]

Suzuki et al.[150] retrospectively analyzed 66 RA patients to assess the incidence and risk factors for elevation of serum hepatic alanine (ALT) and aspartate (AST) aminotransferases during MTX therapy. The frequency of elevation of serum AST or ALT was four to five times greater than in patients taking other disease-modifying antirheumatic drugs (DMARDs). Subsequently, the authors prospectively evaluated the effect of adjunctive folic acid on serum ALT and RA activity in 14 patients who exhibited sustained, high serum ALT levels. The ALT levels decreased with folic acid coadministration in all patients within 3 months. Eleven patients treated with folic acid showed no change in RA symptomatology, but three exited the study because of exacerbation of their RA symptoms. These researchers advised that "careful monitoring of serum hepatic aminotransferases is necessary in patients with predisposing factors, especially those receiving more than 0.15 mg/kg of MTX weekly."[150] They cautioned that although folic acid coadministration can reverse the sustained elevation of ALT, it might also exacerbate RA in some patients.

In a prospective, randomized, double-blind, placebo-controlled study, Griffith et al.[151] (2000) tested the benefits of folate support in RA patients receiving ongoing MTX treatment (<20 mg weekly) by withdrawing folic acid (5 mg/day) from one group and substituting a placebo. The authors monitored all toxicity (including absolute changes in hematological and liver enzyme indices), recorded patient reports of changes in drug efficacy, and tracked discontinuation of MTX over 1 year. Among the 25 subjects who concluded the study early, a significantly larger proportion (17; 46%) of those receiving MTX alone discontinued the drug, versus eight (21%) in the group remaining on folic acid. The placebo/MTX group reported an increased incidence of nausea (45% vs. 7%) at 9 months, and two patients in that group discontinued because of neutropenia. Although subjects in the placebo group exhibited significantly lower disease activity on several of the variables measured, the researchers adjudged that "these were probably not of clinical significance." Overall, these findings indicate that folic acid coadministration reduced adverse effects and enabled patient tolerance and compliance without significantly interfering with MTX's therapeutic activity.[151]

Also in 2000, van den Berg et al.[152] showed that 83.5% of patients (61 of 85) treated with concomitant folic acid during low-dose MTX therapy for RA continued treatment for more than 1 year, compared with 53.1% of patients (23 of 49) not receiving folic acid support. The authors attributed this pattern of decreased patient discontinuation of MTX to folic acid's effects in reducing adverse effects from the medication.

In a 48-week, randomized, double-blind, placebo-controlled clinical trial involving 434 RA patients, van Ede et al.[153] compared the effects of MTX plus placebo, folic acid (1 mg/day), or folinic acid (2.5 mg/week) with regard to discontinuation of MTX because of adverse effects and MTX dosage, efficacy, and toxicity. The initial MTX dosage was 7.5 mg/week; dosage increases were allowed up to a maximum of 25 mg/week for insufficient responses. Folate dosages were doubled once the dosage of MTX reached 15 mg/week. These researchers reported that parameters of disease activity improved equally in all groups, although subjects in both folate groups required slightly higher dosages of MTX to obtain similar symptomatic improvement. However, only 17% of the folic acid group and 12% of the folinic acid group discontinued MTX therapy because of toxicity-related adverse effects, in contrast to 38% of the placebo group. The authors attributed these between-group differences to a decreased incidence of elevated liver enzyme levels in the folate groups. No other between-group differences were found in the incidence, severity, or duration of other adverse events, including GI and mucosal effects.

Hoekstraet al.[154] analyzed data from a 48-week, multicenter, randomized clinical trial involving 411 patients with RA treated with MTX, comparing folates and placebo to assess factors associated with toxicity, final dose, and drug efficacy. Coadministration of folates and MTX was strongly related to the lack of hepatotoxicity, as well as reduced levels of drug discontinuation and efficacy of MTX therapy. Reaching a final dose of MTX of 15 mg/week or more was related to folate supplementation and the absence of prior GI events. Other baseline characteristics predictive of MTX treatment outcome included body mass index, gender, use of nonsteroidal anti-inflammatory drugs (NSAIDs), and creatinine clearance.

Khanna et al.[155] examined the effect of folic acid on the efficacy of MTX treatment in RA patients at 12 months in two Phase III, randomized controlled trials of leflunomide in which MTX was used as a comparator. A U.S. study involved 482 patients with active RA; of these, 179 received at least one dose of MTX, and all were mandated to receive 1 mg of oral folic acid once or twice daily. A multinational European study involved 999 patients with active RA; of these, 489 received at least one dose of MTX, and oral folic acid was not required, although 50 received folate after developing an adverse event. After using propensity scores to adjust for differences in the baseline characteristics of folic acid users and non–folic acid users, the authors concluded that 9% to 21% fewer MTX-treated RA patients taking folic acid had 20%, 50%, or 70% improvement, according to American College of Rheumatology (ACR) standards, at 52 weeks compared with those who did not receive folic acid. Thus, 17% more patients in the group who did not receive folic acid met ACR improvement criteria, whereas ACR 50% responses were 14% higher in the non–folic acid group and ACR 70% responses 12% higher; such findings suggest that adjunctive folic acid may impair the efficacy of MTX in such patients. Furthermore, they reported relatively similar rates of adverse events among U.S. and European subjects, 93% and 94%, respectively, but a significantly higher occurrence of elevated liver transaminase levels among European subjects (62%), most of whom were not taking folic acid, in contrast to 29% of U.S. study patients, most of whom were taking folic acid. The authors also emphasized that physicians should consider a possible exacerbation when their RA patients taking MTX are started on folic acid, suggesting these patients may require a higher MTX dose.[155]

Kirby et al.[156] investigated folic acid–prescribing patterns among dermatologists in the United Kingdom treating psoriasis patients with MTX. Of the 153 physicians who responded to the survey, 75% reported that they coadministered folic acid, 46% considered folic acid effective in reducing drug-induced nausea, and 60% reported that such nutrient support did not impair MTX efficacy in the treatment of psoriasis.

The efficacy of and tolerance for MTX therapy varies from patient to patient. Pharmacogenomic variability represents one important factor influencing clinical response and patient compliance. For example, the ability of leukemia cells to accumulate methotrexate polyglutamate (MTXPG) is an important determinant of the antileukemic effects of MTX. Kager et al.[157]

measured in vivo MTXPG accumulation in leukemia cells from 101 children with acute lymphoblastic leukemia (ALL) to determine distinct mechanisms of subtype-specific differences in MTXPG. They determined that "B-lineage ALL with either TEL-AML1 or E2A-PBX1 gene fusion, or T-lineage ALL, accumulate significantly lower MTXPG compared with B-lineage ALL without these genetic abnormalities or compared with hyperdiploid (fewer than 50 chromosomes) ALL." They analyzed expression of 32 folate pathway genes in diagnostic leukemia cells from 197 children using oligonucleotide microarrays and found that ALL subtype-specific patterns of folate pathway gene expression were significantly related to MTXPG accumulation. Numerous studies have documented the incidence of increased intolerance to MTX and related antifolate therapies among individuals with genetic polymorphisms affecting folate metabolism.[158-164] The utility of folic acid coadministration in such individuals, once identified, may appear self-evident, but well-designed clinical trials are warranted and surely will be forthcoming.

For example, ongoing research by Sanderson and colleagues at St. Thomas' Hospital in London is focusing on new tools for predictive pharmacogenomics of antifolates, with a focus on treatment of inflammatory bowel disease. They have observed an association between genetic variation in levels of the enzyme thiopurine methyltransferase (TPMT) and inosine triphosphate pyrophosphatase (ITPase) and a significant risk of adverse responses (or lack of response) to these antifolate agents. (See later Mercaptopurine, Azathioprine, and Thioguanine [Thiopurines] section for further discussion.) Pretreatment assessment of these enzyme levels can provide a valuable tool in either avoidance of the drug or use at a lower dose to avoid adverse effects.

In a multicenter, cross-sectional study involving 226 adult patients treated with weekly MTX for more than 3 months, Dervieux et al.[165] investigated the contribution of red blood cell (RBC) MTXPGs, RBC folate polyglutamates, and a pharmacogenetic index to the clinical status of RA patients. They calculated a composite pharmacogenetic index comprising low-penetrance genetic polymorphisms in reduced folate carrier (RFC-1 G80A), AICAR transformylase (ATIC C347G), and thymidylate synthase (TSER*2/*3). Using a multivariate analysis, they found that lower RBC MTXPG levels (median, 40 nmol/L) and a lower pharmacogenetic index were associated with a higher number of joint counts, higher disease activity, and Health Assessment Questionnaire (HAQ). An RBC MTX PG level below 60 nmol/L and a low pharmacogenetic index were associated with an increased likelihood of poor therapeutic response to MTX. These authors concluded that "therapeutic drug monitoring of methotrexate treatment combining pharmacogenetic and intracellular metabolite measurements may be useful to optimize methotrexate treatment" by enabling "more sophisticated" methods for optimizing dosing, personalizing care, and minimizing adverse effects. They also suggested that "prospective studies are warranted to investigate the predictive value of these markers for MTX efficacy."[165]

Myelosuppression, neutropenia, and mucositis are among the most common and serious toxicities of pemetrexed, a newer antifolate drug developed for cancer treatment. Emerging evidence from research and clinical practice indicates that coadministration of oral folic acid or intramuscular vitamin B_{12} mitigates the toxicity profile of pemetrexed and clinical outcomes in difficult-to-treat cancers without impairing drug pharmacokinetics or compromising its antitumor effect, even over multiple treatment cycles.[131,166-169] For example, in a Phase III study involving 456 chemotherapy-naive patients with malignant pleural mesothelioma, Vogelzang et al.[170] found that the combination of pemetrexed and cisplatin improved survival time, time to progression, and response rates compared with controls treated with cisplatin alone. Notably, after 117 patients had enrolled, "folic acid and vitamin B_{12} were added to reduce toxicity, resulting in a significant reduction in toxicities in the pemetrexed/cisplatin arm ... without adversely affecting survival time." Furthermore, in a review of pemetrexed's pharmacology, Calvert[132] noted that multivariate analyses have "demonstrated that pretreatment total plasma homocysteine levels significantly predicted severe thrombocytopenia and neutropenia, with or without associated grade 3/4 diarrhea, mucositis, or infection." She concludes: "Routine vitamin B_{12} and folic acid supplementation have resulted in decreased frequency/severity of toxicities associated with pemetrexed without affecting efficacy, making this novel antifolate a safe and efficacious anticancer agent."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Tolerance, safety, and compliance issues are significant in clinical management of patients treated with methotrexate and other antifolates. Physicians prescribing or administering these medications are strongly advised to inform patients regarding the high probability of drug-induced adverse effects on folate status and the clinical implications. Pharmacogenomic assessment (e.g., MTHFR, TPMT) can play a critical role in predicting drug efficacy and tolerance, especially with regard to folate metabolism and probable requirements, and in crafting an individualized treatment strategy. In most individuals, measured folic acid coadministration may enhance treatment efficacy and outcomes by reducing toxicity and adverse effects and increasing tolerance and compliance.

In treating patients with methotrexate for rheumatoid arthritis, psoriasis, and inflammatory bowel disease, large doses of folic acid can reduce adverse effects without compromising therapeutic activity. However, close supervision and regular monitoring of plasma drug levels and folate status, as well as plasma Hcy levels, are essential to safe and effective clinical management.

Concomitant use of folic acid during maintenance-phase antifolate treatment for leukemia and other forms of cancer is more controversial and requires a more careful, individualized, and closely managed approach to clinical care. Excessive repletion of folate may interfere with the intended therapeutic action of the medication in suppressing DNA synthesis and cellular proliferation of the malignant clone.

The administration of 5-FTHF (folinic acid) or 5-MTHF may be more efficacious in patients with high Hcy levels despite folic acid, B_{12}, pyridoxine, and methyl donor supplementation; in patients with low levels of dihydrofolate reductase enzyme activity; in those taking medications or supplements that suppress dihydrofolate reductase activity; and in patients with compromised liver or bone marrow function who might not reduce folate adequately.

Bile Acid Sequestrants

Evidence: Cholestyramine (Locholest, Prevalite, Questran), colestipol (Colestid).
Extrapolated, based on similar properties: Colesevelam (Welchol).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Nutrient Depletion Probability: **2. Probable** — Evidence Base: ● **Consensus**

Coadministration Benefit Probability: **2. Probable** — Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Through their intended effect of limiting absorption and assimilation of dietary lipids, bile acid sequestrants may prevent absorption and reduce bioavailability of folic acid as well as other nutrients, such as the fat-soluble vitamins, A, D, E, and K.[57,171-174]

Through complementary mechanisms, folinic acid and cholestyramine can be used together to counter methotrexate toxicity.

Research

In 1979, Leonard et al.[175] demonstrated that cholestyramine and colestipol bound, to a great extent, vitamin B_{12}–intrinsic factor complex, folic acid, and iron citrate in vitro. Likewise, in studying the mechanisms of intestinal folate transport, Strum[176] found that cholestyramine (20 mg) adsorbs 95% of pteroylglutamate (folate) in vitro.

Using a rodent model, Hoppner and Lampi[177] observed that cholestyramine significantly reduced the intestinal deconjugation, absorption, and bioavailability of folic acid compared with brewer's yeast folate.

Several human studies have specifically documented the effects of bile acid sequestrants on folate absorption and bioavailability. In a trial involving 20 children and young adults with familial hypercholesterolemia, Farah et al.[178] investigated the effects of cholestyramine in the context of a diet low in cholesterol and high in polyunsaturated fats. Cholestyramine administration was associated with a significant decrease in mean serum folate levels in female patients. Tonstad et al.[179] conducted a study involving 37 boys and 29 girls age 10 to 16 years with familial hypercholesterolemia, first in an 8-week, double blind, placebo-controlled protocol, then in open treatment for 44 to 52 weeks. Levels of serum folate, vitamin E, and carotenoids were reduced in the colestipol group. Only a minority of adolescents adhered to the new formulation of orange-flavored "colestipol granules" for the full year. Nevertheless, the authors concluded that "folate and possibly vitamin D supplementation is recommended." Subsequently, in a randomized controlled trial involving children with familial hypercholesterolemia, Tonstad et al.[180] and another Norwegian team of investigators found that heterozygosity and homozygosity for the C677T mutation in the MTHFR gene was associated with low serum folate and increased susceptibility to elevation of plasma tHcy during cholestyramine treatment. These authors recommended folic acid coadministration as "prudent in these children" because of the independent relationship between elevated plasma tHcy and cardiovascular disease.

The ability of hypocholesterolemic resins to adsorb and reduce bioavailability of both folic acid and methotrexate (MTX) may be relevant in countering the toxicity of this potent antimetabolite, well-known for a range of adverse effects influencing tolerance and compliance. Interestingly, cholestyramine may be used to enhance the biliary excretion of MTX, which acts as an antifolate through competitive inhibition.[181] Based on multiple experiments examining the relative adsorption of MTX and calcium leucovorin (folinic acid) onto cholestyramine in vitro, Merino-Sanjuan et al.[182] suggested that "cholestyramine may be a potentially useful adjunctive therapy in the treatment of an overdose of MTX." Fernandez et al.[183] described severe MTX-induced toxicity secondary to renal failure in a patient with non-Hodgkin's lymphoma. "Corrective measures included folinic acid rescue therapy, cholestyramine resin administration, hydration and urine alkalinization, urine pH monitoring, and extracorporeal clearance techniques."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing bile acid sequestrants are advised to coadminister folic acid, vitamins B_{12} and B_6, mixed tocopherols and tocotrienols, vitamin D, coenzyme Q10, and other synergistic nutrients within a comprehensive and individualized strategy of integrative therapeutics for the prevention and treatment of cardiovascular disease. The relationship between folate status and homocysteine would be adequate by itself to justify increased intake of dietary folate and supplemental folic acid, of at least 800 µg/day, in such a patient population. The probable interference with absorption and bioavailability of folate and other relevant nutrients by these hypocholesteremic resins further heightens the imperative for enhanced nutriture. Daily administration of a high-potency multivitamin/mineral combination will replace the nutrients impeded by the drug. Folic acid (as well as other nutrients and medications) should be taken 1 hour before or 4 to 6 hours after bile acid sequestrants to reduce impairment of absorption and obtain optimal bioavailability.

Chloramphenicol

Chloramphenicol (Chloromycetin).

Interaction Type and Significance

◇≈≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**
⊕⊕⊕ **Beneficial or Supportive Interaction, Not Requiring Professional Management**
◇ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable** to **1. Certain** — Evidence Base: ● **Consensus** but ○ **Preliminary**

Effect and Mechanism of Action

Drug-induced anemia is well established as an adverse effect of chloramphenicol.[110] Aplastic anemia has resulted from chloramphenicol in a small percentage of patients. Folic acid administration may reduce adverse effects of chloramphenicol to some degree. In patients prescribed folic acid for preventive benefits or therapeutic effects, concurrent administration of chloramphenicol for an extended period (or sometimes only a short period) can interfere with the hematopoietic response to folic acid and reduce effectiveness of folic acid in the treatment of anemias.

Research

Specific research on the interaction between chloramphenicol and dietary folate or supplemental folic acid is lacking.

However, consensus as to probable effects and outcomes is based on widely recognized functions and activities of the two substances.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Physicians are advised to monitor closely all major hematological parameters in patients prescribed chloramphenicol. Known toxicity has generally led to its disuse, except when no suitable alternative is available or the mortality of the treated disease is high.

Colchicine

Interaction Type and Significance
◈≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**
⊕⊕⊕ **Beneficial or Supportive Interaction, Not Requiring Professional Management**
◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **4. Plausible** to **2. Probable**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action
Colchicine is reported to depress blood folate levels.

Research
Depression of whole-blood folate activity by colchicine was demonstrated in 1965 and has not since been the subject of direct research.[184] No clinical trials have been published on the mitigation of adverse effects through folic acid coadministration. Further research through well-designed clinical trials may be warranted.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Physicians prescribing colchicine should closely monitor both folate and Hcy levels in patients. Pending substantive research through well-designed clinical trials, coadministration of folic acid, 800 µg/day, can provide a safe and potentially effective means of compensating for drug-depletion effects and may support the clinical strategies toward reducing cardiovascular risk.

Fenofibrate, Bezafibrate, and Related Fibrates

Evidence: Bezafibrate (Bezalip), fenofibrate (Lofibra, Tricor, Triglide).
Extrapolated, based on similar properties: Ciprofibrate (Modalim), clofibrate (Atromid-S).
Related but evidence against extrapolation: Gemfibrozil (Apo-Gemfibrozil, Lopid, Novo-Gemfibrozil).

Effect and Mechanism of Action
A consistent body of evidence demonstrates that fibrates, particularly fenofibrate and bezafibrate, cause marked elevations in total plasma homocysteine (tHcy) levels. The molecular mechanisms involved have not been elucidated, but multiple mechanisms may contribute to this effect. Numerous studies show that coadministration of folic acid, especially with synergistic nutrients, can mitigate this particular adverse drug effect, but such intervention does not appear to alter clinical outcomes and thus may not constitute an "adverse clinical event."

Nutrient depletion resulting from hypolipidemic drugs, as indicated by plasma levels, appears to be lacking, a secondary factor of lesser clinical significance, or simply one that has not been adequately demonstrated within the design and time frame of the available clinical trials.[185] Impairment of renal function, alteration of creatine-creatinine metabolism, and changes in methyl transfer are regarded as more probable mechanisms.[186,187] Many of the effects of fibrates are known to be mediated by the peroxisome proliferator-activated receptor alpha (PPAR-α), a transcription factor belonging to the nuclear receptor family, and fibrates appear to increase homocystinemia through a PPAR-α–mediated mechanism.[188,189] For example, bezafibrate is a known activator of PPARs that can activate both PPAR-α and PPAR-β.

These and other findings suggest that the Hcy form elevated by fibrates may be protein-bound Hcy rather than atherogenic, reduced Hcy. Furthermore, although folic acid effectively reduces the fibrate-induced elevation of tHcy and creatinine, it does not affect the drug-induced elevation of total plasma cysteine (tCys).[190]

Research
An extensive body of scientific research has explored the effects of fibrates on Hcy levels, the role of folate in these effects, and the impact of such adverse effects and compensatory folate support within the overall strategy of cardiovascular risk reduction and outcomes. Fibrates are among the drugs of choice in conventional treatment of hypertriglyceridemia and low levels of high-density lipoprotein (HDL) cholesterol, both recognized as significant risk factors for cardiovascular disease. Increased blood levels of homocysteine, an amino acid derived from the methionine cycle, are generally associated with increased risk of endothelial damage, atherosclerosis, and coronary, cerebral, or peripheral vascular disease, although it is uncertain whether such elevations in Hcy represent a cause or a consequence of the pathological process. Some fibrates, particularly fenofibrate and bezafibrate, raise tHcy levels by 20% to 40%, but evidence from human research is still lacking to demonstrate that agents in this drug class induce depletion of folic acid or other nutrients known to modulate Hcy. Notably, multiple studies have found that gemfibrozil does not increase Hcy. Thus the overall trend in the literature shows that fibrate administration, particularly fenofibrate and bezafibrate, causes often-dramatic elevations in Hcy levels and that folic acid coadministration can neutralize this adverse effect, but suggests cardiovascular outcomes are unaffected by fibrate-induced hyperhomocysteinemia.

Significant evidence demonstrates that fenofibrate, bezafibrate, and potentially other frequently prescribed fibrates

greatly increase plasma Hcy levels, and that coadministration of folate and synergistic nutrients can reduce this effect, even though fibric acid derivatives apparently do not reduce blood concentrations of these key nutrients. De Lorgeril et al.[191] reported a 46% increase in plasma Hcy in patients treated with fenofibrate for 12 weeks. Later in 1999, Dierkes et al.[192] reported that fenofibrate (200 mg) and bezafibrate (400 mg) significantly reduced triglycerides but also increased plasma Hcy by 44% and 17.5%, respectively, in 20 male patients (age 39-56) with hypertriglyceridemia but normal renal and thyroid function after 6 weeks of therapy. In discussing the underlying mechanisms, the authors noted that "the vitamin status does not appear to be involved in the first line, because folate, cobalamin, and vitamin B_6 (in the bezafibrate group) remained unaltered." In contrast, they emphasized that "creatinine and cystatin C increased, suggesting an alteration of renal function." The tHcy concentrations increase as renal function deteriorates, and fibrates increase serum creatinine moderately and reversibly.

In 2001, Dierkes et al.[193] conducted a randomized, double-blind crossover study involving hyperlipidemic men for 6 weeks to investigate the ability of nutrient coadministration to mitigate the Hcy elevation induced by fenofibrate. Subjects administered fenofibrate plus folic acid (650 μg), vitamin B_6 (5 mg), and vitamin B_{12} (50 μg) demonstrated an increase in Hcy concentration of 13% ± 25%, whereas those given fenofibrate plus placebo exhibited an increase of 44% ± 47%. The authors advised that "fenofibrate may counteract the cardioprotective effect of lipid lowering" and that nutrient coadministration "may therefore be warranted for routine use." Folic acid supplementation in patients treated with fenofibrate significantly reduced the increase in plasma Hcy levels.

In 2003, in a randomized, open-label study of 22 patients with mixed hyperlipidemia, Melenovsky et al.[190] compared the effect of micronized fenofibrate (200 mg daily) alone versus fenofibrate plus folic acid (10 mg every other day) on plasma Hcy levels over a 9-week treatment period. Overall, plasma Hcy levels increased by 6.85 μmol/L in subjects treated with fenofibrate only, but increased by 2.01 μmol/L in the group treated with both fenofibrate and folic acid, a statistically significant difference.

Although they arrived at similar conclusions, none of these studies were designed to determine whether amelioration of this adverse effect increases the clinical benefit of fibrates.[190-193]

Bissonnette et al.[185] investigated tHcy levels as a post hoc analysis after testing the effect of micronized fenofibrate on postprandial lipemia in the fasted and fed states. The randomized, placebo-controlled, double-blind study involved 20 men with established coronary artery disease (CAD), or at least two cardiovascular risk factors, who had elevated plasma triglyceride levels and reduced HDL cholesterol levels, and in whom a fibrate was clinically indicated. As expected, fenofibrate caused a marked reduction in all triglyceride-rich lipoprotein parameters, but administration was also associated with an increase in fasting tHcy and fed tHcy levels, 6 hours after the fat load. The fenofibrate-induced changes in tHcy level were not associated with changes in plasma levels of folate, vitamins B_6 or B_{12}, or creatinine, but methionine and cysteine were significantly increased.

Thus, several research teams have concluded that the effects of fibrates, particularly fenofibrate, in elevating plasma tHcy levels could compromise their putative cardioprotective properties, and that concomitant support with folate and related nutrients may contribute to the overall clinical strategy.

Among conventional hypolipidemic agents, statin drugs have exhibited a significant lack of adverse effects on folate relative to fibrates. In response to concern that elevated tHcy could compromise the cardiovascular benefit from lipid lowering by fibrates, Mayer et al.[193a] conducted an open, randomized, prospective crossover study to investigate the effects of fenofibrate. The 24 volunteers had total cholesterol of 6 mmol/L or higher and triglycerides less than 5 mmol/L, with normal blood pressure, normal blood glucose, and without any pharmacotherapy or clinical vascular or metabolic disease. In successive 6-month phases, the researchers measured lipids, tHcy, folate, vitamin B_{12}, and renal function markers after diet, after 200 mg of fenofibrate (3 months in monotherapy followed by 3 months in combination with 10-mg folate), and then after fluvastatin (3 months of 40 mg followed by 3 months of 80 mg). They found that fenofibrate monotherapy increased tHcy from 10.0 to 14.2 μmol/L while coadministration of folate decreased tHcy to 10.6 μmol/L. Fuvastatin, however, did not significantly influence the tHcy concentrations. In a trial involving 128 patients with primary hyperlipidemia, Milionis et al.[194] compared the effects of atorvastatin, simvastatin, and fenofibrate on serum Hcy levels. Although neither statins nor fenofibrate had any effect on serum vitamin B_{12} and folic acid levels, Hcy levels were significantly increased only by fenofibrate and did not change from baseline after statin treatment.

Emerging research into the molecular mechanisms underlying the differential effects of fibrates on Hcy subfractions may help to understand their tendency to increase tHcy, establish the relative benefits of their hypolipidemic effects, and elucidate the strategic implications of such factors in preventing cardiovascular disease. Plasma tHcy comprises both reduced, free oxidized Hcy and protein-bound Hcy; the reduced Hcy is thought to be the atherogenic, but minor, subfraction. In a set of animal experiments, Luc et al.[189] demonstrated that activation of PPAR-α mediates the effect of fenofibrate on gene expression and modulates the effect of fenofibrate on Hcy levels. In particular, the usual fenofibrate-induced increase in Hcy levels was completely abolished in PPAR-α–deficient mice. Likewise, Legendre et al.[188] applied a rodent model in investigating the effects of fibrates known to be mediated by the nuclear receptor PPAR-α. Using PPAR-α–deficient mice, they found that fenofibrate increases serum tHcy by inducing a selective increase of the protein-bound fraction. Furthermore, in comparing the effects of fenofibrate versus fenofibrate plus folate in rats, they observed that fenofibrate increased serum tHcy by 69%, whereas the coadministration of folate with fenofibrate increased tHcy by only 7%. Nevertheless, as with the mice, only the protein-bound fraction of Hcy was increased in the rats administered fenofibrate; the atherogenic, reduced Hcy was unaffected.

Thus, both studies concluded that fenofibrate and other fibrates increase homocystinemia in a PPAR-α–dependent manner, and that such findings constitute a valid animal model for analyzing the molecular mechanisms of fibrate-induced elevations in dyslipidemic patients.[188,189] Findings from animal studies can be taken only as provisional, but they suggest a more complete and clinically effective knowledge of cardiovascular risk factors requires that research fully account for the specific variables within each physiological parameter (e.g., forms of Hcy or cholesterol), the interplay among multiple risk factors, and the influences of individual genomic variability on susceptibility and therapeutic response.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing fibrates, particularly fenofibrate and bezafibrate, are advised to coadminister folic acid, vitamin B_{12}, vitamin B_6, and riboflavin based on their synergistic role in the comprehensive strategy of preventing and treating cardiovascular disease. Even though evidence indicates that these hypolipidemic agents do not deplete these nutrients, coadministration is prudent based on their beneficial effect in lowering Hcy levels and otherwise countering the disease process. Such modulation of hyperhomocysteinemia is generally a clinically appropriate tactic, even if, as suggested by the animal research just discussed, fibrate-induced Hcy elevation is of the nonatherogenic form. Thus, regular monitoring of tHcy levels is essential in patients taking fibrates, with special attention to subfractions. Evidence indicates that such nutrient administration carries a high safety profile and does not interfere with the therapeutic activity of the medication.

Multiple interventions, coordinated and evolving within an integrative strategy, can often provide the most effective means of preventing and treating the pathophysiological processes of endothelial damage, atherosclerosis, and coronary, cerebral, or peripheral vascular disease. Within the standards of conventional practice, gemfibrozil or statins represent the other primary options for addressing hypertriglyceridemia or dyslipidemia, respectively. Concomitant use of L-carnitine, coenzyme Q10, magnesium, fish oils (omega-3 fatty acids), mixed tocopherols and tocotrienols, and vitamin D may also be appropriate, according to the characteristics and needs of the individual patient, any comorbid conditions, and medications. The research regarding fibrates and their effects on folate and Hcy illustrates the need for further studies and evolution of clinical practice in assessing cardiovascular risk. Refined laboratory evaluation of complex and interdependent biomarkers should not only include C-reactive protein and Hcy, but also further develop the implications of variations, such as free versus bound Hcy.

Fluoxetine and Related Selective Serotonin Reuptake Inhibitor and Serotonin-Norepinephrine Reuptake Inhibitor (SSRI and SSRI/SNRI) Antidepressants

Evidence: Fluoxetine (Prozac, Sarafem).
Extrapolated, based on similar properties: Citalopram (Celexa), duloxetine (Cymbalta), escitalopram (S-citalopram; Lexapro), fluvoxamine (Faurin, Luvox), paroxetine (Aropax, Deroxat, Paxil, Seroxat), sertraline (Zoloft), venlafaxine (Effexor).

Effect and Mechanism of Action

Affective disorders such as depression are caused, at least in part and in certain individuals, by a deficiency of serotonin (5-hydroxytryptamine, 5-HT), noradrenaline (norepinephrine), dopamine, or a combination of these key monoamines. Folate and vitamin B_{12} are major determinants of one-carbon metabolism, in which *S*-adenosylmethionine (SAMe), a key methyl donor in numerous methylation reactions, is synthesized from methionine. Folate plays a pivotal role in the synthesis of tetrahydrobiopterin, which is the cofactor for the hydroxylation of phenylalanine and tryptophan and is the rate-limiting step in the synthesis of these and related neurotransmitters. Thus, coadministration of folic acid (or enhancement of dietary intake of folates) in conjunction with fluoxetine or other conventional antidepressants may produce an additive or synergistic effect, particularly on serotonin.

Research

Folate deficiency, impaired methylation, and hyperhomocysteinemia have been associated with depression and related mood disorders in many studies. In individuals with certain genomic characteristics, folate deficiency may play an even greater role in impaired metabolism of serotonin, SAMe, dopamine, and noradrenaline. Poor therapeutic response to antidepressants may be related to depressed folate status. Both gender and certain polymorphisms (e.g., MTHFR C677T polymorphism) influence folate and homocysteine (Hcy) metabolism and their relationship to depression and response to antidepressants.[195] In a systematic review and meta-analysis of randomized controlled trials involving treatment of depression with folic acid, Taylor et al.[196] concluded that "limited available evidence suggests folate may have a potential role as a supplement to other treatment for depression," but that it is "currently unclear if this is the case both for people with normal folate levels, and for those with folate deficiency." Folic acid administration can be beneficial in many individuals, and coadministration has enhanced efficacy of antidepressants in certain cases. Enhanced folate nutriture may also help reduce the cardiovascular risk factors associated with the hyperhomocysteinemia prevalent in one third or more of individuals diagnosed with depression.

Decreased serum/RBC folate and serum vitamin B_{12} and an increase in plasma Hcy have been associated with greater susceptibility to depression and poorer response to antidepressant treatment. According to a review by Coppen and Bolander-Gouaille,[197] Hong Kong and Taiwan populations with traditional Chinese diets (rich in folate), including patients with major depression, have high serum folate concentrations. However, these countries have very low lifetime rates of major depression. In a large population-based study, Norwegian researchers observed an association between depression and hyperhomocysteinemia and the 677CT polymorphism in the MTHFR gene. For the TT MTHFR genotype, the odds ratio for depression was 1.69 compared with the CC genotype. Folate and vitamin B_{12} were not associated with anxiety disorder or depression in general, but the risk of depression was tripled in middle-aged women with serum folate less than 5 nmol/L.[198] Likewise, in geriatric populations, both depression and dementia have been associated with lower folate levels.[199,200]

In a study on the effects of folic acid fortification of flour in the United States since 1998, Ramos et al.[201] report that plasma folate concentrations are associated with depressive symptoms in elderly Latina women despite dietary folic acid fortification. Notably, using radioassay to determine plasma folate concentrations, these researchers reported that the prevalence of folate deficiency (plasma folate ≤6.8 nmol/L) in the cohort of elderly Latinos (age 60 or older) in the Sacramento, California, area as less than 1%, significantly lower than almost every other estimate of folate deficiency in the general population, let alone the elderly. The possible inconsistencies in these findings indicate the need for continued research into both the adequacy of standard methods of testing for folate deficiency and the effectiveness of folic acid fortification of foods. Overall the assembled data and clinical prudence suggest the need for folic acid supplementation at a significantly higher dosage level than typically attainable through such policies and methods.

A series of clinical trials have consistently found that patients with low folate status are more susceptible to depression, slower to respond to antidepressant medications, and more refractory to fluoxetine treatment. In an experiment involving 213 depressed adults treated with fluoxetine, 20 mg/day, Mischoulon et al.[202] found that "neither macrocytosis nor anemia predicted low serum folate/B_{12}, or antidepressant refractoriness." Fava et al.[203] investigated folate, vitamin B_{12}, and homocysteine status in 213 outpatients with major depressive disorder taking 20 mg/day of fluoxetine for 8 weeks. Subjects with low serum folate levels were more likely to be diagnosed with melancholic depression and were significantly more likely not to respond to fluoxetine. Also, Hcy and B_{12} levels were not associated with depressive subtype or treatment response. Similarly, in a double-blind trial involving 55 patients with major depressive disorder, Papakostas et al.[198] found that low serum folate levels, but not elevated Hcy or low vitamin B_{12} levels, were associated with poorer response to fluoxetine treatment. In a related study, these researchers measured serum folate, vitamin B_{12}, and Hcy at baseline and followed 71 outpatients with remitted major depressive disorder for 28 weeks of continued treatment with fluoxetine (40 mg/day) to monitor for depressive relapse. The presence of low serum folate levels, but not low B_{12} or elevated Hcy level, was associated with relapse during continued treatment with fluoxetine.[204] In a third study involving 110 outpatients with major depressive disorder (MDD) who responded to an 8-week trial of fluoxetine, Papakostas et al.[205] observed that subjects with low folate levels (≤2.5 ng/mL) were more likely to experience a later onset of clinical improvement by an average 1½ weeks than eufolatemic patients. They noted a lack of association between B_{12} and Hcy levels and time to clinical improvement.

Coadministration of folic acid appears to enhance the antidepressant action of fluoxetine. In a randomized, placebo-controlled trial involving 127 patients diagnosed with major depression, Coppen and Bailey[206] demonstrated enhancement of the antidepressant action of fluoxetine (20 mg/day) by concomitant folic acid (500 µg/day). Subjects administered folic acid showed a significant increase in plasma folate. However, among the fluoxetine plus folate group, increases in plasma folate levels, decreases in Hcy levels, and improvements in depression scores were all significantly stronger in women than in men. Reports of adverse effects were significantly higher in the fluoxetine plus placebo group than in those given folic acid. These authors concluded: "Folic acid is a simple method of greatly improving the antidepressant action of fluoxetine and probably other antidepressants." They recommend a folic acid dosage sufficient to decrease plasma Hcy and note the higher dose requirements for folic acid in men to obtain a therapeutic response; as to the exact dose, they suggest that further research is required "to ascertain the optimum dose of folic acid."[206]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians treating individuals susceptible to or diagnosed with depressive disorders are advised to discuss the potential benefits of folic acid supplementation and enhancing dietary folate intake. In patients for whom prescribing an antidepressant such as fluoxetine is appropriate, concomitant folic aid (800 µg/day), preferably with vitamin B_{12} (1 mg daily), can often enhance the action of the medication with no attendant risk. Assessment of folate, B_{12}, and Hcy status is warranted and may be clinically useful, as might testing for MTHFR polymorphisms, because those with low activity of MTHFR may be more responsive to L-5-methyl folate than to folic acid.

Isoniazid, Rifampin, and Related Antitubercular Agents

Evidence: Isoniazid (isonicotinic acid hydrazide; INH, Laniazid, Nydrazid), pyrazinamide (PZA; Tebrazid), rifampicin (Rifadin, Rifadin IV); combination drugs: isoniazid and rifampicin (Rifamate, Rimactane); isoniazid, pyrazinamide, and rifampicin (Rifater).
Similar properties but evidence lacking for extrapolation: Cycloserine (Seromycin), ethambutol (Myambutol), ethionamide (2-ethylthioisonicotinamide; Ethide, Ethiocid, Ethomid, Etomide, Mycotuf, Myobid, Trecator SC).

Effect and Mechanism of Action

Isoniazid is generally considered the most potent antitubercular medication and is always used in conjunction with other drugs to prevent development of resistance. These drugs appear to adversely affect the action of folate and potentially induce depletion. However, the incomplete evidence thus far available suggests that such effects may be indirect, through the metabolic interrelationships among various vitamins, rather than direct effects on folate itself.

Isoniazid, the hydrazide derivative of isonicotinic acid, interferes with the synthesis of lipids, nucleic acids, and the mycolic acid of the cell walls of pathogenic mycobacteria such as *Mycobacterium tuberculosis*. Although its precise mode of action is not known, many of the adverse effects associated with isoniazid, such as peripheral neuropathy, result from its activity as a synthetic analog of pyridoxine and the subsequently induced relative pyridoxine deficiency. This interference of isoniazid with vitamin B_6 appears to be the primary mechanism for its well-known interference with the synthesis of vitamin B_{12}; both effects will interfere with the synthesis and activity of folate.[171] In individuals being treated with phenytoin, isoniazid may also adversely affect folate by decreasing the excretion of the anticonvulsant or enhancing its activity. Notably, isoniazid can induce seizures in susceptible individuals.

Rifampin blocks RNA synthesis by binding to the beta subunit of the bacterial DNA-dependent RNA polymerase.

Research and Reports

Drug-drug interactions involving isoniazid and rifampin are widely known, but systematic research into interactions between these agents and nutrients, specifically folate, is lacking. Numerous studies and case reports, primarily from the 1960s and 1970s, suggest that isoniazid and rifampin can interfere with the synthesis or activity of folate and have the potential to induce depletion.[207-216] Many secondary sources present such drug-induced adverse effects as though they were well documented. Such assertions are plausible, and the general consensus appears to approach the likelihood of a clinically significant interaction as "probable." Low serum folate levels have been reported in patients undergoing isoniazid therapy. Nevertheless, evidence from large, well-designed clinical trials

is lacking to support these attributions, and the reports available primarily describe the adverse effects of these agents in the context of multiple interdependent nutrients, particularly vitamins B_3, B_6, and B_{12}, rather than folate or folic acid per se. Furthermore, a renewal of research would be necessary to determine the frequency, severity, and circumstances of clinically significant adverse reactions due to drug-induced effects upon folate, and thus refine the general occurrence or peculiar conditions needed to substantiate a conclusive interactions assessment.

In a randomized, placebo-controlled trial involving children age 1 to 35 months living in Zanzibar, Sazawal et al.[18] found that "supplementation with iron and folic acid in preschool children in a population with high rates of malaria can result in an increased risk of severe illness and death." Routine prophylactic folate supplementation in such situations should be avoided pending further research. However, within the context of an active program "to detect and treat malaria and other infections, iron-deficient and anaemic children can benefit from supplementation."

The effect of isoniazid or rifampin, alone or in combination with other antituberculosis drugs, on the human fetus is not known. Safety for use during pregnancy has not been established. No isoniazid-related congenital anomalies have been found in reproduction studies in mammalian species (mice, rats, and rabbits). However, offspring of rodents given oral doses of 150 to 250 mg/kg/day of rifampin during pregnancy have exhibited an increase in congenital malformations, primarily spina bifida and cleft palate.

Note: Therapeutic levels of rifampin interfere with standard laboratory assays for serum folate and vitamin B_{12}.[217] Alternative testing methods, such as the neutrophilic hypersegmentation index (NHI), need to be considered when assessing folate and vitamin B_{12} concentrations in individuals being treated with rifampin, although if abnormal, the NHI cannot distinguish between a B_{12} deficiency and a folate deficiency. It can be used, however, as an indication to administer both nutrients, which regardless is sound practice.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing antitubercular drugs as monotherapy or in combination should be aware of potential adverse effects on folate status caused by these medications, directly or more likely indirectly. In particular, long-term administration of isoniazid may lead to pyridoxine deficiency and may prevent isoniazid-induced niacin deficiency. Some physicians may choose to monitor folate, B_3, B_6, and B_{12} status and coadminister a multivitamin only if deficiency is observed. Given the high safety profile, low cost, and minimal potential for significant adverse effects, prudence suggests that prophylactic supplementation may be judicious. Many experienced practitioners of nutritional therapeutics prescribe nutrients in higher dosage levels to patients undergoing isoniazid or rifampin therapy, for example, folic acid (800 µg/day) and vitamin B_6 (50-100 mg/day). Nevertheless, prophylactic folic acid (and iron) may be contraindicated for children in malarial environments.

These potent antitubercular agents should be prescribed during pregnancy only when therapeutically absolutely necessary. Likewise, given the high degree of uncertainty and the severity of teratogenic potential, their use in women capable of bearing children should be carefully weighed against the benefits of therapy. Coadministration of folic acid (800 µg/day) is appropriate in the event that administration of antitubercular drugs is required.

Levodopa and Related Antiparkinsonian Agents

Carbidopa (Lodosyn), levodopa (L-dopa; Dopar, Larodopa); combination drugs: levodopa and benserazide (co-beneldopa; Madopar); levodopa and carbidopa (Atamet, Parcopa, Sinemet, Sinemet CR); levodopa, carbidopa, and entacapone (Stalevo).

Effect and Mechanism of Action

Homocysteine (Hcy) is often elevated in individuals with Parkinson's disease, and levodopa can aggravate this pathological tendency. Metabolism of levodopa requires vitamin B_6 and can induce B_6 depletion if available supplies are inadequate. Coadministration of dopa decarboxylase inhibitors such as carbidopa limits peripheral degradation of levodopa and prevents vitamin B_6 depletion, but also increases conversion of levodopa to 3-*O*-methyldopa (3-OMD) by catechol-*O*-methyltransferase (COMT), the key enzyme in the metabolism of Hcy. COMT requires magnesium (Mg^{++}) and *S*-adenosylmethionine (SAMe), which is synthesized from adenosine triphosphate (ATP) and methionine, as a methyl donor and yields *S*-adenosylhomocysteine (SAH), which is converted to total homocysteine (tHcy). Plasma tHcy depends on folic acid and vitamins B_2, B_6, and B_{12}, which work together to support remethylation from tHcy to methionine.[218] However, methylation of levodopa (and dopamine) by COMT interferes with this process by consuming methyl groups in the transmethylation reaction, thereby causing significant increases of SAH concentrations in tissues, which is rapidly converted to Hcy, as well as significant decreases of SAMe.

Folate intake, in conjunction with vitamin B_6, may contribute to the prevention or treatment of Parkinson's disease and other forms of dementia, or folate and B_6 may work with antiparkinsonian medications by enhancing their therapeutic effects or reducing their adverse effects.

Research

The high occurrence of elevated Hcy levels in parkinsonian patients has attracted the attention of clinicians and researchers since the 1990s.[219,220] In addition to being a major risk factor for atherothrombotic disease, hyperhomocysteinemia is also strongly associated with an increased risk of dementia and cognitive impairment, both of which are common in the course of Parkinson's disease. Growing evidence indicates that Hcy may damage DNA in the substantia nigra, the area of the brain affected in Parkinson's disease. Kuhn et al.[219] observed significantly elevated plasma Hcy levels in subjects with Parkinson's disease and speculated that Hcy may be an independent risk factor for vascular disease in Parkinson's disease. However, they cautioned that this pattern of "elevated levels of homocysteine may be either caused by an unknown endogenous metabolic disturbance or by antiparkinsonian treatment, because no association to severity or duration of disease was found."

Emerging but mixed evidence indicates that the effect of L-dopa on plasma Hcy is accentuated under conditions of impaired Hcy metabolism and may be influenced by B-vitamin status, including folate deficiency. Animal studies have indicated that levodopa-induced hyperhomocysteinemia is a consequence of significant *O*-methylation and that the COMT inhibitors can prevent such elevation of Hcy concentrations by reducing the *O*-methylation of levodopa.[221,222] Using a rat model, Daly et al.[223] demonstrated that plasma Hcy concentration was significantly higher in male rats 1 hour after intraperitoneal injection with 100 mg L-dopa/kg, and this increase was greater in the folate-deficient rats than in the replete controls. In a second experiment involving nondeficient female rats, such drug-induced elevations of Hcy persisted with daily L-dopa injections over 17 days, although less so than in animals treated with L-dopa for only 1 day. In a 1999 letter, Muller et al.[224] reported increased Hcy levels in parkinsonian patients undergoing long-term L-dopa therapy compared with previously untreated parkinsonian patients and controls. The authors expressed concern that L-dopa was promoting atherosclerosis and vascular disease. Other letters from clinicians, such as Yasui et al.,[225] have also reported levodopa-induced hyperhomocysteinemia in patients with Parkinson's disease. Muller et al.[226] reported a decrease in methionine and SAMe levels and increased Hcy in a study involving 20 Parkinson's patients treated with levodopa and dopa decarboxylase inhibitors and corresponding controls. These same researchers investigated *O*-methylation in treated parkinsonian subjects and found that Hcy was significantly elevated in the group with higher 3-OMD concentrations and positively correlated to 3-OMD.[227]

Rogers et al.[228] investigated the influence of L-dopa on elevated plasma Hcy levels and CAD in a study involving 235 patients with Parkinson's disease, 201 of whom had been treated with levodopa, with the remaining 34 levodopa naive. Mean plasma Hcy levels were significantly higher in patients treated with levodopa, and patients with Hcy levels in the higher quartile had increased prevalence of CAD compared with levodopa-naive patients. However, the authors observed no difference in the plasma concentration of folate, cobalamin, or MMA between the two groups and concluded that folate or vitamin B_{12} deficiency does not explain the elevated Hcy levels. In contrast, a study involving 40 subjects diagnosed with idiopathic Parkinson's disease, 20 of whom were taking levodopa and the other 20 levodopa naive, Miller et al.[229] observed that mean plasma Hcy concentration was higher in the treatment group than in the controls and correlated with plasma folate, vitamin B_{12}, and pyridoxal-5'-phosphate (B_6) concentrations in the treatment group, but not in the controls. They concluded that the extent to which L-dopa caused hyperhomocysteinemia in Parkinson's patients is influenced by B-vitamin status, and that increased B-vitamin intake is necessary to maintain normal plasma Hcy concentrations in patients treated with L-dopa. In a review, Lokk[229a] (2003) concluded that levodopa therapy can affect latent folic acid and vitamin B_{12} deficiency and further contribute to risk of elevated Hcy levels in patients with Parkinson's disease.

These findings indicate that levodopa-induced hyperhomocysteinemia, of varying degree, can be caused by competition at the site of methylation, rather than by a deficiency of folate or other B vitamins, but that coexisting risk factors for elevated Hcy (e.g., smoking) or compromised nutrient status can contribute to an additive effect.

Clinical outcomes with Parkinson's disease, hyperhomocysteinemia, and nutrient status vary among individuals, and the mixed research findings suggest the need for research into the influences of such underlying genetic variation. Yasui et al.[230] measured plasma Hcy and cysteine levels in 90 Parkinson's patients with the MTHFR C677T (TT) genotype. The authors not only found that Hcy levels were elevated by 60% in levodopa-treated Parkinson's patients, but also observed that TT-genotype patients exhibited the most marked Hcy elevation, and their Hcy and folate levels were inversely correlated. Subsequently, Woitalla et al.[218] compared plasma folic acid, B_6, B_{12}, and tHcys levels in 83 levodopa-treated Parkinson's patients and 44 controls. Patients with the CT (heterozygous) or TT (homozygous) genotype had significantly higher tHcy levels than controls or Parkinson's patients with the CC (wild-type) allele. Furthermore, although concentrations of B_6 or B_{12} did not differ, folic acid was significantly higher in parkinsonian patients with the CT mutation.

Levodopa-induced hyperhomocysteinemia can aggravate the neurodegenerative processes contributing to dementia, depression, vascular disease, and Parkinson's disease. O'Suilleabhain et al.[231] conducted neuropsychometric tasks and tested plasma Hcy levels in 97 patients with a mean Parkinson's duration of 3.6 years to determine if hyperhomocysteinemia in Parkinson's patients is associated with depression or with cognitive or physical impairments. Subjects with elevated Hcy level were slightly older (68 vs. 62 years), were more depressed, had worse cognition, and performed worse on neuropsychometric tasks than normohomocysteinemic patients. Notably, those with hyperhomocysteinemia had similar plasma concentrations of vitamin B_{12} and folate. In a study involving 31 levodopa-treated patients with Parkinson's disease and 27 control subjects, Muller et al.[232] investigated peripheral neuronal dysfunction, specifically sural nerve axonal neurodegeneration, in patients treated with antiparkinsonian drugs using electrophysiological sural nerve conduction assessment. Sensory nerve action potentials significantly differed between Parkinson's patients and controls, but sensory nerve conduction velocity results showed no significant differences. Daily levodopa/dopa decarboxylase inhibitor intake was significantly related to tHcy levels, with significant associations between tHcy levels and sensory nerve action potentials. The authors suggested that sensory nerve action potentials might serve as a surrogate marker for the levodopa metabolism–induced elevation of Hcy levels.

Use of other pharmacological therapies for Parkinson's disease, such as COMT inhibitors (COMT-I) or dopamine agonists, may provide an effective alternative to levodopa-induced Hcy elevation and attendant risks, including decreased folate levels. O'Suilleabhain et al.[233] prospectively measured the effects of levodopa initiation on plasma tHcy and B-vitamin status, as well as the effects of levodopa dose changes and treatment with dopamine agonists and entacapone. They compared vitamin B_{12}, folate, and tHcy concentrations, at baseline and after several months of treatment, in 30 patients initiating levodopa, 15 whose L-dopa dose was doubled, 14 whose L-dopa dose was halved or stopped, 15 starting or stopping entacapone, and 16 patients initiating or doubling dopamine agonist monotherapy. The tHcy concentration increased from 8.7 to 10.1 μmol/L, and average vitamin B_{12} concentration decreased from 380 to 291 pmol/L an average of 94 days after initiation of 604 (240-1050) mg/day of L-dopa. Furthermore, although subjects who doubled their daily L-dopa dose exhibited tHcy elevations from 9.5 to 11.1 μmol/L, no significant effects were observed with L-dopa reduction, agonist treatment, and entacapone treatment. Thus, these authors concluded that initiation of L-dopa "elevates tHcy and lowers

vitamin B_{12} concentration to modest degrees,"[233] but that clinical implications, if any, were uncertain.

An Italian research team has been conducting ongoing research into the effects of various antiparkinsonian drugs on Hcy. In 2005, Lamberti et al.[234] compared plasma levels of Hcy, B_{12}, and folate in 26 Parkinson's patients treated with levodopa, 20 treated with levodopa plus a COMT-I, and 32 controls. Plasma Hcy was increased significantly in the two Parkinson's groups and significantly lower in the group treated with levodopa plus COMT-I. Folate concentrations were significantly lower in the levodopa-treated group, but statistical analysis indicated that the difference in mean Hcy levels observed among Parkinson's patients was associated with COMT-I coadministration rather than folate concentrations. No significant differences were observed in vitamin B_{12} levels. In a parallel study, Zoccolella et al.[220] compared Hcy, B_{12}, and folate levels in 45 Parkinson's patients (15 in each of three groups receiving dopamine agonists, L-dopa, or L-dopa plus a COMT-I) and in 15 controls. They determined that "L-dopa administration significantly increases Hcy concentrations and that the addition of COMT-I effectively reduces the homocysteinemia." Also in 2005, Valkovic et al.[235] found that mean plasma Hcy concentration was higher in 19 Parkinson's patients receiving levodopa monotherapy than in subjects receiving a combination of levodopa and the COMT-I entacapone or in a control group of 17 subjects receiving dopamine agonists.

Even though the relationship between folate (and vitamin B_{12}) and Hcy and the effects of levodopa on Hcy are well established, evidence from human trials specifically investigating the potential benefits of nutrient coadministration are limited. Chen et al.[236] prospectively investigated intake of folate, vitamin B_6, or vitamin B_{12} in 248 men and 167 women with documented Parkinson's disease diagnoses to determine whether higher nutrient intake was related to a lower risk of disease. Folate intake was not associated with the risk of Parkinson's disease, nor was intake of vitamins B_6 or B_{12}. The authors concluded that their data "does not support the hypothesis that higher intake of folate or related B vitamins lowers the risk of Parkinson's disease." However, in an Italian study related to those previously cited, Lamberti et al.[237] compared plasma Hcy, folate, and cobalamin levels in 20 Parkinson's patients treated with L-dopa at baseline and after 5 weeks of treatment with cobalamin and folate with levels in 35 controls. Hcy levels were higher in Parkinson's patients treated with L-dopa compared with age and gender–matched controls, and coadministration of cobalamin and folate was effective in reducing Hcy concentrations.

Further research involving well-designed clinical trials, especially long-term prospective cohort studies, is warranted to establish further the efficacy of folate (and B_{12}) administration in patients undergoing levodopa therapy, alone in or in combination with other antiparkinsonian drugs, as a countermeasure against drug-induced hyperhomocysteinemia, and to formulate therapeutic strategies for safe and effective coadministration.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians treating individuals with Parkinson's disease or related conditions are advised to prescribe concomitant folic acid, cobalamin (B_{12}), and pyridoxal-5'-phosphate (B_6), especially in light of the high incidence of strokes among such patients. MTHFR genotyping and regular tHcy monitoring are also recommended in Parkinson's patients. Although conclusive evidence is lacking to support claims that increased folate intake might prevent the onset of Parkinson's disease, folic acid supplementation is safe and inexpensive and may support healthy neurological function, counter Hcy elevation, and reverse adverse effects of levodopa, especially in those with the MTHFR C677T (TT) genotype or other factors increasing susceptibility to folate deficiency and hyperhomocysteinemia.

No evidence yet indicates that coadministration of folic acid or vitamin B_{12} would impair the therapeutic activity of levodopa or related medications. However, supplemental B_6 at levels greater than 10 to 15 mg/day could override the ability of carbidopa or benserazide (in Sinemet and Madopar, respectively) to limit the effects of vitamin B_6 on levodopa. The levels of B_6 found in most multivitamins are unlikely to interfere with the medication's therapeutic activity. In general, nutrients administered concomitantly with antiparkinsonian medications are best ingested with meals at least 2 hours before or after levodopa or at bedtime with a small amount of food.

Lithium Carbonate

Lithium Carbonate (Camcolit, Carbolith, Duralith, Eskalith, Li-Liquid, Liskonum, Litarex, Lithane, Lithobid, Lithonate, Lithotabs, PMS-Lithium, Priadel).

Nutrient Depletion

Probability: **5. Improbable**

Evidence Base: ◉ **Emerging** to ● **Consensus**

Effect and Mechanism of Action

Folate and vitamin B_{12} play major roles in one-carbon metabolism, in which SAMe is formed and methyl groups are made available for neurological function.

Research

Limited research suggests that low folate levels do not appear to characterize patients treated with lithium, but folate status may influence therapeutic response to lithium therapy. Stern et al.[238] measured serum and RBC folate levels in 17 outpatients receiving prophylactic lithium carbonate for recurrent major affective disorder. They observed "no evidence for low folate concentrations or for any significant correlation between folate levels and affective morbidity." Subsequently, a team of Chinese researchers investigated whether folate concentrations were lower in patients undergoing long-term lithium therapy, and if the medication might play a role in decreasing such levels. Lee et al.[239] found that serum folate correlated negatively with lithium dose and serum level among 46 Chinese and mostly manic-depressive (85%) outpatients attending a lithium clinic in Hong Kong. However, mean folate levels in the lithium-treated patients did not differ from lithium-free outpatients, and "virtually no patients had low serum (0%) or erythrocyte (2%) folate." Nevertheless, they noted that patients "with a good response to lithium in the previous one year had a higher mean serum folate level than those with unsatisfactory response." They concluded that "folate at high concentrations enhances lithium prophylaxis," even though "data suggest that folate deficiency is uncommon among Chinese psychiatric outpatients."[239] Notably, neither of these studies specifically

focused on whether increased folate intake (food or supplements) might enhance the efficacy of lithium therapy, decrease adverse effects, or allow reductions of therapeutic lithium dose.

The general finding in human trials indicates that concomitant folic acid administration can enhance the therapeutic efficacy of lithium. In a 1982 study involving 107 patients receiving long-term lithium, Coppen and Abou-Saleh[240] found that "those with lower plasma folate concentration had a higher affective morbidity than those with higher folate, both at the time and during the previous two years." In 1986, Coppen et al.[241] determined that folic acid enhances lithium prophylaxis in reducing affective morbidity. In a double-blind trial, they administered folic acid (200 μg/day) or placebo to 75 patients receiving lithium therapy. Patients with the highest plasma folate concentrations exhibited a significant reduction in their affective morbidity, with a 40% reduction in affective morbidity among subjects in whom plasma folate increased to 13 ng/mL or higher. Based on these findings, the authors suggested that a daily dose of 300 to 400 μg folic acid would be useful in long-term lithium prophylaxis.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing lithium therapy, especially on a long-term basis, are advised to discuss with patients the potential therapeutic benefit of concomitant folic acid administration, typically 200 to 400 μg/day or more. Higher folic acid dosage may be appropriate in some patients, based on diet, comorbid conditions, other medications, and genomic variability (e.g., MTHFR genotype). Evidence is lacking to suggest that lithium use depletes folate, or that folic acid reduces adverse effects associated with lithium. Given the probability of an additive or synergistic effect from coadministration, close supervision, regular monitoring, and dose titration are warranted, particularly with introduction of folate or change in dose of either agent.

Mercaptopurine, Azathioprine, and Thioguanine (Thiopurines)

Mercaptopurine (6-mercaptopurine, 6-MP, NSC 755; Purinethol), azathioprine (asathioprine; Azamun, Imuran, Thioprine), thioguanine (6-thioguanine, 6-TG, 2-amino-6-mercaptopurine; Lanvis).

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **4. Plausible** to **2. Probable**

Evidence Base: ▽ **Mixed** and ○ **Preliminary**

Effect and Mechanism of Action

Mercaptopurine, azathioprine, and thioguanine are cytotoxic antimetabolites used in the treatment of irritable bowel syndrome, leukemia, and some cancers. The mechanisms involved in their therapeutic activity have not been fully elucidated. Thiopurine *S*-methyltransferase (TPMT) catalyses the *S*-methylation of all three drugs. Mercaptopurine requires intracellular anabolism by hypoxanthine guanine phosphoribosyltransferase (HGPTPT, or HGPRT) to become cytotoxic. Likewise, azathioprine is an immunosuppressive prodrug, the *S*-imidazole precursor of 6-mercaptopurine, converted to 6-MP in the liver by TPMT. Intracellular activation of thioguanine, a 6-thiopurine analog of the naturally occurring purine bases hypoxanthine and guanine, results in incorporation into DNA as a false purine base.

Mercaptopurines act through purine antagonists and consequently tend to induce macrocytic nonmegaloblastic anemia. Serum folate levels are typically low in patients treated with these medications. Folate coadministration may moderate the adverse effects of these agents, thereby enhancing tolerance and facilitating efficacy. However, determining whether folate also interferes with the anticancer efficacy of this class of drugs requires further clinical research.

Research

Many patients are intolerant or resistant to thiopurine drugs, and their clinical management remains a challenge. Myelosuppression is the major dose-limiting effect with these agents. Hematopoietic toxicity, rapid bone marrow suppression, and leukopenia present a particularly significant risk in individuals with an inherited deficiency of TPMT or HGPTPT, even at normal dose levels.[242-249] Notably, relative leukopenia is typically not associated with clinical response.[250] Adverse drug reactions and intolerance to azathioprine, occurring in 15% to 28% of patients, may be attributable more often to polymorphism in the ITPA gene and inosine triphosphate pyrophosphatase (ITPase) deficiency, which results in the benign accumulation of the inosine nucleotide ITP; preliminary evidence, however, is mixed.[251-253] All these enzymes are involved in folate handling.

Genetic variation in the way individuals handle folate can be predicted to influence activity of the TPMT enzyme, which may assist in predicting adverse drug reactions in some patients. For example, polymorphisms in the gene encoding MTHFR may have an indirect impact on thiopurine drug methylation by influencing levels of the methyl donor SAMe.[253] As a result of genetic variation, 1 in 300 of the Caucasian population have a total lack of TPMT and are at high risk of severe toxicity if given azathioprine; 1 in 10 individuals have half the level and are also at increased risk of side effects. With prior knowledge of such genetic polymorphisms and related enzyme levels, the drug can be avoided or used at a lower dose, or other strategies can be used to minimize adverse effects.

The available findings of drug-induced depletion of folate are limited but consistent with scientific knowledge of renal transplant patients in general and patients treated with azathioprine in particular. In assessing the impact of renal transplant and azathioprine on folate status, Zazgornik et al.[254] monitored serum folic acid levels in 26 chronic hemodialysis patients, 52 renal transplant recipients, and 20 healthy controls using radioimmunoassay. Diminished serum folic acid levels were found not only in patients shortly after surgery, but also in patients with excellent graft function up to 6 years after transplantation. The mean serum folic acid level was significantly lower in both the dialyzed patients and the renal transplant recipients than in the controls. The highest serum folic acid level was observed in a transplant patient who had not taken azathioprine for 2 years. Macrocytosis was found in 52% of the renal transplant patients and was observed only in patients with good graft function treated with azathioprine. Serum vitamin B_{12} levels were within the normal range in both dialyzed and renal transplant patients. No intervention trials of folic acid administration in renal transplant patients taking azathioprine have been done, so the question remains whether folate replacement might improve clinical outcomes or

increase risk of graft rejection by interfering with azathioprine-induced immune suppression.

Concomitant folic acid may protect proliferative capacity of the bone marrow and moderate hematological parameters of drug toxicity in patients treated with these purine antagonists. In a retrospective longitudinal study, Lennard et al.[255] investigated myelosuppression and the effect of folate coadministration on 6-mercaptopurine (6-MP) remission maintenance therapy in 10 children with acute lymphoblastic leukemia (ALL). During the control period they observed significant correlations between 6-MP dose and 6-thioguanine (6-TG) nucleotide concentration, the active cytotoxic metabolite of 6-MP, and also between 6-TG nucleotide concentrations and the peripheral neutrophil count at 14 days. With the introduction of folic acid these relationships were no longer evident, and the children tolerated significantly higher doses of 6-MP longer before neutropenia developed. Although folate does not affect the conversion of 6-MP to 6-TG, white blood cell (WBC) counts were elevated for a longer period despite the same exposure to 6-TG, indicating possible interference with the cytotoxicity of 6-TG on neutrophils. Thus, although they reported "no significant difference in red cell 6-thioguanine nucleotide concentration in the absence and presence of folate supplements," the authors expressed concern that "folate supplements may interfere with remission maintenance therapy in ALL."[255] Similarly, in a trial involving 53 children with ALL in maintenance treatment with methotrexate (MTX) and 6-MP, Schroder et al.[255a] administered daily folic acid (75-200 μg) in vitamin tablets to 25 subjects for at least the preceding 3 months. Compared with children who received no folic acid, subjects receiving folic acid exhibited improved proliferative capacity of the bone marrow, as demonstrated by significantly higher erythrocyte folate (ery-folate) concentration, higher platelet counts, higher leukocyte counts, higher neutrophil counts, and lower erythrocyte mean cell volumes. Nevertheless, these authors recommended that "since none of the children was folate deficient as judged by the ery-folate [level],... vitamins given to children in maintenance treatment with MTX and 6-MP for ALL should not contain folic acid."

The present data indicate that folic acid appears to protect normal neutrophils from 6-TG and antagonize the effects of MTX and 6-MP on normal hematopoiesis. However, folate may or may not antagonize these antimalignancy effects; that is, folate may or may not protect leukemia (ALL) cells, even though it appears to protect normal neutrophils from the cytotoxic effect of these drugs. Schroder et al.[255a] assumed that folic acid protects normal WBCs from the cytotoxic effect of 6-TG and therefore might protect leukemia cells as well. Such speculation may or may not be well founded. Folate coadministration also might actually improve clinical outcomes. There have been documented instances of natural products that kill cancer cells without affecting normal cells or, conversely, protect normal cells from cytotoxic agents without protecting malignant cells. Such determinations could only be made in this case by investigating relapse of ALL as the endpoint of the trial. This would require a fairly large study, giving half the children folic acid and the other half placebo (and control for dietary folate, not easy in adults, let alone children), and using relapse of leukemia as the endpoint. Institutional review boards (IRBs) might consider this an unethical experiment, even though risk of missing a clinical benefit must be balanced against risk of losing therapeutic efficacy. The question arises whether folic acid might have an opposite effect on 6-TG and ALL cells versus its effect on 6-TG and normal neutrophils. At least this issue should be further studied in vitro and in animal models. The possibility of increased tolerance of maintenance chemotherapy by folate supplementation leading to improved clinical outcomes in childhood ALL warrants further investigation.

Regular monitoring, with periodic blood counts every 2 weeks initially and then every 3 months thereafter, is required given the action of these drugs in interrupting production of RBCs, WBCs, and platelets. In a study of 57 patients with inflammatory bowel disease treated with low-dose 6-MP, Bernstein et al.[256] determined that "leukopenia was not uncommon in patients treated with low-dose 6-MP, but was not clinically significant." Furthermore, macrocytosis may occur in the absence of vitamin B_{12} and folate deficiencies. The authors thus concluded that, despite the risk of myelosuppression, weekly blood count monitoring was not necessary when administering low-dose 6-MP therapy.

Evidence is lacking from large prospective or population-based studies on the use of these immunosuppressants during pregnancy. Effects on folate metabolism could play a potentially significant role in pregnant women.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing purine antagonists such as mercaptopurine, azathioprine, or thioguanine are advised to investigate the patient's folate status and coadminister folic acid as indicated. The evidence for benefit from such nutrient support is preliminary and inconclusive and suggests that concomitant folate administration might impair the therapeutic activity of these medications. Screening for polymorphisms and gene promoter activity, particularly the TPMT gene, before initiation of azathioprine therapy may be valuable in predicting pharmacogenomic responses and assisting drug tolerance. Close supervision, regular monitoring, and a coordinated strategy involving health care professionals experienced in both conventional pharmacology and nutritional therapeutics are essential to providing safe and effective individualized treatment within such an integrative approach.

Metformin and Related Biguanides

Evidence: Metformin (Dianben, Glucophage, Glucophage XR). Extrapolated, based on similar properties: Buformin (Andromaco Gliporal, Buformina); combination drugs: glipizide and metformin (Metaglip), glyburide and metformin (Glucovance); phenformin (Debeone, Fenformin).

Effect and Mechanism of Action

Metformin can reduce the absorption and lead to lower serum levels of folate, total vitamin B_{12}, and transcobalamin II (TCII)–B_{12} complex levels. Metformin interferes with calcium-dependent membrane action and impairs B_{12}–intrinsic factor complex uptake by ileal cell surface receptors.[257,258] Although this involves at least one mechanism, food-cobalamin

malabsorption or drug-induced changes in intestinal bacterial flora have also been suggested.[259,260] The available evidence is insufficient to determine whether the reported increase in total homocysteine (tHcy) levels is secondary to reduced folate levels, vitamin B_{12} levels, or a combination of both.

Decreased nutrient bioavailability plays a central role in the moderate elevations in plasma Hcy levels observed with long-term metformin therapy. Hyperhomocysteinemia is more prevalent in diabetic populations, women with polycystic ovary syndrome, and other patients likely to be prescribed biguanide therapy than among the general population.[174,261,262] Drug-induced elevations would further increase the risk of diabetes-associated conditions, such as coronary artery disease (CAD), vascular disease, and hypertension resulting from adverse effects on platelets, clotting factors, and endothelium, although not necessarily retinopathy or albuminuria.[263-266]

Note: The biguanide class was introduced when metformin and phenformin were developed in 1957. Metformin first became available in France in 1979 and has been widely used in Europe since that time. Phenformin and buformin, other biguanides, are well-established causes of lactic acidosis and have been removed from the U.S. market because of the high incidence of this adverse effect. Metformin was eventually found to be 20 times less likely to cause lactic acidosis and was cleared for use in the treatment of type 2 diabetes in the United States in 1994. Nevertheless, phenformin and buformin are still available internationally as oral agents for the treatment of diabetes and have reportedly been used in the United States.

This discussion focuses on metformin, and the evidence presented is based primarily on research involving metformin. Some studies mentioned also include phenformin and buformin or provide findings that may reasonably be extrapolated to these related biguanides.

Research

Long-term use of metformin has largely been associated with elevated Hcy levels in a wide range of human trials, although findings regarding the severity and clinical significance of this effect have varied.

The initial research into metformin-induced adverse effects on nutritional status focused on vitamin B_{12}. Carpentier et al.[267] compared the hematological effects in 30 diabetic patients treated with metformin versus those in 27 patients treated with insulin and 13 treated with sulfonylureas. Compared with the other groups, serum levels of vitamin B_{12} were significantly lower in patients receiving metformin, with five subjects exhibiting serum levels of vitamin B_{12} below 270 pg/mL and five others with borderline values. However, no differences were observed between the three groups in the mean serum folic acid levels, RBC counts, RBC volumes, or hemoglobin concentrations. These authors noted that the study period was not long enough to determine accurately whether vitamin B_{12} deficiency would develop. In a 1980 case report, Callaghan et al.[268] reported that megaloblastic anemia caused by vitamin B_{12} malabsorption was associated with long-term metformin treatment.

DeFronzo and Goodman[268a] observed effects on serum vitamin B_{12} and folic acid in two large, randomized, parallel-group, double-blind controlled studies comparing metformin, glibenclamide, and diet over 29 weeks in moderately obese patients with non–insulin-dependent diabetes mellitus (NIDDM) whose diabetes was inadequately controlled by diet alone. They reported that "serum folate concentrations did not change in either the metformin or placebo groups" but that "serum vitamin B_{12} concentration at week 29 was lower in the metformin group (by 22 percent) but did not change in the placebo group." No changes were observed in hematocrit or hemoglobin in either group.

Drug-induced depletion of folate and vitamin B_{12} appears to play a key role in biguanide-induced hyperhomocysteinemia, but testing methodology and patient variables may influence the occurrence and severity of this adverse effect. In 1997, Hoogeveen et al.[269] investigated fasting serum tHcy level in a cross-sectional study involving 40 NIDDM patients who had received treatment with metformin (500-2550 mg/day) for at least 6 months and 71 matched NIDDM metformin-naive patients. Mean serum tHcy level was 11.5 µmol/L fn the metformin-exposed patients, "slightly higher" than the 10.6 µmol/L in the nonexposed patients. Also in 1997, in an open, prospective, randomized study involving 60 nondiabetic male patients with coronary heart disease, Carlsen et al.[270] compared the effects of metformin on serum tHcy and related parameters with or without metformin (up to 2000 mg/day) in the context of diet and lifestyle advice and lovastatin (40 mg/day). After 12 and 40 weeks of metformin treatment, tHcy levels increased moderately but significantly in the metformin group relative to the control group while serum vitamin B_{12} levels decreased, with both trends greater over time. Serum folate levels did not change after 12 weeks, but decreased by 8.0% after 40 weeks compared to controls. However, serum levels of tHcy and methylmalonic acid (MMA) did not change. Based on this last variable, the authors concluded that "it remains an open question whether the increase in tHcy levels is secondary to reduced vitamin B_{12} levels, folate levels or a combination of both."[270]

Similarly, Hermann et al.[271] reported that serum B_{12} remained unchanged in a 12-month, placebo-controlled, double blind trial investigating glycemic improvement from coadministration of metformin in 16 insulin-treated, obese type 2 diabetes patients. However, comparing the effects of metformin and sulfonylurea therapy, Bauman et al.[258] reported that metformin induced a 29% decline in serum levels of vitamin B_{12} but a 36.6% drop in serum holotranscobalamin II (holo-TCII). Similarly, in a subsequent cross-sectional cohort study, Hermann et al.[272] found that by "considering the four variables reflecting vitamin B_{12} status, apart from MMA there were more patients in the metformin group with abnormalities indicating vitamin B_{12} deficiency." Moreover, such effects were exhibited "most clearly for holotranscobalamin," for which none of the control subjects had values less than the lower reference value, whereas eight (16%) of the metformin-treated subjects had reduced levels.

In an epidemiological study, Smulders et al.[264] applied multiple-regression analysis to 85 NIDDM subjects. In a subset of 31 subjects treated with metformin, levels of Hcy and vitamin B_{12} were similar to those without metformin. Also, low-normal values of folate (<20 nmol/L), vitamin B_{12} (<350 pmol/L), and creatinine clearance, as well as postmenopausal status in women, were significant predictors of fasting Hcy level, whereas B_6 levels (<80 nmol/L), creatinine clearance, and female gender were determinants of post-methionine load Hcy levels.

In a randomized, placebo-controlled trial, Wulffele et al.[273] investigated the effects of metformin therapy (vs. placebo) for 16 weeks on serum concentrations of Hcy, folate, and vitamin B_{12} in 353 patients treated with insulin for type 2 diabetes mellitus. Compared with placebo, metformin was associated with a "modest" increase in serum Hcy levels (4%; 0.2-8 µmol/L),

and decreases in folate (−7%) and vitamin B_{12} (−14%). Furthermore, applying structural equation modeling, they demonstrated that the increase in Hcy was an indirect effect mediated by direct effects on folate and vitamin B_{12}, rather than a direct effect on Hcy by metformin. The authors concluded that a persistent increase in serum Hcy of 3 μmol/L was associated with an increased risk of coronary heart disease and stroke in nondiabetic individuals, and that available evidence indicates that this risk may be even greater in diabetic patients.

Wolever et al.[259] found that miglitol (Glyset), an alpha-glucosidase or alpha-amylase inhibitor, prevents the metformin-induced fall in serum folate and vitamin B_{12} in subjects with type 2 diabetes. Keeping dietary folate intake consistent, they observed that "serum folate and vitamin B_{12}, respectively, did not change on placebo, but fell by 14% and 15% on metformin and rose by 12% and 23% on miglitol." Notably, with the combination of metformin and miglitol, "both folate and vitamin B_{12} tended to rise, but the difference from metformin was only significant for folate." These authors concluded that "that increased carbohydrate delivery to the colon increases intestinal biosynthesis of folate."

In a study involving nine women with polycystic ovary syndrome (PCOS) conducted at the Center for Perinatal Studies at Swedish Medical Center in Seattle, Vrbikova et al.[262] found that a second-trimester Hcy elevation was associated with a 3.2-fold increased risk of preeclampsia. The authors noted that women with PCOS were already at increased risk for atherosclerosis, and that elevated Hcy could also contribute to pregnancy complications.

The adverse effects of metformin on folate and vitamin B_{12} status, Hcy levels, and related cardiovascular risk can often be mitigated by coadministration of folate, B_{12}, and calcium. In a 12-week, prospective, randomized, double-blind placebo-controlled study, Aarsand and Carlsen[274] studied whether administration of folate reduces serum tHcy levels in patients receiving long-term metformin treatment. All subjects who had been receiving metformin (minimum of 1000 mg/day) for at least 1 year were included, and all baseline serum tHcy levels were within the reference range. In addition to metformin, one group received concomitant folate (0.25 mg/day) in addition to iron (Fe^{++}; 60 mg/day), whereas the placebo group received only 60 mg/day of Fe^{++}. Of the 28 subjects who finished the trial, 26 had been diagnosed with NIDDM, two with hyperlipidemia. Subjects in the folate group demonstrated reduced serum levels of tHcy (vs. placebo group) by 13.9% and 21.7% at weeks 4 and 12, respectively, as well as increased serum levels of vitamin B_{12} (9.9% and 9.6%) and folate (96.9 and 89.9%). In the trial cited earlier, Bauman et al.[258] investigated the effects of metformin antagonism on B_{12}–intrinsic factor complex uptake by ileal cell surface receptors, a calcium-dependent membrane action. After observing "diminished B_{12} absorption and low serum total vitamin B_{12} and TCII-B_{12} levels" in patients receiving metformin therapy, they found that calcium coadministration reverses metformin-induced B_{12} malabsorption.

In a related study with uncertain clinical implications, Child et al.[275] investigated the effect of oral folic acid on Hcy, glutathione, glycemia, and lipids in type 2 diabetic patients. After administering folic acid (10 mg daily) for 3 months to 27 diabetic patients (26 male, one female; age 48–68) with microalbuminuria, they observed an increase in RBC folate that correlated with a reduction in microalbuminuria. Notably, "plasma glutathione increased despite reduction in its precursor Hcy," but correlated with levels of vitamin B_6; however, this change in glutathione correlated inversely with change in hemoglobin A_{1c} (HbA_{1c}), total cholesterol, and triglycerides and positively with HDL cholesterol. Thus, oral folic acid supplementation reduced plasma Hcy level and increased glutathione level in subjects with type 2 diabetes, but levels of HbA_{1c}, triglycerides, and HDL cholesterol deteriorated. In addition, the authors noted that "some aspects of the response to folate may be different in patients on metformin."[275]

Lifestyle interventions can be more effective than metformin for curbing the incidence of diabetes in individuals at high risk. Continued research emerging from the work of the Diabetes Prevention Program (DPP) Research Group emphasizes that although metformin can be effective, a broader strategic approach emphasizing diet and exercise can produce more fundamental benefits. Analyzing DPP trial data in the *New England Journal of Medicine*, Knowler et al.[276] showed that, overall, metformin reduced the risk of diabetes by about 31%, compared with a 58% reduction for those assigned to intensive nutrition and exercise counseling. The study's 3234 participants were significantly overweight and had "impaired glucose tolerance." Approximately 1000 subjects were put on a low-fat diet (25% of overall calories), told to engage in moderate physical exercise, such as walking for 30 minutes, received training in goal setting and problem solving, and were invited to participate in group events. In addition to reducing diabetes risk, the lifestyle intervention group exhibited reduced body weight by 5% to 7%. In a subsequent analysis, Molitch et al.[277] concluded that, on the basis of these rates, the estimated number of persons who would need to be treated for 3 years to prevent one case of diabetes during this period is 6.9 for the lifestyle intervention versus 13.9 for metformin. Likewise, Orchard et al.[278] calculated that "diet and exercise delayed the onset of type 2 diabetes by about 11 years, while metformin delayed the onset by about three years." Increased dietary intake of folate-rich foods, especially dark-green leafy vegetables, would fit well within such an approach.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians treating patients with dysglycemia, diabetes, PCOS, or related conditions using metformin are advised to integrate such biguanide therapy within a comprehensive therapeutic strategy. Regular exercise and a diet emphasizing low-glycemic-load carbohydrates and healthy sources of fats (such as olive oil or fish oils) can provide the most effective foundation for such an approach. Coadministration of folic acid (400 μg once or twice daily), vitamins B_{12} and B_6, and calcium can help reduce associated risks and adverse effects attributable to the medication, particularly cardiovascular risks linked to elevated Hcy levels.

Close supervision, active support for lifestyle changes, and regular monitoring are all essential to successful intervention. Folate and Hcy levels, as well as liver function, should be checked regularly. Total serum cobalamin is not sufficiently specific and does not reflect intracellular B_{12} deficiency. Screening for genetic polymorphisms, especially MTHFR genotype, affecting folate status and Hcy susceptibility may be appropriate because interindividual variability may be significant for both therapeutic response to biguanides and folate metabolism. Serum holo-TCII is a sensitive marker of cobalamin balance, more accurately assessing B_{12} availability for the cells, but this analysis may not be feasible in routine clinical practice. MMA and tHcy can reflect intracellular B_{12} deficiency, but these metabolites may also increase in various clinical conditions, most notably with impaired renal function.

Neomycin

Neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
5. Improbable or
2. Probable (depending on duration)

Evidence Base:
⊙ **Preliminary,** but generally regarded as
● **Consensus**

Effect and Mechanism of Action

Oral neomycin can decrease absorption and/or increase elimination of folic acid and other nutrients, including beta-carotene, calcium, carbohydrates, fats, iron, magnesium, potassium, sodium, and vitamins A, B_{12}, D, and K.[279,280] These effects increase with time in long-term neomycin therapy and can be most significant in elderly persons.[281]

Research

In 1966, Faloon et al.[282] documented the adverse effects of neomycin on intestinal absorption of nutrients.[282] In 1969, Hardison and Rosenberg[283] further elucidated the effect of neomycin on bile salt metabolism and fat digestion in humans. Subsequently, the adverse effects of neomycin on nutrient status were explored extensively in the pioneering work of D.A. Roe (1923–1993) of Cornell University, Division of Nutritional Sciences, through publications such as "Drug-Induced Nutritional Deficiencies" (1976). As such, this characterization has largely become the "consensus" of the literature documenting adverse drug effects and drug-induced nutrient depletions, without passing through the stages of published case reports, human trials, reviews, and so on, which constitute the emerging standard within the scientific literature of drug-nutrient interactions. Further research may be warranted.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing a course of oral neomycin longer than a few days are advised to coadminister a multivitamin-mineral supplement containing folic acid. Depletion is improbable with short-term use of oral neomycin associated with surgery or perioperative care. A course of probiotic flora is also appropriate following broad-spectrum antibiotics to restore normal gut ecology and prevent sequelae adversely affecting vitamin B_{12} synthesis and folate metabolism.

Nitroglycerin and Related Nitrates

Nitroglycerin (glyceryl trinitrate, GTN; Deponit, Minitran, Nitrek, Nitro-Bid, Nitro-Dur, Nitro-Time, Nitrodisc, Nitrogard, Nitroglyn, Nitrolingual, Nitrol, Nitrostat, Transderm-Nitro, Tridil).

Extrapolated, based on similar properties: Isosorbide dinitrate (ISDN, Isordil, Sorbitrate); combination drug: hydralazine and isosorbide dinitrate (BiDil); isosorbide mononitrate (Imdur, ISMN, ISMO, Isotrate, Monoket).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
2. Probable

Evidence Base:
◉ **Emerging**

Effect and Mechanism of Action

Nitroglycerin and other organic nitrates have been used clinically as nitric oxide (NO)–donating agents for more than 100 years in cardiovascular therapeutics and continue to be widely used in ischemic heart disease, even though knowledge of their intimate mechanism of action is incomplete. Progressive attenuation of their efficacy (tolerance) is a frequent problem in patients with acute coronary syndromes undergoing continuous, long-term therapy, as is cross-tolerance to endothelial NO; tolerance can also occur within 24 to 48 hours after administration of a nitrate medication.

Nitrate medications appear to cause tolerance by inducing nitric oxide synthase (NOS) dysfunction, probably as a result of reduced bioavailability of tetrahydrobiopterin. This metabolic syndrome is characterized by mitochondrial dysfunction and mediated significantly by inhibition of vascular aldehyde dehydrogenase (ALDH-2).[284] Also, Loscalzo[285] suggests that nitrate "depletes NADPH and an NADPH-dependent cofactor essential for the enzymatic activity of endothelial nitric oxide synthase." Several mechanisms may explain this phenomenon, including nitrate-mediated depletion of intracellular thiols, enhanced mitochondrial reactive oxygen species (ROS) formation, and increased superoxide production. Endothelial nitric oxide synthase (eNOS) is an enzyme that predominantly produces NO under normal physiological conditions, controlled by the regulatory coenzyme calmodulin, the substrate L-arginine, and the cofactor tetrahydrobiopterin. However, in the context of dyslipidemia and other pathophysiological conditions, eNOS production shifts from NO to superoxide. Thus, increased intracellular oxidative stress appears to be a mechanism for nitrate tolerance.

Folic acid can prevent nitroglycerin-induced nitrate tolerance and cross-tolerance to endothelial NO by enhancing the regeneration and bioavailability of tetrahydrobiopterin in the context of the oxidative stress associated with long-term nitroglycerin administration. The mechanisms of this activity have not been fully elucidated. Dihydrofolate reductase reduces dietary folate to tetrahydrofolate using reduced nicotinamide-adenine dinucleotide phosphate (NADPH) as a cofactor. NADPH is also a required cofactor for NOS activity and for the synthesis of tetrahydrobiopterin from the direct and salvage pathways. However, NOS is unable to function either as an L-arginine oxidase or as an oxygen reductase when supplies of NADPH are compromised. "Thus, one plausible argument for the benefits of folate in nitrate tolerance is that it [nitrate] depletes NADPH and an NADPH-dependent cofactor essential for the enzymatic activity of endothelial nitric oxide synthase."[285] However, evidence is lacking to confirm or refute this proposed mechanism.

Folic acid and its active form, 5-methyltetrahydrofolate (5-MTHF), have been shown in some studies to prevent uncoupling of the eNOS, reduce eNOS-mediated superoxide production, enhance NO synthesis by NOS, and restore impaired NO bioavailability, particularly in dyslipidemic conditions.[286-292] Such inhibition of eNOS uncoupling could contribute to improved endothelial function. The tetrahydrobiopterin radical appears to be directly involved in the facilitated catalysis of eNOS by 5-MTHF and thus the formation of NO.[293] Related research showing the benefits of ascorbic acid in potentiating eNOS activity, by increasing intracellular tetrahydrobiopterin, complements the hypothesis that the tetrahydrobiopterin radical plays a role in NO synthesis by mediating reductive activation

of the ferrous heme-O_2 moiety of the eNOS enzyme.[294] Other research indicates that the pteridine-binding domain in NOS is similar to the folate-binding site of dihydrofolate reductase.[295]

Continued research will determine the validity and significance of each of these hypotheses and clarify the relative role of each mechanism in folate's apparent ability to improve endothelial function and ameliorate nitrate tolerance.

Research

Clinical research investigating therapeutic synergies using folic acid in concert with nitrate preparations is only in the initial phases. Although a body of research exists on the mechanisms in the relationship between nitrates and nitric acid, including the potential roles of folates, a comprehensive model of folate and its activities has yet to be elucidated.

In an animal study, Gruhn et al.[296] found that administration of tetrahydrobiopterin improves endothelium-dependent vasodilation in nitroglycerin-tolerant rats and concluded that "altered bioavailability of tetrahydrobiopterin is involved in the pathophysiology of endothelial dysfunction seen in nitroglycerin tolerance." Subsequently, Sydow et al.[284] observed decreases in vascular mitochondrial aldehyde dehydrogenase (ALDH-2) activity, nitroglycerin (GTN) biotransformation, and cyclic guanosine monophosphate (cGMP)–dependent kinase activity in rats treated for 3 days with GTN infusions. Multiple inhibitors and substrates of ALDH-2 had little effect on tolerant vessels, whereas these agents reduced both GTN stimulation of cGKI and GTN-induced vasodilation in control vessels. Furthermore, "GTN increased the production of reactive oxygen species (ROS) by mitochondria," and "antioxidants/reductants decreased mitochondrial ROS production and restored ALDH-2 activity." These findings indicate that mitochondrial ROS and inhibition of vascular ALDH-2 play a significant role in mediating nitrate tolerance.

In a small, randomized, double-blind trial, Gori et al.[297] tested the effects of concomitant folic acid (10 mg daily for 1 week, a relatively high dose) on development of tolerance to continuous transdermal GTN (0.6 mg/hour) in 18 healthy male volunteers (age 19-32). In measurements taken on the return visit, folic acid "prevented GTN-induced endothelial dysfunction, as assessed by responses to intraarterial acetylcholine and *N*-monomethyl-L-arginine." The authors also noted that "responses to intraarterial GTN were significantly greater than those observed after transdermal GTN plus placebo" in the subjects treated with folic acid plus transdermal GTN. Thus, they concluded that "oxidative stress contributes to nitrate tolerance," and that "supplemental folic acid prevents both nitric oxide synthase dysfunction induced by continuous GTN and nitrate tolerance in the arterial circulation of healthy volunteers."

These data are consistent with the mechanisms previously discussed and provide a foundation for continued research into an expanded role for folic acid coadministration in preventing nitrate tolerance and enhancing the therapeutic effects of nitrate therapy. Confirmatory findings in high-powered, well-designed clinical trials would have major implications for the treatment of atherothrombotic vascular disease.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing nitroglycerin or related nitrate preparations are advised to coadminister folic acid to prevent tolerance to the medication over time and as part of the broader strategy for reduction of cardiovascular risk. Evidence from complementary research suggests that such patients might also benefit from concomitant L-arginine, vitamin C, coenzyme Q10, vitamin B_{12}, and magnesium. Implementation of such an integrative strategy requires close supervision and regular monitoring, most effectively by a multidisciplinary team incorporating health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics.

Effect and Mechanism of Action

Exposure to nitrous oxide (N_2O) can produce megaloblastic anemia, neuropathy, and birth defects, all caused primarily by induced deficiency of vitamin B_{12} and secondarily by the effects of vitamin B_{12} deficiency on folate metabolism. Such adverse effects of N_2O were well established long before the mechanisms of its effects on folate and vitamin B_{12} were elucidated. Nitrous oxide can significantly interfere with activity of vitamin B_{12}, alter intracellular folate coenzyme levels, perturb the normal pathways of folic acid metabolism by oxidizing the enzyme-B_{12} (Co+) complex formed during catalysis, and thereby inactivate methionine synthase.[298-300] Anesthesia with N_2O may also impair DNA synthesis in bone marrow cells.[301] Notably, researchers have often employed N_2O as a probe for investigating the folate–vitamin B_{12} interrelationships because of these well-known effects.[302]

Thus, N_2O exposure can cause an accumulation of cytosolic 5-methyltetrahydrofolate (5-MTHF; e.g., in liver and pancreas), at the expense of other reduced folates, specifically tetrahydrofolate (THF) and 5-formyltetrahydrofolate (5-FTHF), which in turn can lead to significantly lower total mitochondrial folates.[303,304] This phenomenon is known as the ***methyl trap hypothesis***, first presented in 1962, which states that, in the context of methionine synthase inactivation resulting from vitamin B_{12} deficiency, folates are trapped as 5-MTHF, the synthesis of which is not reversible in vivo.[305,306]

Research

Researchers have studied the adverse effects of N_2O on folate activity and the benefits of folic acid administration for more than 20 years. Using the deoxyuridine (dU) suppression test in 1985, Amos et al.[301] investigated secondary development of folate deficiency and delayed recovery after N_2O anesthesia in 48 patients admitted to an intensive care unit (ICU). The pattern of correction of the abnormal dU suppression tests on admission to the ICU, after N_2O anesthesia, was "typical of that seen in vitamin B_{12} deficiency"; 3 days later "the pattern had changed to that usually seen in folate deficiency." Likewise, "serum folate levels fell to subnormal values," and although elevated after N_2O administration, urinary folate excretion was "insufficient by itself to explain the development of folate deficiency." Moreover, administration of physiological amounts of folic acid accelerated the recovery of the bone marrow abnormalities present after N_2O anesthesia.

In a 1986 rat study, Keeling et al.[307] found that coadministration of folinic acid provided protection against N_2O teratogenicity. "The incidence of major skeletal abnormalities in the

untreated nitrous oxide group was significantly increased to five times that of the control groups, whereas the incidence in the nitrous oxide group receiving folinic acid was not significantly different from control."

Two teams of researchers conducted parallel experiments investigating the short-term effects of N_2O on folate and vitamin B_{12} metabolism in rats and human patients. Koblin et al.[308] found that exposure to nitrous oxide (60% N_2O, 40% O_2) in rats of various ages greatly enhanced urinary excretion of formic acid and formiminoglutamic acid (FIGLU), compounds that are elevated in the urine of mammals with a deficiency in folate. Urinary formic acid excretion increased threefold to 25-fold the first day after 6 hours of N_2O exposure and returned to background levels by the second day after exposure in all age groups. Urinary FIGLU excretion increased 100-fold to 300-fold the first day after N_2O exposure, with the highest FIGLU excretion rates in the elderly rats and the lowest in the young rats. FIGLU excretion rates returned to baseline levels by the second day after N_2O exposure in all age groups. Increasing age was progressively associated with decreased plasma folate, but no age-dependent changes were observed in RBC folate, liver folate, or plasma vitamin B_{12} levels.

Subsequently, Koblin et al.[309] investigated folic acid metabolism in 49 surgical patients exposed to isoflurane alone or combined with N_2O. They found no increase in urinary formic acid and FIGLU in 23 patients exposed to N_2O for total hip replacement. However, patients undergoing resection of acoustic neuromas (with mean duration of anesthesia of 9.3 hours) exhibited a small, transient increase in the FIGLU/creatinine ratio, which peaked at the end of anesthetic exposure and returned toward control levels by the first day after anesthesia and surgery. The researchers noted a lack of predictive association between low preoperative levels of RBC folate and low-normal levels of serum vitamin B_{12} and an increase in formic acid or FIGLU in response to N_2O. They concluded: "Although an occasional patient may prove highly susceptible to and develop signs of severe vitamin B_{12} and folic acid deficiency after exposure to N_2O, our findings suggest that this is a rare event."[309]

In a study involving 40 patients under N_2O anesthesia for 70 to 720 minutes, Ermens et al.[310] demonstrated that postoperative plasma levels of folate and homocysteine (Hcy) increased up to 220% and 310%, respectively, in a manner correlating significantly with exposure time. This response appeared rapidly, after 75 minutes of N_2O exposure, and required several days to return to normal levels. Plasma Hcy levels had not returned to preoperative levels within 1 week in eight patients receiving N_2O anesthesia. Based on these findings, the authors suggested that elevated plasma Hcy levels may be used for monitoring N_2O-induced cobalamin inactivation and the resultant disturbance of Hcy and folate metabolism.

In related 1991 in vitro research using blast cells from leukemia patients, Ermens et al.[303] found that 8 hours' exposure to N_2O caused an equal decrease of 10-FTHF and 5-FTHF in both acute myeloid leukemia (30%) and acute lymphoid leukemia (45%), whereas 5-MTHF increased (130%). They concluded that N_2O treatment of leukemic cells causes an accumulation of 5-MTHF at the expense of other folate forms. In a similar 1997 experiment, Horne et al.[304] investigated the effects of N_2O inactivation of methionine synthase on the compartmentation of folate metabolism in rat pancreas. Rats exposed to N_2O exhibited cytosolic 5-MTHF concentrations that were significantly greater (59% of total folates) and THF concentrations significantly lower (32%) than those in controls. Exposure to N_2O was associated with significantly lower activity of methionine synthase and concentration of THF and 5-FTHF, but not 5-MTHF or 10-FTHF, thus leading to significantly lower total mitochondrial folates. These findings are consistent with emerging knowledge of the mechanisms involved.

Issues of adverse effects of N_2O may represent a significant risk to medical and dental personnel exposed daily to low levels of anesthetic. Salo et al.[311] gathered peripheral blood samples from eight anesthetists and seven internists in a survey of potential occupational health hazard to operating theater personnel chronically exposed to trace N_2O concentrations. They observed no definite signs of B_{12}-N_2O interaction in peripheral blood counts or films, serum vitamin B_{12} or plasma, or erythrocyte folate concentrations.

The issue of how this interaction might affect individuals abusing nitrous oxide has not been addressed in a systematic or direct manner and deserves consideration as a potential area of concern.

Reports

Nunn et al.[312] reported the case of a "seriously ill patient" who exhibited "megaloblastic changes in his bone marrow" following N_2O anesthesia for 105 minutes. After a 7-hour delay and administration of folinic acid (30 mg), a second round of N_2O was administered; 4 hours later his marrow was normal.

Flippo and Holder[299] reviewed five cases in which "patients unsuspected of having vitamin B_{12} deficiency developed subacute combined degeneration of the spinal cord following nitrous oxide anesthesia." They attributed these adverse effects to N_2O-induced "irreversible oxidation to the Co++ and Co forms that renders vitamin B_{12} inactive" and that impairs DNA synthesis and the methylation of myelin basic protein involved in the maintenance of the myelin sheath. They cautioned that "patients with vitamin B_{12} deficiency are exceedingly sensitive to neurologic deterioration" after N_2O anesthesia, which, if unrecognized, could cause "irreversible" deterioration and "may result in death."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians are advised to consider assessment of vitamin B_{12} and folate status as part of preoperative care in patients who will be receiving major anesthesia that includes N_2O. Administration of folic acid (1000 μg/day) and vitamin B_{12} (100 μg/day), beginning 1 week before and extending through 1 week after prolonged exposure to N_2O, is prudent if the patient is susceptible to or has a history of nutrient deficiency and if N_2O exposure will be of extended duration. Such concerns are amplified and further monitoring and compensatory nutrient support warranted in pregnant women because of the significantly greater risk inherent in transient depletion of folate levels, particularly in early gestation. Patients with normal vitamin B_{12} and folate levels who undergo N_2O anesthesia for less than 2 hours generally do not require supplementation; however, such prophylaxis would be safe, compatible, and inexpensive.

Evidence is lacking to support a recommendation for routine supplementation by medical or dental staff regularly exposed to N_2O. However, consideration should be given to the need for B_{12} and folate administration to individuals who have a recent history of, or are known to be currently engaged in, the habitual use of N_2O as a recreational drug. Urinary MMA level and plasma tHcy determination might be sensitive markers for monitoring in both situations.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

COX-1 inhibitors: Diclofenac (Cataflam, Voltaren); combination drug: diclofenac and misoprostol (Arthrotec); diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), furbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen); combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen); indomethacin (indometacin; Indocin, Indocin-SR), ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Aleve, Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin).
COX-2 inhibitor: Celecoxib (Celebrex).

Effect and Mechanism of Action

In vitro and animal research indicates that the "antifolate activity of NSAIDs, and hence cytostatic consequences, are important factors in producing anti-inflammatory activity."[39] Some NSAIDs, such as sulindac and sulfasalazine (SASP), are known antifolates. With chronic use and when taken in high doses, many NSAIDs may exert antifolate activity by impairing folate absorption and transport, which could decrease serum folate concentrations and cause deficiency.[38,39,313-315] Furthermore, many NSAIDs (including ibuprofen, indomethacin, mefenamic acid, naproxen, piroxicam, salicylic acid, sulindac, and sulphasalazine) and NSAID-like drugs act as competitive inhibitors of enzymes involved in folate metabolism and transport, including phosphoribosyl aminoimidazolecarboxamide formyltransferase transformylase (AICAR transformylase), dihydrofolate reductase, methylenetetrahydrofolate reductase, and serine transhydroxymethylase. Other in vitro experiments indicate that these NSAIDs can act as folate antagonists and inhibit the THF-dependent biosynthesis of serine from glycine and formate (i.e., C1 index) by human blood mononuclear cells (BMCs). In contrast, aspirin, acetaminophen, and antipyrine were weak inhibitors of these enzymes; acetaminophen exerted a weak inhibitory effect on the C1 index. Notably, both aspirin and salsalate exert anti-inflammatory effects after conversion to salicylic acid, which possesses greater antifolate activity than either parent compound.[39,314]

Other NSAIDs, such as *p*-aminosalicylic acid (an older antituberculosis agent), may decrease folic acid absorption in the GI tract and decrease serum folate concentrations.[316] Furthermore, *p*-aminosalicylic acid is also a structural analog of *p*-aminobenzoic acid (PABA) and thus inhibits de novo folate synthesis.

Research

Most evidence regarding the effects of NSAIDs on folate comes from in vitro and animal research, as previously reviewed. Some of these studies derive from human studies, but not clinical trials. Thus, although a coherent body of data indicates that NSAIDs exert multiple actions that may be deleterious to folate levels and functions, only preliminary evidence is available from human trials to confirm these phenomena and delineate the associated factors or determine their clinical significance.

Baggott et al.[39] observed in vitro that the C1 index of BMCs from rheumatoid arthritis (RA) patients receiving drugs with minimal antifolate activity (e.g., acetaminophen) is higher than the C1 index from RA patients receiving NSAIDs with more potent antifolate activity (e.g., sulindac, sulfasalazine, naproxen, ibuprofen). "The mean activity of the transformylase in BMCs taken from healthy humans was 1.98 nmol of product/h per 10^6 cells and the activity was positively correlated with BMC folate levels."

Analyzing serum and blood samples from a healthy female subject following a fixed diet for 11 days and taking 650 mg aspirin orally every 4 hours during the middle 3 days, Lawrence et al.[38] observed a "brisk, significant but reversible fall in total and bound serum folate and a small but insignificant increase in urinary folate excretion." Noting also that aspirin in vitro "displaced significant amounts of bound serum folate," they concluded that "aspirin in therapeutic doses can contribute to subnormal serum folate values, and if it increases urinary folate excretion even slightly, may impair folate balance." (See also Acetylsalicylic Acid.)

No direct evidence has confirmed that folate coadministration is beneficial for individuals taking most NSAIDs. Conversely, no evidence to date has suggested that concomitant folate administration might interfere with the therapeutic activity of such NSAIDs, although this may be possible given the role of antifolate activity in the mechanisms of action observed in many of these drugs. Nevertheless, the positive clinical outcomes regarding coadministration of folate with methotrexate in autoimmune arthritides indicates that folate does not necessarily interfere with the therapeutic action of antifolate drugs.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing NSAIDs should consider discussing with patients the potential benefits of concomitant folic acid (400 µg once or twice daily) and increased dietary folate intake with frequent, long-term, or high-dose NSAID therapy. Monitoring for folate deficiency using serum/RBC folate levels and plasma Hcy may be advisable.

Substantive evidence is lacking to confirm, or even suggest, that routine low-dose NSAID use is likely to affect folate status adversely in most individuals. The available evidence indicates that the adverse effect may be marginal in some cases and could be severe in a few patients, particularly with chronic use at higher dosage levels. Such concerns may be particularly relevant in pregnant women and in patients with compromised dietary folate status or susceptibility caused by individual genomic variability.

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen). Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).

Effect and Mechanism of Action

Oral contraceptives (OCs) may lower serum and RBC folate, but such changes do not appear to induce folate deficiency or cause anemia or megaloblastic changes under most circumstances. OCs are also associated with lowered levels of cyanocobalamin, which in turn can adversely affect folate status and related hematological parameters.[317,318] The mechanisms of such possible effects have not been elucidated. In 1968, Shojania et al.[319] noted the high incidence of folate deficiency in pregnancy and proposed that "one would expect a similar effect in women on longterm oral contraceptives, which are known to produce a pseudopregnancy state."

Folic acid may protect against precancerous cervical dysplasia in women, especially those taking OCs.

Research

It has been well established that birth control pills, especially those containing higher estrogen doses, impair folate metabolism and tend to deplete folic acid, with several possible adverse repercussions, especially increased risk of cervical dysplasia and vascular thrombosis. However, evidence is mixed regarding the probability of occurrence and clinical significance of such an adverse effect; the issue remains contentious. Differing estrogen doses in various OC formulations, as well as such confounding variables as dietary folate intake and genetic polymorphisms affecting folate, may account for some of the inconsistency in research findings.[320]

Folic acid deficiency enhances OC-induced platelet hyperactivity and oxidative stress. In various studies in female rats and also in women, OCs were found to induce a platelet hyperactivity related to increased oxidative stress. Many researchers suspect that OCs deplete folate stores and point to cases of megaloblastic anemia reported to occur in women taking OCs.

Using a rat model, Durand et al.[321] determined that dietary folic acid deficiency contributed to the thrombogenicity of OCs and "magnified OC-induced oxidative stress, which resulted in platelet hyperactivity by elevating the pro-oxidant homocysteine plasma concentration." Animals were fed for 6 weeks with either a folic acid–deficient diet (250 µg/kg folic acid) or a control diet (750 µg/kg folic acid). Half the animals in each group received an OC (ethinyl estradiol plus lynestrenol). The authors observed that folic acid deficiency and OCs "individually potentiated platelet aggregation in response to thrombin and ADP [adenosine diphosphate] and the release and metabolism of arachidonic acid, in particular, the biosynthesis of thromboxane. These platelet activities were further enhanced in animals given both the folic acid–deficient diet and the OC treatment." Furthermore, folic acid deficiency "enhanced the pro-oxidant state in OC-treated rats characterized by (1) a fall in platelet and plasma n-3 fatty acids, (2) an increase in plasma lipid peroxidation products such as conjugated dienes, lipid peroxides, and thiobarbituric reactive substances, [and] (3) a rise in *ex vivo* erythrocyte susceptibility to free radicals." Also, OC administration "led to a reduction of plasma and erythrocyte folate concentrations associated with a moderate hyperhomocysteinemia." Despite the limitations of this animal model, the authors concluded that their findings "suggest that in addition to cigarette smoking, inadequate folic acid intake might predispose those taking OC to vascular thrombosis."[321]

Most human studies have found that OC use adversely affects folate status, but conclusions vary depending on estrogen dose levels, methods of assessing folate levels, and duration of trial period. In a preliminary 1968 study of 86 women (24 normal nonpregnant women of childbearing age and 62 women taking OCs), Shojania et al.[319] determined that the OC group showed, on average, a significantly lower serum folate level than the control group, with 30% (19) of the OC women exhibiting a serum folate level lower than the lowest value in the control group. The authors recommended that the "serum folate level of women on long-term oral contraceptives be determined, especially when they stop the medication and plan for conception."

Subsequently, in a 1975 review, Lindenbaum et al.[322] reported that "in some series, but not in others, serum and/or red cell folate concentrations have been reduced in oral contraceptive users" but that "a disturbance in folate balance serious enough to cause symptoms (i.e., megaloblastic anemia) occurs very rarely." In a 1991 study, Mooji et al.[323] compared folate concentration in serum and RBCs, as well as other nutrient levels, over four cycles in 29 women taking OCs (containing 30 µg of ethinyl estradiol) and 31 women serving as non-OC controls, with both groups administered a multivitamin and folic acid supplement. OCs did not lower serum and RBC folate levels or induce folate deficiency, at least within the limited time frame of the trial. The authors concluded that "supplementation during OC use or just after discontinuing treatment cannot be justified for healthy young women," but added that, "in the case of women with a critical vitamin balance or higher folate needs, multivitamin supplementation may be considered."

In 1993, Steegers-Theunissen et al.[324] compared serum folate levels after oral folate loading in a study of the kinetics of folic acid monoglutamate involving 29 users of OCs containing less than 50 µg of estrogen and in 13 women serving as controls. Median serum folate concentrations after oral folate loading were decreased in OC users, reaching statistically significant lower levels after 210 minutes (260 nmol/L) compared with controls (400 nmol/L). Apparently, OCs with less than 50 µg estrogen significantly affected folate kinetics and vitamin B_{12} levels. Even so, the authors concluded that "folate and vitamin B_{12} status does not seem to be at risk."

In 1998, Green et al.[325] investigated the impact of "currently available" OCs, as well as smoking and alcohol, on serum and RBC folate and serum B_{12} and homocysteine in 229 adolescent females (age 14-20) in Canada. Use of OCs was associated with an estimated 33% lower serum B_{12} level than nonuse, but OC use (as well as alcohol use and smoking) was not significantly associated with lower serum or RBC folate levels, after controlling for folate intake.

The investigators in many of these studies concluded that the effect of OCs on folate is not clinically significant, but their findings are generally limited by the parameters employed to assess folate status and the short duration of the trials.

A "rigorous meta-analysis" of 14 studies by Baillargeon et al.[326] found that "current use" (i.e., use at the time of the event or within 3 months) of low-dose OCs "significantly increases the risk of both cardiac and vascular arterial events," including vascular arterial complications with third-generation OCs. Overall, the use of low-dose OCs was associated with a doubling of the risk of cardiovascular outcomes (myocardial infarction or ischemic stroke), with both second-generation and third-generation OCs being associated with a significantly increased risk of ischemic stroke (relative risk, 2.12). The association between third-generation OC use and myocardial infarction proved nonsignificant.

Researchers often allude to but generally do not directly address the implications for women who might subsequently become pregnant. To address this critical issue, Martinez and Roe[327] investigated residual effects of OCs on the folate status of pregnant women who had discontinued intake of these drugs within 6 months of conception. They found that OC users demonstrated "lower plasma and red blood cell folate values than did the respective control subjects." Factoring in seasonal variability in RBC folate values, which were lower in the winter months, RBC folate values were more affected by previous drug use in the winter group than in the summer group. Also, dietary folate exhibited a significant effect on plasma and RBC folate, and blood folate values were significantly lower in OC users for any given level of folate intake. Correlation of post–OC use folate levels versus non-OC users and risk of subsequent neural tube defect (NTD) pregnancies would be useful.

Researchers and clinicians have long debated the role of folate in the relationship between OC use and the occurrence of cervical dysplasia and cancer. In 1973, Whitehead et al.[328] reported megaloblastic changes in the cervical epithelium in association with OC therapy and reversal with folic acid. In 1982, Butterworth et al.[329] published promising initial research from a 3-month, double-blind placebo-controlled trial where megadoses of folic acid (10 mg daily) were associated with regression of cervical intraepithelial neoplasia (CIN) among OC users. In a 1975 review, Lindenbaum et al.[322] concluded that "about 20 percent of women taking contraceptive hormones manifest mild megaloblastic changes on Papanicolaou smears of the cervicovaginal epithelium which disappear after folic acid therapy," but that (then) "current evidence, however, would not indicate that any significant benefit would ensue from routine folate supplementation in women on oral contraceptives."

In 1996, Zarcone et al.[330] found that folic acid supplements did not alter the course of established cervical dyplasia. Further, at this time, no substantial evidence has been published to support the view that folic acid supplementation alone can play a significant role in the treatment of cervical cancer. In related research concerning human papillomavirus (HPV), often associated with cervical dysplasia, Kwasniewska et al.[331] determined that statistically lower levels of folic acid were found in the women with CIN-HPV (+) and cited other studies showing that lower levels of antioxidants coexisting with low levels of folic acid increase the risk of CIN development. In contrast, Sedjo et al.[332] found "no significant associations ... between HPV persistence and dietary intake of folate, vitamin B_{12}, vitamin B_6, or methionine from food alone or from food and supplements combined or from circulating folate" in 201 women with a persistent or intermittent HPV infection. Moreover, among women not using OCs, folic acid has not been found to improve abnormal Pap smears. However, folate replacement in the range of 5 to 20 mg has been associated with reversal of dysplasia, particularly HPV-related dysplasia (which is the vast majority). The older literature was unaware of the relationship between HPV and cervical dysplasia, and some of the negative studies may have used too low a folic dose. There may also have been disproportionate numbers of MTHFR mutations in the negative studies. Studies should be repeated that control for these factors, with either genetic testing or use of activated folate.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing OCs are advised to discuss with their patients the potential adverse effects of these exogenous hormones on the status of folate and other nutrients, especially vitamin B_6. Folate testing may be warranted, but coadministration of folic acid (400-800 µg/day) with vitamin B_6 (50-100 mg/day) can provide safe and inexpensive support against cardiovascular and other potential adverse effects without interfering with the intended contraceptive effect. Enhanced dietary folate intake and folic acid supplementation are especially important for women who stop using OCs with the intention (or simply the possibility) of becoming pregnant. Those who are diagnosed with cervical dysplasia or who are concerned with increased risks of stroke might particularly benefit from incorporating folic acid into a therapeutic program under the care of a nutritionally trained health care professional. Vitamin B_{12} status should also be checked by serum B_{12} levels or serum/urine MMA levels and corrected as necessary whenever high-dose folic acid therapy is implemented.

Pancreatic Enzymes, Pancreatin, and Related Proteolytic Enzymes

Pancreatic enzymes, pancreatin, proteolytic enzymes.

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability:
4. Plausible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Proteolytic enzymes, including pancreatin, have been reported to form insoluble complexes with folate and interfere with absorption. Diminished absorption of dietary folate could lead to folate deficiency.[333]

Research

In vitro and human studies have reported impairment of folic acid absorption in the presence of oral pancreatic extracts. Russell et al.[334] described higher serum folate levels "among newly diagnosed, untreated patients with pancreatic insufficiency than among treated patients despite greater fat malabsorption in the former group." Further, in vivo experiments

involving "folate absorption tests using tritium-labeled pteroylmonoglutamatic acid showed folate absorption to be enhanced in pancreatic insufficiency patients as compared to control subjects." Also, "pancreatic extract significantly inhibited folate absorption" in both normal subjects and patients with pancreatic insufficiency. The authors recommended that "folate status should be monitored in patients being treated for pancreatic insufficiency," especially when pancreatic extract and bicarbonate are coadministered. Further research is warranted.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Health care professionals prescribing pancreatin and other proteolytic enzymes are advised to suggest concomitant supplementation with folic acid (400 µg/day) to counteract any resultant decrease in folate absorption and prevent diminished folate status. Monitoring of folate levels may be appropriate in patients with susceptibility to or history of folate deficiency or comorbid conditions, in whom folate deficiency could cause enhanced risk. Administering folate supplements several hours before or after intake of pancreatic enzyme preparations would also appear prudent.

Pyrimethamine

Pyrimethamine (Daraprim); combination drug: sulfadoxine and pyrimethamine (Fansidar).

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability:
3. Possible or
2. Probable

Evidence Base:
◉ **Emerging** to
● **Consensus**

Effect and Mechanism of Action

Pyrimethamine is a competitive inhibitor of dihydrofolate reductase that acts as a folic acid antagonist and can reduce serum folic acid levels. Pyrimethamine is widely recognized as a cause of megaloblastic anemia resulting from a folate deficiency. In combination with sulfadiazine, it is often used in the treatment of toxoplasmosis. However, bone marrow suppression, resulting predominantly from depression of folate metabolism and causing neutropenia and thrombocytopenia, is a frequent toxic adverse effect. Coadministration of folic acid (or more often, 5-MTHF as folinic acid) can mitigate adverse effects on folate levels and function but could decrease pyrimethamine efficacy because of pharmacodynamic antagonism.

Fansidar, an antimalarial agent, is a combination of sulfadoxine and pyrimethamine that inhibits sequential steps involved in the biosynthesis of tetrahydrofolic acid. Thus, interference with protozoal nucleic acid and protein production is achieved by depleting folic acid, an essential cofactor in the biosynthesis of nucleic acids. Sulfadoxine competitively inhibits the enzyme dihydropteroate synthetase; it is a structural analog of PABA. The dual sequential action of these two agents creates a synergistic effect that enables reduction of the minimum effective dose of each medication but amplifies the antifolate effects.

Research

Although the mechanism of action of pyrimethamine and its adverse effects on folate status are widely acknowledged, the frequency and conditions of clinically significant interactions are not well known. At lower doses the need for folic acid coadministration has not been researched adequately to enable well-founded conclusions. The risk of bone marrow suppression can increase significantly with concurrent use of pyrimethamine and other antifolates, such as methotrexate or sulfa antibiotics. At higher doses, such as used in treatment of toxoplasmosis and *Pneumocystis carinii* pneumonia, folate support may be necessary. However, such concurrent administration may impair the therapeutic activity of pyrimethamine, although this has not been established with careful clinical research.

Of several dihydrofolate reductase inhibitors tested against *P. carinii* in a rat model, Walzer et al.[335] noted that "all drugs were well tolerated except pyrimethamine, which caused bone marrow depression; folinic acid ameliorated this adverse reaction but did not interfere with *P. carinii* treatment." This suggests that the previous caution regarding potential interference with therapeutic activity of pyrimethamine by at least some forms of folic acid may not be a concern.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing pyrimethamine, alone or in combination with other agents, are advised to consider coadministration of folic acid or 5-MTHF as a preventive measure. Folinic acid is the form of 5-MTHF most often used in conventional practice, 5 to 15 mg/day (orally, intravenously, or intramuscularly) until normal hematopoiesis restored, although L-5-MTHF (Metafolin) may be preferable, because it is the chiral form used by the body. Folate and pyrimethamine levels should be monitored regularly. Pyrimethamine dose may also need to be reduced or the medication discontinued if folate deficiency develops, depending on patient response. Caution is also warranted in patients with hepatic or renal impairment. Pyrimethamine may precipitate hemolytic anemia in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Although the safety of pyrimethamine in pregnancy has not been well researched, prudence suggests that increased folic acid supplementation may be warranted with female patients who are or might become pregnant.

Sulfasalazine and Related Sulfonamide Antibiotics (Systemic)

Sulfasalazine (salazosulfapyridine, salicylazosulfapyridine, suphasalazine; Apo-Sulfasalazine, Azulfidine, Azulfidine EN-Tabs, PMS-Sulfasalazine, Salazopyrin, Salazopyrin EN-Tabs, SAS).

● **Consensus**

Effect and Mechanism of Action

Sulfonamides, including sulfasalazine, interfere with the absorption, bioavailability, and activity of folic acid, as well as adversely affecting vitamin B_6 and vitamin K. Sulfasalazine can impair absorption and transport of folic acid and dietary folate, most likely acting as a competitive inhibitor.[314,336-338] The target of sulfonamides, and the basis for their selectivity, is the enzyme dihydropteroate synthase (DHPS) in the folic acid pathway.[339] Sulfasalazine also inhibits other folate-dependent enzymes, particularly dihydrofolate reductase, methylenetetrahydrofolate reductase, and serine transhydroxymethylase, as discussed earlier with interactions involving NSAIDs as a class. Animal research indicates that "sulfasalazine interferes with a folate recognition site which is common to these enzymes and to the intestinal transport system."[313] Sulfasalazine-induced blood dyscrasias might involve folic acid depletion. "The mechanisms by which sulfasalazine antagonizes folate metabolism are dose-dependent and, consequently, higher doses might precipitate folate deficiency."[340]

Research

Sulfasalazine is well known for adversely affecting folate, but some controversy exists as to whether the drug by itself can cause clinically significant deficiencies of folic acid. Megaloblastic anemia caused by sulfasalazine has responded to drug withdrawal alone.[341] However, a high proportion of the literature indicates a multifactorial causality for folate depletion in the affected populations, with the adverse effects of sulfasalazine being an important but not necessarily adequate stress. The conditions for which sulfasalazine is typically prescribed are often associated with malabsorption, poor diet, old age, and chronic inflammation. For example, a high proportion of individuals with inflammatory bowel disease and ulcerative colitis exhibit compromised folate status.[342]

In addition to the increased risks associated with hyperhomocysteinemia resulting from drug-induced folate deficiency, the association between folate status and colorectal cancer risk may be especially relevant to individuals in such populations. Ulcerative colitis, folate-related polymorphisms, and folate deficiency have all been linked to an increased risk for colon cancer.[343-348] A wide range of authors further suggest that increased folate intake may play a preventive (and/or therapeutic) role against some colorectal cancers.[348-354] Significant research demonstrates the contributory role of sulfasalazine in the etiology of folate deficiency among patients treated for ulcerative colitis. However, other evidence suggests that although sulfasalazine impairs folate absorption among such patients, "this only becomes significant if other reasons for folate deficiency are also present."[336,355] Thus, optimal folate status represents an important factor in the therapeutic strategy for care of patients with ulcerative colitis and irritable bowel disease and increased risk for colorectal cancer.

The available evidence indicates that the risk of clinically significant folate deficiency may not be high among patients treated with sulfasalazine generally, but that high doses increase adverse effects, including deficiency, and that folate deficiency could play a significant role in both GI and overall disease risk. However, a review of the range of human studies in this area also suggests that the researchers' choices for laboratory measures to assess absorption and metabolism folate and their implications may be influential in shaping the findings and conclusions.

In 1981, Halsted et al.[336] found that sulfasalazine inhibits the absorption of folates in patients with ulcerative colitis. In 1982, Longstreth and Green[342] analyzed hematological data, including serum and RBC folate assays, from 45 outpatients with chronic colitis, 27 of whom were receiving maintenance doses of sulfasalazine. Mean hemoglobin, hematocrit, serum folate, and RBC folate levels were similar overall in sulfasalazine users and nonusers. However, among the sulfasalazine users, "RBC folate was inversely correlated with drug dose; serum folate was not," and those "taking 2 g or more of sulfasalazine daily had lower mean RBC folate levels (221.2 ± 27.3 ng/mL) than patients either taking less (371.7 ± 35.0 ng/mL) or nonusers (330.3 ± 30.3 ng/mL)." Also, mean RBC corpuscular volume (MCV) was related to drug dose but not to RBC folate. The authors concluded: "Although maintenance sulfasalazine use rarely causes clinically significant folate deficiency, subclinical tissue depletion occurs as a dose-related effect."[342]

In a case-control study of patients with chronic ulcerative colitis, Lashner et al.[356] found a 62% lower risk of colon cancer with folate supplementation, compared to ulcerative colitis patients who did not supplement with folic acid. In a later study involving 98 patients with ulcerative colitis, Lashner and a different team[357] found that individuals who have ulcerative colitis and who supplement folic acid had a 55% lower risk of developing colon cancer. The dose of folate varied with the risk of neoplasia, and folate use also varied with the degree of dysplasia. Although these findings were not statistically significant, the authors concluded that daily folate supplementation may protect against the development of dysplasia or neoplasia in ulcerative colitis patients. Although diverse factors contribute to colon cancer, many researchers suggest that folic acid deficiency may increase susceptibility, and that folic acid supplementation and enhanced dietary folate intake may have a preventive effect.

The implications of sulfasalazine therapy on folate status in patients treated for rheumatoid arthritis (RA) parallel those of patients with bowel disorders. In a prospective study of 30 subjects, Grindulis and McConkey[340] investigated the effects of sulfasalazine on folate deficiency in RA patients, who often have low serum and RBC folate concentrations. Pretreatment serum and RBC folate concentrations were low-normal. They administered 2 g sulphasalazine over 24 weeks, using 500 mg penicillamine daily for controls, although knowledge of possible interactions between folate status and penicillamine is incomplete. No change was observed in serum and RBC folate concentrations in either group. However, MCV increased only in patients taking sulfasalazine, possibly reflecting reticulocytosis secondary to drug-induced hemolysis. Measurement of reticulocyte counts might clarify any future investigation in this area.

In 1996, Krogh Jensen et al.[315] analyzed plasma total homocysteine (tHcy, as a sensitive marker of folate deficiency), serum folate, erythrocyte (RBC) folate, serum cobalamin, and routine indices of hemolysis in 25 arthritis outpatients treated

with sulfasalazine, to assess the frequency of folate deficiency and hemolysis among such patients. Notably, none of the subjects had taken folate-containing vitamins for at least 8 weeks preceding the trial; it is unclear whether this was by exclusion design or simply reflective of the patient population. The control group consisted of 72 healthy hospital staff. The patient group exhibited median plasma tHcy that was significantly higher than controls, with five patients (20%) having plasma tHcy levels that exceeded the upper-normal limit. Median serum folate was significantly lower in the patient group, with 11 patients (40%) exhibiting depressed serum folate. Notably, there was no difference in the levels of RBC folate between the two groups, and only three patients (12%) had RBC folate values below the reference interval. Furthermore, no patient had cobalamin deficiency, as assessed by serum cobalamin and methylmalonate, but the treated group exhibited significantly lower *S*-cobalamin levels. These findings also indicate it is "unlikely that any patient had increased plasma tHcy due to cobalamin deficiency." The authors also reported that 12 of the 24 treated subjects in whom HbA_{1c} was measured had decreased levels indicating chronic hemolysis. They proposed that the chronic hemolysis caused by sulfasalazine "might explain the similar RBC folate values in the two groups because of a relatively higher folate content of young erythrocytes." The authors concluded that observed patterns in plasma tHcy among those treated with sulfasalazine "suggest that a substantial number of patients may have folate deficiency at the tissue level."[315] Their findings also demonstrate the need for determination of and testing with sensitive indicators of folate status, which RBC folate does not appear to be.

Initial research indicates that drug-induced effects on folate are not likely to have teratogenic effects, but evidence is limited and inconclusive. In a population-based case-control study of the safety of sulfasalazine use during pregnancy, Norgard et al.[357a] found no significant increased prevalence of selected congenital abnormalities in the children of women treated with sulfasalazine during pregnancy. Further research is warranted.

Reports

In 1986, Logan et al.[358] reported that sulfasalazine-associated pancytopenia may be caused by acute folate deficiency. They described three patients who, after taking sulfasalazine for more than 2 years, "suddenly developed severe pancytopenia with gross megaloblastic changes in the marrow." Administration of "high dose oral folic acid" achieved a "good response" in two patients, "but the third required folinic acid." The authors proposed acute folate deficiency as the apparent mechanism involved, noting that "the requirement for folinic acid in one case suggests that the known inhibition of folate metabolism by sulphasalazine also contributes." Furthermore, they observed that "the syndrome appears to be associated with high dosage and slow acetylator status." Subsequently, therapy was well tolerated in two patients after the drug was "restarted at reduced dosage with folate supplements"; both patients were "slow acetylators." The progression of disease in the third patient, however, led to colectomy, and her acetylator status was not determined.

In a 1999 review, Hoshino et al.[359] reported a case of ulcerative colitis with folate-deficient megaloblastic anemia induced by sulfasalazine.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing sulfasalazine for longer than 2 weeks should be alert to risk factors for compromised folate status, monitor blood and tissue folate levels using sensitive indicators, and coadminister folic acid, typically 500 to 600 µg twice daily, when appropriate. Folate has no known risks at the suggested levels and can potentially provide a number of benefits to those taking sulfasalazine. In particular, folate supplementation during sulfasalazine administration is recommended, especially to reduce the risk of dysplasia or cancer in patients with ulcerative colitis. Recommendations within conventional practice have favored high-folate foods rather than folic acid supplements, but increased intake through both forms seems reasonable and more likely to be effective. Clinically significant adverse effects are improbable with sulfasalazine therapy of 2 weeks or less. Even though evidence of heightened risks during pregnancy is lacking, prudence suggests that all women undergoing sulfasalazine therapy supplement with 1000 µg or more of folic acid for 6 months before becoming pregnant and continuing throughout pregnancy.

The available research consistently demonstrates that sulfasalazine exerts multiple adverse effects on folate and suggests that such antagonistic effects on folate metabolism are dose dependent. Consequently, higher doses (and longer duration of treatment) will tend to increase risk and degree of adverse effects and might precipitate folate deficiency. Such risks increase in patients with genetic predispositions to folate metabolism dysfunctions or other factors contributing to compromised folate status. Given the low cost and nontoxic nature of folic acid, enhanced intake (via supplements or foods) represents a simple, low-risk adjunctive therapy for every patient taking sulfasalazine, unless otherwise indicated.

Tetracycline Antibiotics (Systemic)

Demeclocycline (Declomycin), doxycycline (Atridox, Doryx, Doxy, Monodox, Periostat, Vibramycin, Vibra-Tabs), minocycline (Dynacin, Minocin, Vectrin), oxytetracycline (Terramycin), tetracycline (Achromycin, Actisite, Apo-Tetra, Economycin, Novo-Tetra, Nu-Tetra, Sumycin, Tetrachel, Tetracyn); combination drugs: chlortetracycline, demeclocycline, and tetracycline (Deteclo); bismuth, metronidazole, and tetracycline (Helidac).

Effect and Mechanism of Action

The several mechanisms of interaction between the tetracycline class of antibiotics and folic acid are complex and conflicting, depending on dose, duration, timing, and patient characteristics. Folic acid may interfere with the absorption and effectiveness of tetracycline antibiotics if ingested simultaneously, and vice versa.[360] Tetracyclines inhibit bacterial protein synthesis by binding to the 30S ribosome, blocking access of the aminoacyl tRNAs at the "A" acceptor site on the mRNA-ribosome complex. These drugs may interfere with the activity

and induce the depletion of folic acid and other nutrients, particularly other B vitamins.[361] Additionally, extended or recurrent use of antibiotics can cause folate depletion by eliminating the healthy intestinal flora, a major source of endogenous biosynthesis of folate (and B_{12}).[362,363] Many patients with conditions for which tetracyclines are prescribed have depleted folate nutriture.

Research

Omray and Varma[360] demonstrated that oral administration of a vitamin C– and vitamin B–complex formulation could impair absorption and reduce bioavailability of tetracycline hydrochloride through pharmacokinetic interference. However, numerous clinicians and authors fail to mention such risks or advise appropriate corrective measures in discussions of coadministration of these agents.

Some patient populations receiving antibiotic therapy have pathophysiological conditions, medical history, and lifestyle/dietary factors characterized by malnutrition, malabsorption, or nutrient depletion. For example, evidence spanning four decades indicates that tetracyclines and folic acid may provide enhanced therapeutic efficacy in many situations (e.g., treatment of tropical sprue), but that separation of oral intake may be essential to efficacy.[364] Westergaard[365] summarizes the evolution and rationale of the primary treatment strategy as follows:

> Patients with tropical sprue typically present with macrocytic anemia due to malabsorption of folate and/or vitamin B_{12}. Treatment of tropical sprue with folic acid replacement was introduced more than 50 years ago and has become standard medical treatment. Vitamin B_{12} replacement is usually added if there is evidence of B_{12} deficiency or malabsorption. Treatment of tropical sprue with folate and B_{12} cures the macrocytic anemia and the accompanying glossitis, and often results in increased appetite and weight gain. However, even prolonged treatment with these vitamins fails to restore villus atrophy, and malabsorption usually persists. The benefit of antibiotic treatment of tropical sprue was first documented during World War II, when sulfonamides were used to treat epidemics of tropical sprue in British and Italian troops in India. Antibiotic treatment has since become the standard treatment, and tetracycline has replaced sulfonamides. The recommended length of treatment with tetracycline is 6 months and it is given in combination with folate.

Reports

Similarly, in a discussion of several cases of tropical sprue among indigenous patients in Australia, with a history of excessive alcohol intake and characterized by alteration in the intestinal microflora, overgrowth of coliform bacteria, mucosal damage and malabsorption, and protein loss, Hanson[366] recommended that concomitant tetracycline use, specifically doxycycline, and folic acid therapy "can be rapidly and dramatically effective, although the tetracycline course should continue for 3-6 months."

Note: Falsely low serum folate concentrations may occur with the *Lactobacillus casei* assay method in patients receiving tetracycline therapy.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing tetracycline antimicrobials, repeatedly or for more than 2 weeks, are advised to coadminister folic acid; a moderate supplemental dose of 400 to 800 µg/day typically is adequate. These levels may also be obtained through a diet rich in leafy green vegetables, beans, beets, citrus, meat, and wheat germ. The importance of such nutrient support is amplified in pregnant women and individuals with compromised nutritional status or a history of high alcohol intake.

No evidence demonstrates an increased risk for major birth defects in children exposed to tetracycline in the first trimester of pregnancy. Nevertheless, tetracyclines are generally contraindicated after the first trimester of pregnancy (and in children <8 years old) because they tend to cause staining of teeth, hypoplasia of dental enamel, and abnormal bone growth in children and in the fetuses of pregnant women.

Coadministration of probiotic flora along with vitamins B_{12} and K is usually appropriate. The aim of an integrative approach combining tetracycline, folate, and vitamin B_{12} is to restore intestinal mucosal structure, normalize absorptive function, correct folate and B_{12} deficiencies, and correct any macrocytic anemia.

In most patients, only the probiotic flora are appropriate when a shorter course of a tetracycline (7-10 days) is administered as a countermeasure to the antibiotic-induced disruption of healthy intestinal ecology. Regular supplementation with vigorous cultures of *Lactobacillus acidophilus, Bifidobacterium bifidus,* and other probiotic bacteria for 2 to 4 weeks can safely and effectively preclude or reverse subsequent antibiotic-induced folate depletion; up to 6 months of probiotic intake may be necessary to fully reestablish the symbiotic intestinal flora in patients receiving more than one course of antibiotics.

Tetracycline should be administered at least 2 hours before or 4 hours after oral intake of folic acid, alone or as part of a B-complex or multivitamin formulation, to avoid interference with gastric absorption. Evidence for such an adverse interaction is minimal, but prudence suggests that such simple precautions may be beneficial.

Triamterene and Related Potassium-Sparing Diuretics

Evidence: Triamterene (Dyrenium).
Extrapolated, based on similar properties: Amiloride (Midamor), spironolactone (Aldactone); combination drugs: amiloride and hydrochlorothiazide (Moduretic); spironolactone and hydrochlorothiazide (Aldactazide); triamterene and hydrochlorothiazide (Dyazide, Maxzide).

- ⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
3. Possible

Evidence Base:
◉ **Emerging** to
● **Consensus**

Effect and Mechanism of Action

Triamterene impairs folate absorption and bioavailability and may contribute to folate depletion, at least in part because of its structural similarity to folic acid. Animal research also found that triamterene acted as a competitive inhibitor of folate absorption in the rat intestine.[367] Triamterene also acts as a relatively weak folate antagonist by inhibiting dihydrofolate reductase, which is necessary to converting unreduced dietary

folates into tetrahydrofolates, the biologically active folates. Triamterene has been known to contribute to the appearance of megaloblastosis in patients with decreased folic acid stores.[114,368-370]

Research

For more than four decades, researchers have investigated the mechanisms as well as the frequency and circumstances of clinically significant triamterene-induced adverse effects on folate, particularly teratogenesis and hyperhomocysteinemia. In 1967, Maass et al.[371] first investigated the effect of triamterene on folic reductase activity and reproduction in the rat. In 1986, Zimmerman et al.[367] investigated the effect of triamterene on folic acid absorption in the rat jejunum. Applying an in vivo intestinal loop method, triamterene inhibited the intestinal absorption of folic acid in a dose-dependent fashion, with 50% inhibition of systemic absorption occurring at a luminal concentration of 0.01 mmol/L of triamterene. However, animal studies are not always predictive of human response.

Schalhorn et al.[368] documented the dose-related inhibitory effect of triamterene and its metabolites on human leukocyte dihydrofolate reductase. The authors concluded by emphasizing the potential significance of these findings in relation to "the possible toxic side effects of long-term triamterene treatment in patients suffering from alcoholic cirrhosis, who may have impaired metabolism of triamterene and a concomitant severe folate deficiency."

Mason et al.[372] studied 272 elderly individuals in two free-living populations receiving chronic diuretic therapy and found normal folic acid levels and no signs of folic acid deficiency among 32 patients who used triamterene at unknown dose levels on a long-term basis, but lacked additional risks for folic acid deficiency. The possibility of confounding variables limits the strength of findings from this observational study.

The administration of multivitamin supplements containing folic acid appears to diminish the occurrence of birth defects associated with periconception exposure to triamterene and other folic acid antagonists.[373] Hernández-Díaz et al.[76] investigated possible adverse effects of a broad range of folic acid antagonists (including trimethoprim, triamterene, carbamazepine, phenobarbital, and primidone) during pregnancy in an ongoing case-control study of birth defects (1979–1998) in the United States and Canada. First, they studied the exposure to folic acid antagonists that act as dihydrofolate reductase inhibitors (including triamterene) and to certain antiepileptic drugs in 3870 infants with cardiovascular defects, 1962 infants with oral clefts, and 1100 infants with urinary tract defects; the control group consisted of 6249 infants with structural defects and 2138 infants with chromosomal or mendelian defects. The authors determined that the "relative risks of cardiovascular defects and oral clefts in infants whose mothers were exposed to dihydrofolate reductase inhibitors during the second or third month after the last menstrual period, as compared with infants whose mothers had no such exposure, were 3.4 and 2.6 respectively." Furthermore, they observed that the "use of multivitamin supplements containing folic acid diminished the adverse effects of dihydrofolate reductase inhibitors, but not that of antiepileptic drugs."[76] Subsequently, these researchers examined related data to determine whether periconception exposure to folic acid antagonists (FAAs) might increase the risk of neural tube defects (NTDs), specifically spina bifida, anencephaly, and encephalocele. Their findings suggest that "a number of FAAs may increase NTD risk, and they provide estimates of risk for selected drugs."[79] However, these data concerned a number of folate antagonists and, as such, are limited in their applicability to triamterene.

A probable link between hypertension and folate deficiency, via homocysteine (Hcy), suggests that any adverse effects by diuretics on folate status could contribute to increased risk for cardiovascular disease. Comparing blood samples from 17 hypertensive patients receiving long-term diuretic therapy and 17 hypertensive patients not taking diuretics, Morrow and Grimsley[374] observed that, in general, long-term diuretic therapy (>6 months) is associated with a significant increase in serum Hcy concentration and a significant decrease in RBC folate concentration. In 2005, Forman et al.[266] found that higher total folate intake was associated with a decreased risk of incident hypertension, particularly in younger women.

Reports

Case reports in the literature describe patients, particularly with cirrhosis or otherwise-compromised liver function, who developed megaloblastic anemia while being treated with triamterene, most often at higher doses (150-600 mg/day).[114,375]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Patients receiving antihypertensive therapy using triamterene or related diuretics may benefit from the Hcy-lowering effects of folic acid, particularly if they have a history of, or significant risk factors for, inadequate folate intake, nutrient depletion, or hyperhomocysteinemia. Such concomitant nutrient support may be prudent, even though evidence indicates that triamterene at typical doses is not likely to affect folate status to a clinically significant degree in most patients. Folate supplementation during (or before) pregnancy is essential, and an increased dose may be warranted in women treated with triamterene; other treatment options might also need to be considered.

Even though the research thus far indicates adverse effects from triamterene in patients with folate deficiency, it is important to note that the diet of a significant portion of the population in the United States, Canada, the United Kingdom, and similar settings does not provide the recommended levels of folate. Assessment of tissue folate and plasma tHcy levels, within the context of the individual patient's risk factors including (e.g., diet, family history, genomic polymorphisms), is essential to shaping a customized and evolving integrative strategy for prevention and treatment of cardiovascular disease.

A therapeutic strategy incorporating coadministration of folic acid might require using 5-MTHF, the vitamin's activated form, such as folinic acid, in some patients, because triamterene interferes with the vitamin's activation, thus rendering common folic acid supplements potentially ineffective. Research is lacking to confirm or disprove this possibility.

Trimethoprim-Sulfamethoxazole

Cotrimoxazole and related trimethoprim-containing antibiotics: Trimethoprim (Proloprim, Trimpex); combination drug: trimethoprim and sulfamethoxazole (cotrimoxazole, co-trimoxazole, SXT, TMP-SMX, TMP-sulfa; Bactrim, Bactrim DS, Cotrim, Septra, Septra DS, Sulfatrim, Uroplus). Related drugs: Dapsone (DDS, diaminodiphenylsulphone; Aczone; Avlosulfon), sulfonamides, sulfones.

Effect and Mechanism of Action

Trimethoprim and sulfamethoxazole (cotrimoxazole) interfere with the bacterial biosynthesis of folic acid by inhibiting tetrahydrofolate synthesis.[376] Trimethoprim acts as folate antagonist by inhibiting dihydrofolate reductase, which is necessary to converting unreduced dietary folates into tetrahydrofolates, the biologically active form.[377,378] It is generally considered that trimethoprim inhibits the bacterial enzyme more efficiently than the human enzyme (sensitivity of bacterial enzyme 10000-fold > mammalian), and therefore the drug theoretically has only a minimal risk of adverse effects on biosynthesis of folic acid in humans. However, the risk of folate depletion and inhibition of granulopoiesis can be significant with high-dose or prolonged use, presumably more so in the presence of folate deficiency; neutropenia may result. Sulfamethoxazole and other sulfonamides interfere with folate by competitively displacing PABA from its binding site on dihydropteroate synthase, the enzyme that catalyzes a key step in the biosynthesis of folic acid.[379] Teratogenicity and macrocytic anemia are known adverse effects associated with cotrimoxazole-induced folate deficiency.

Concomitant intake of folic acid at high doses could theoretically decrease efficacy of trimethoprim and sulfamethoxazole because of antagonistic effects. Coadministration of 5-methyltetrahydrofolate (5-MTHF), such as folinic acid (leucovorin calcium), instead of folic acid, is usually appropriate given the inhibition of dihydrofolate reductase by the antibiotics.

Research

Sulfamethoxazole and trimethoprim are known inhibitors of tetrahydrofolate synthesis and may partially deplete reduced folate levels.[376,377] Furthermore, folic acid deficiency increases risks of toxicity from these agents. This interaction is widely acknowledged. Trimethoprim-sulfamethoxazole (TMP-SMX) is associated with folic acid deficiency anemia, but the incidence of this adverse effect is generally believed to be rare. Overall, consensus has yet to emerge as to the frequency, severity, and circumstances of clinically significant events or management of potential interference between trimethoprim and folic acid.

Kahn et al.[377] found that administration of trimethoprim (1 g/day) for more than 14 days appears to impair folate utilization to some extent, which may lead to hematological changes reversible with folic acid (400 μg/day). Bjornson et al.[380] conducted two linked studies investigating the antifolate action contributing to the neutropenia occasionally observed in patients treated with TMP-SMX. First, they administered TMP-SMX to 12 healthy adults and observed that the "number of circulating granulocytes and granulocyte progenitors was not significantly altered by a 5-day course of therapy." However, they conducted experiments that simulated the in vivo condition of folate deficiency to investigate the antifolate action of these drugs on circulating granulocyte precursors (CFU-C) from normal donors and the mechanism of inhibition on granulopoiesis. Trimethoprim (8 μg/mL) resulted in a 47% decrease in the total number of colonies, whereas the combination of 8 μg/mL trimethoprim and 40 μg/mL sulfamethoxazole resulted in a 52% decrease in the number of colonies. In both situations, adding folinic acid to the culture prevented this inhibitory effect. In contrast, sulfamethoxazole (40 μg/mL) alone exerted "no discernible effect on granulopoiesis."[380]

In a study of 12 AIDS/HIV patients with or suspected of *Pneumocystis carinii* pneumonia, Bygbjerg et al.[381] found that neither folic acid nor folinic acid reversed cotrimoxazole-induced cytopenia. They concluded, however, that although "routine prescription of folinic acid is not recommended," supplementation with folic acid is inexpensive and "may be beneficial and should be prescribed." Subsequently, Safrin et al.[382] reported that coadministration of folinic acid with TMP-SMX for *P. carinii* pneumonia in AIDS patients is associated with an increased risk of therapeutic failure and decreased survival rate.

No evidence has appeared to support the proposition that administration of folic acid or an activated 5-MTHF might significantly impair the therapeutic activity of trimethoprim or sulfamethoxazole. It is now generally accepted that concomitant folic acid, in typical doses, does not interfere with the antibacterial activity of trimethoprim or TMP-SMX.[383,384]

Reports

Numerous case reports have described "neutropenia developing during even brief periods of oral therapy, particularly in individuals with either folate deficiency or increased folate requirements."[380]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing trimethoprim and sulfamethoxazole, alone or in combination, should be aware that these agents may impair folate metabolism to a clinically significant extent. Concomitant folate may prevent or reverse adverse effects on folate activity and hematopoietic processes but generally is not necessary unless the patient has a preexisting folate deficiency, increased folate requirements, or otherwise-compromised folate status. Trimethoprim and TMP-SMX should be prescribed with caution in patients with known or potential folic acid deficiency; close supervision and regular monitoring of folate status are warranted.

Although some researchers and clinicians suggest that administration of folinic acid (leucovorin calcium) may be necessary to achieve such effects, because of drug-induced inhibition of dihydrofolate reductase, others have found that folic acid can usually achieve a therapeutic response. Pharmacogenomic variants related to folate metabolic pathways may also influence which form is required. Other forms of 5-methyltetrahydrofolate, such as 6(S) 5-MTHF (L-methyl folate or Metafolin), would be expected to be equally efficacious.

Many authorities caution against use of trimethoprim and sulfamethoxazole during pregnancy. Concomitant folic acid becomes imperative if such medications are necessary during pregnancy, with a dose of at least 800 μg/day being appropriate.

Zidovudine/AZT

Zidovudine (azidothymidine, AZT, ZDV, zidothymidine; Retrovir); combination drugs: zidovudine, and lamivudine (Combivir); abacavir, lamivudine, and zidovudine (Trizivir).

Interaction Type and Significance

◇≈≈ Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management

≈≈ Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management

☼ Prevention or Reduction of Drug Adverse Effect

Probability: 2. Probable to 1. Certain

Evidence Base: ● Consensus

Effect and Mechanism of Action

Hematological toxicity is the most common adverse effect related to long-term administration of zidovudine (AZT), with macrocytosis developing in a large majority of AZT-treated subjects, despite folate and vitamin B_{12} supplementation. The macrocytosis is caused by AZT interfering with DNA replication in bone marrow RBC precursors. As a nucleoside analog, AZT interferes with HIV DNA production by reverse transcriptase, but also with non-HIV DNA as well. Folate and B_{12} deficiency leads to RBC macrocytosis, also by interfering with DNA synthesis, but based on deficiency versus toxicity. Consequently, administration of folate/B_{12} may fail to ameliorate AZT's hematological toxicity.

Research

In a rodent model using CBA/Ca mice, Cronkite et al.[385] found that "higher doses of folate given daily" resulted in partial amelioration of AZT-induced macrocytic anemia. A B_{12}/folate regimen was ineffectual.

In several placebo-controlled studies, macrocytosis, anemia, and granulocytopenia were the most significant adverse effects associated with zidovudine use, especially among patients with advanced, symptomatic HIV disease. Significant anemia most often occurred after 4 to 6 weeks of therapy and in many cases required dose adjustment, discontinuation of zidovudine, or blood transfusions.[386] In 2002, Romanelli et al.[387] conducted a retrospective chart review in an outpatient HIV clinic and concluded that "macrocytosis may be useful in assessing adherence to zidovudine-containing antiretroviral regimens."

Manfredi et al.[388] investigated the kinetics of modifications of some hematological parameters of erythroid series in 65 patients with HIV infection treated with AZT for a mean duration of 7.6 months and correlated the observed evolution of these laboratory changes with the onset of severe anemia. They reported "no correlation between an elevated mean corpuscular volume and the development of severe anaemia (Hb less than or equal to 9 g/dL) in an individual patient; a fall in the reticulocyte count appears to be the earliest peripheral blood sign of the development of bone marrow toxicity."

In 1993, Snower and Weil[389] studied 100 consecutive inpatients in a large metropolitan urban hospital with mean corpuscular volumes greater than 110 fL. Of these, 44% were AIDS patients receiving zidovudine, 19% were alcoholic patients, and 12% had malignant neoplasms. Only 3% were folate deficient and 4% vitamin B_{12} deficient by conventional measures. The authors concluded that "zidovudine has become the most common cause of macrocytosis in the hospitalized urban patient population," and "vitamin B_{12} and folate deficiencies have decreased in proportion."

However, in a prospective, randomized study involving 60 HIV-infected patients receiving zidovudine, Falguera et al.[390] compared hematological toxicity of either ZDV (AZT, 500 mg daily) alone or in combination with folinic acid (15 mg daily) and intramascular vitamin B_{12} (1000 μg monthly). During the study, vitamin B_{12} and folate levels were significantly higher in vitamin-treated patients, but no differences in hemoglobin, hematocrit, mean corpuscular volume, or white cell, neutrophil, or platelet count were observed between groups at 3, 6, 9, and 12 months. Moreover, they observed "severe hematologic toxicity" in four zidovudine-only patients and seven assigned to the vitamin-treated group. They reported "no correlation between vitamin B_{12} or folate levels and development of myelosuppression." The authors concluded that coadministration of vitamin B_{12} and folinic acid with AZT therapy "does not seem useful in preventing or reducing ZDV-induced myelotoxicity in the overall treated population, although a beneficial effect in certain subgroups of patients cannot be excluded."[390]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing zidovudine/AZT are advised to monitor closely the folate and vitamin B_{12} status of patients, using sensitive indicators capable of accurately assessing hematological and tissue levels of these vitamins and their functional surrogates, such as homocysteine and methylmalonate. Concomitant administration of folic acid (or 5-MTHF) and B_{12} may be appropriate to prevent or reverse adverse effects, with prophylactic measures generally being prudent in patients with a history of folate deficiency, compromised nutritional status, or other risk factors for susceptibility. However, clinical experience and research indicate that such nutrient support is often inadequate in reducing macrocytosis and marrow suppression in many patients, and that modification of the drug regimen is often necessary.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Acyclovir

Acyclovir (Zovirax)

Acyclovir is a synthetic purine nucleoside analog that achieves its antiviral activity by acting as a purine antagonist, and it is known to induce macrocytic nonmegaloblastic anemia. The mechanism of interaction with folic acid, when it occurs, appears to be direct bone marrow toxicity, rather than being mediated through a folate interaction. However, concomitant folate deficiency would very likely compound any drug toxicity and should therefore be avoided.

Close monitoring of folate status through sensitive indicators is prudent, especially in patients on long-term acyclovir therapy who have a history of folate deficiency, compromised nutritional status, or other risk factors for susceptibility.

Antibiotics

Antibiotics

See also individual agents or classes.

Along with the serious issue of multidrug antibiotic resistance, the loss or impairment of endogenous production of B vitamins, including folate, is one of the most important adverse effects resulting from a substantial course of antibiotics, by significantly damaging or destroying the symbiotic bacterial flora of the intestinal microbiota. *Acidophilus*, bifidobacteria, and other enteral bacteria manufacture folic acid and other B vitamins, such as niacin, biotin, and vitamin B_6.[391-401]

The effects of antibiotics as a broad grouping of agents and drug classes on folate status is more accurately described as "unresearched" rather than unproven. Although knowledge

and appreciation of the manifold functions of healthy bacteria have grown exponentially in recent years, the full clinical significance is not yet understood. Continued research into the systemic long-term effects of broad-spectrum antimicrobials is warranted, with implications on the functions and activity of folic acid deserving special attention.

Concomitant or subsequent administration of folic acid, vitamin B_{12}, and large doses of vigorous variegated probiotic flora provides a safe and inexpensive means of supporting healthy gut ecology and nutrient metabolism to prevent or correct direct and indirect adverse effects from antibiotic therapy, particularly in high doses or with repeated or long-term courses.

Beta-Adrenergic Blocking Agents and Calcium Channel Blockers (Systemic)

Beta-1-adrenergic blocking agents (beta-1 antagonists): Acebutolol (Sectral), atenolol (Tenormin); combination drugs: atenolol and chlorthalidone (Co-Tendione, Tenoretic), atenolol and nifedipine (Beta-Adalat, Tenif); betaxolol (Kerlone), bisoprolol (Zebeta), carteolol (Cartrol), esmolol (Brevibloc), labetalol (Normodyne, Trandate), metoprolol (Lopressor, Toprol XL); combination drug: metoprolol and hydrochlorothiazide (Lopressor HCT); nadolol (Corgard), nebivolol (Nebilet), oxprenolol (Trasicor), penbutolol (Levatol), pindolol (Visken), propranolol (Betachron, Inderal LA, Innopran XL, Inderal); combination drug: propranolol and bendrofluazide (Inderex); sotalol (Betapace, Betapace AF, Sorine), timolol (Blocadren).

Similar properties but evidence indicating no or reduced interaction effects:

Beta-adrenergic blocking eyedrops (ophthalmic forms): Betaxolol (Betoptic), carteolol (Cartrol, Ocupress), levobunolol (Betagan), metipranolol (OptiPranolol), timolol (Timoptic).

Calcium channel blockers: Amlodipine (Norvasc); combination drug: amlodipine and benazepril (Lotrel); bepridil (Bapadin, Vascor), diltiazem (Cardizem, Cardizem CD, Cardizem SR, Cartia XT, Dilacor XR, Diltia XT, Tiamate, Tiazac), felodipine (Plendil); combination drugs: felodipine and enalapril (Lexxel), felodipine and ramipril (Triapin); gallopamil (D600), isradipine (DynaCirc, DynaCirc CR), lercanidipine (Zanidip), nicardipine (Cardene, Cardene I.V., Cardene SR), nifedipine (Adalat, Adalat CC, Nifedical XL, Procardia, Procardia XL); combination drug: nifedipine and atenolol (Beta-Adalat, Tenif); nimodipine (Nimotop), nisoldipine (Sular), nitrendipine (Cardif, Nitrepin), verapamil (Calan, Calan SR, Covera-HS, Isoptin, Isoptin SR, Verelan, Verelan PM); combination drug: verapamil and trandolapril (Tarka).

Folate is essential for the metabolism of the atherogenic amino acid homocysteine (Hcy). The reduction of plasma and erythrocyte folate concentrations is also associated with a moderate hyperhomocysteinemia. Moderate hyperhomocysteinemia is an independent risk factor for cardiovascular disease that may be causal. Numerous studies have confirmed a strong association between lower folate levels and elevated Hcy and the efficacy of enhanced folate intake in the reduction of Hcy levels.[402-417]

The coadministration of folic acid with a beta blocker or calcium channel blocker may provide a synergistic effect in an integrative approach to prevention and treatment of cardiovascular disease involving atherosclerosis, especially coronary artery disease. For example, Landgren et al.[418] studied the effect on plasma Hcy of 6 weeks' treatment with daily oral folic acid doses of 2.5 or 10 mg, compared with no treatment, in patients with a recent history of myocardial infarction (MI). Folic acid lowered plasma Hcy in all but 2 of 33 treated patients, with no difference between the effect of 2.5 and 10 mg of folic acid. In the untreated group, plasma Hcy increased in the post-MI period. Thus far, no clinical trials are available that specifically investigate the efficacy of an integrative approach combining beta blockers with nutrients such as folic acid. Such research is warranted.

Several calcium channel blockers are known to produce "clinically and histologically similar gingival enlargements in certain susceptible patients."[419] Disturbances in folate uptake are among the factors contributing to such drug-induced adverse effects. As with other drugs, the coadministration of folic acid, prophylactically or in response to symptoms, may play a role in preventing and correcting these events.

Supplementation with folic acid could lower Hcy levels and thereby reduce the risk of the cardiovascular conditions for which these medications are usually prescribed on a systemic basis. Although folic acid is essentially nontoxic, physician supervision is appropriate when introducing any new elements into the therapeutic regimen. A moderate supplemental dose of folic acid is usually about 400 µg/day, in the form of a folic acid supplement or as part of a multivitamin formula. These levels can also be obtained through a diet rich in beets, leafy green vegetables, beans, citrus, meat, and wheat germ. A higher intake level, in the range of 650 to 800 µg or greater, may be more efficacious in individuals with preexisting cardiovascular disease, a significant family history, less responsive hyperhomocysteinemia, or other risk factors. Furthermore, enhanced intake of vitamins B_6 and B_{12}, as well as betaine, is also essential because these nutrients work with folate to metabolize homocysteine.

Corticosteroids, Oral, Including Prednisone

Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol) prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).

Similar properties but evidence lacking for extrapolation: Inhaled or topical corticosteroids.

Oral corticosteroids, particularly when administered for extended periods or at high dosage levels, can both decrease the activity and effects of folic acid and cause depletion of folate. Such drug-induced adverse effects on folate status may contribute to the hyperhomocysteinemia observed in some patients with autoimmune diseases, such as Crohn's disease and systemic lupus erythematosus (SLE, lupus), undergoing long-term steroid therapy.[420,421] Further research through well-designed clinical trials is warranted.

Physicians prescribing extended courses of oral corticosteroids are advised to monitor all major folate and Hcy levels in these patients. Pending substantive research through clinical trials, coadministration of folic acid, 800 µg/day, can provide a safe and potentially effective means of compensating for drug-related interference and depletion effects and can support clinical strategies toward reducing cardiovascular risk. The probability that inhaled or topical corticosteroids might cause such adverse effects is low or nonexistent, and reports or warnings are lacking in the scientific literature.

Cycloserine

Cycloserine (Seromycin).

For decades researchers have reported that cycloserine may interfere with the absorption and activity of folic acid (as well as of vitamins B_6 and B_{12}).[171,422] Case reports of folate deficiency induced by antitubercular drugs, including cycloserine, were

published in the 1960s.[211] Well-designed clinical trials are lacking to confirm these preliminary and anecdotal findings, assess their clinical implications, and determine whether folic acid coadministration would effectively counter such adverse effects without impairing the therapeutic activity of the medication. Such research may be warranted. Pending further studies, coadministration of folic acid and vitamin B_{12} may be prudent with close supervision and regular monitoring.

Fluorouracil

Fluorouracil (5-FU; Adrucil, Efudex, Efudix, Fluoroplex).
See also Antifolates and Related Antimetabolites.

Folinic acid (leucovorin or Leukovorin) is a form of 5-MTHF often administered in conventional oncology care, particularly to treat metastatic colorectal cancer, enhancing the binding affinity of 5-FU to its target enzyme, thymidylate synthase (TS). In breast and other cancers, for which 5-FU is used as part of combination chemotherapy (e.g., CMF, platinum/5-FU), leucovorin is generally not used because of its increased toxicity in this context. However, leucovorin has continued to be used with 5-FU in the emerging combination chemotherapies for gastrointestinal (GI) cancers (e.g., with oxaliplatin, irinotecan). Evidence is mixed as to whether polymorphisms in the TS and dihydropyrimidine dehydrogenase (DPD) genes contribute to interpatient variability in 5-FU pharmacokinetics, response, and toxicity, although significant DPD deficiency is a well-established cause of life-threatening 5-FU toxicity.[423,424]

In 1995, Mainwaring and Grygiel[425] published case reports describing severe fluorouracil toxicity in two patients coincident with taking multivitamins containing folic acid. One patient, a woman with carcinoma of the rectum, was treated with intravenous fluorouracil (500 mg/m^2) daily for 5 days, commencing a month after surgery. She was admitted at the end of the chemotherapy exhibiting numerous signs interpreted as fluorouracil toxicity, including anorexia, severe mouth ulcerations, bloody diarrhea, and vaginal bleeding. An inventory of her oral intake revealed that she was taking 5 mg folic acid within a B-complex multivitamin, as well as loperamide, sulfasalazine, hormone replacement therapy (HRT), and vitamins K and B_{12}. A month later, when chemotherapy was resumed after discontinuation of folic acid, she tolerated the treatment well, and signs of toxicity were absent. Similarly, the second patient, a man, experienced severe mouth ulceration and bloody diarrhea 2 days after starting treatment with fluorouracil for colon cancer. Discontinuation of his daily multivitamin preparation, containing 500 µg folic acid, allowed resumption of 5-FU with no such adverse effects during subsequent courses at the same dosage level. Apparently, the elevated folate levels caused by supplementation had increased the inhibition of thymidine synthesis by fluorouracil and increased the toxicity of the chemotherapeutic agent. Thus the adverse reaction in these cases resulted more from shortcomings in physician-patient communication and lack of supervision than from an irresolvable incompatibility, especially because a 5-MTHF agent such as folinic acid is much more potent than folic acid.

Although these reports do not meet the full standards of qualification, the observed events are consistent with the effects of folinic acid. Patients undergoing chemotherapy with 5-FU should be advised to avoid folic acid intake, and supplements should be inspected for its presence; a trusting therapeutic relationship and frank communication are necessary to obtain full disclosure from many patients using nutritional supplements. Although use of folic acid in the form of leucovorin or other L-methyl folates may be plausible, research on coadministration in such cases is lacking and may be warranted. Close supervision and regular monitoring would be essential in any such application, as indicated by the risks of self-administration detailed in these case reports.

Furosemide and Related Loop Diuretics

Bumetanide (Bumex), ethacrynic acid (Edecrin), furosemide (Lasix), torsemide (Demadex).
See also Triamterene and Related Potassium-Sparing Diuretics.

Decreased folic acid levels and increased Hcy levels are associated with long-term furosemide therapy for hypertension.[374] Higher total folate intake is associated with a decreased Hcy levels and decreased risk of incident hypertension, particularly in younger women.[266,320,426] Conversely, elevated plasma Hcy levels are associated with increased risk of atherosclerosis and cardiovascular disease.[402,427-430]

In general, patients receiving antihypertensive therapy using furosemide or related loop diuretics are likely to benefit from the Hcy-lowering effects of folic acid and vitamin B_{12}, as well as concomitant magnesium, coenzyme Q10, and mixed tocopherols. Assessment of the individual patient's risk factors, including diet, family history, and genomic polymorphisms, is essential to crafting a customized and evolving integrative strategy for prevention and treatment of cardiovascular disease.

Coadministration of folic acid may be prudent, safe, and inexpensive but has not been specifically investigated. Well-designed and adequately powered clinical trials are warranted.

Medroxyprogesterone

Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); medroxyprogesterone, oral (Cycrin, Provera); medroxyprogesterone, injection (depot medroxyprogesterone acetate, DMPA; Depo-Provera, Depo-subQ Provera 104); progestin and estrogen injectable: estradiol cypionate and medroxyprogesterone acetate (Cyclofem, Lunelle).
See also Oral Contraceptives.

In a 1-year study of predominantly malnourished women from two urban centres in India (Bombay/Mumbai and Hyderabad) and one rural center in Thailand (Chiang Mai), Joshi et al.[431] found that 3-month injectable depot medroxyprogesterone acetate (DMPA) used for contraception was associated with increased blood folate and serum vitamin A. The clinical implications of these findings are unclear, and further research is warranted.

Raltitrexed

Raltitrexed (ZD-1694; Tomudex).
See also Antifolates and Related Antimetabolites.

Raltitrexed is a quinazoline folate analog indicated in the treatment of advanced colorectal cancer. It causes DNA fragmentation and cell death, selectively inhibiting TS and thereby interfering with the de novo synthesis of thymidine triphosphate (TTP) and DNA synthesis. The manufacturer and some researchers have cautioned that concomitant folic acid may interfere with the action and reduce the efficacy of raltitrexed and recommended that folic acid intake be avoided immediately before or during raltitrexed administration.[432-434] Coadministration of leucovorin is similarly contraindicated. These interactions have been proposed on theoretical grounds and have not been confirmed by clinical trials or systematic review of qualified case reports. Raltitrexed is contraindicated during pregnancy and for at least 6 months after discontinuation of treatment if either partner is receiving raltitrexed.[434]

Pemetrexed (Alimta), a similar drug, has shown no decrease in efficacy but a significant decrease in toxicity when coadministered with folate and vitamin B_{12}. Thus the earlier antifolates discussion may be relevant in extrapolating speculative approaches to the interactions involving folate and raltitrexed.

Thiazide Diuretics

Bendroflumethiazide (bendrofluazide; Naturetin); combination drug: bendrofluazide and propranolol (Inderex); benzthiazide (Exna), chlorothiazide (Diuril), chlorthalidone (Hygroton), cyclopenthiazide (Navidrex); combination drug: cyclopenthiazide and oxprenolol hydrochloride (Trasidrex); hydrochlorothiazide (Aquazide, Esidrix, Ezide, Hydrocot, HydroDiuril, Microzide, Oretic); combination drugs: hydrochlorothiazide and amiloride (Moduretic); hydrochlorothiazide and captopril (Acezide, Capto-Co, Captozide, Co-Zidocapt); hydrochlorothiazide and enalapril (Vaseretic); hydrochlorothiazide and lisinopril (Prinzide, Zestoretic); hydrochlorothiazide and losartan (Hyzaar); hydrochlorothiazide and metoprolol (Lopressor HCT); hydrochlorothiazide and spironolactone (Aldactazide); hydrochlorothiazide and triamterene (Dyazide, Maxzide); hydroflumethiazide (Diucardin), methyclothiazide (Enduron), metolazone (Zaroxolyn, Mykrox), polythiazide (Renese), quinethazone (Hydromox), trichlormethiazide (Naqua).
See also Furosemide and Related Loop Diuretics and Triamterene and Related Potassium-Sparing Diuretics.

Some derivative sources have suggested that coadministration of folic acid with thiazide diuretics could reduce adverse drug effects and enhance the efficacy of the broader therapeutic aims. Specific evidence is lacking to substantiate such interactions. However, patients receiving thiazide therapy are likely to benefit from the homocysteine-lowering effects of folic acid and vitamin B_{12}, as well as concomitant magnesium, coenzyme Q10, and mixed tocopherols. Assessment of the individual patient's risk factors, including diet, family history, and genomic polymorphisms, is essential to shaping a customized and evolving integrative strategy for prevention and treatment of cardiovascular disease.

NUTRIENT-NUTRIENT INTERACTIONS

B Vitamins

Vitamin B_2 (riboflavin); vitamin B_6 (pyridoxine); vitamin B_{12} (cobalamin).

The B vitamins work synergistically, so adequate and proportionate amounts of all B vitamins need to be available for optimal functioning. Deficiency (or excess) of any single nutrient can lead to abnormalities in the metabolism, interrelationships, and activity of one or more of the other B vitamins. In particular, vitamins B_2, B_6, and B_{12} work with folate in maintaining healthy homocysteine (Hcy) levels.[417,435,436] Riboflavin (B_2) is the precursor for FAD, the cofactor for methylenetetrahydrofolate reductase (MTHFR).[437,438] For example, Schnyder et al.[439] found that a combination of folate (1 mg), vitamin B_{12} (400 µg), and B_6 (10 mg) significantly reduces Hcy levels and decreases the rate of restenosis after coronary angioplasty. A synergy between vitamin D and mecobalamin (B_{12}) appears to play a preventive role in risk of hip fracture among stroke patients, with Hcy as a predictive factor.[440,441] Combinations of these nutrients are used in health optimization, disease prevention, and therapeutic interventions related to a wide range of body systems and medical conditions, including bronchial dysplasia in smokers, chronic fatigue, and vitiligo.

The emergent trend in the scientific research and clinical practice among providers experienced in nutritional therapeutics suggests that it is important to match generous quantities of B_{12} with folate administration, especially in older people. Supplementing folic acid without B_{12} can stimulate systems that also use B_{12} and result in lower B_{12} levels. Assessment of B_{12} status and concomitant administration of B_{12} with folate are generally advisable to enhance physiological synergies and to prevent masking of B_{12} deficiency. Furthermore, recent research indicates that a fundamental reconfiguration of assessment standards and therapeutic strategy is necessary to achieve correction of serious or even mild deficiency states. Conventional guidelines have recommended folate doses in hundreds of micrograms and B_{12} in single-digit micrograms. However, a landmark study (2005) showed that once individuals become B_{12}-deficient (by MMA levels), they typically require 500 to 600 µg at least (i.e., >200 times the RDA) to correct mild vitamin B_{12} deficiency, particularly elderly patients.[20] Thus, equivalent amounts of B_{12} are generally advisable with folate administration.

Pancreatin and Proteolytic Enzymes

See Pancreatic Enzymes under Nutrient-Drug Interactions.

Vitamin C

Vitamin C

Vitamin C plays a key role in the conversion of folic acid to its active form and helps to reduce folic acid excretion.

Zinc

Zinc

An interaction between zinc and folic acid has often been suggested, at least partly because bioavailability of dietary folate is increased by the action of folate conjugase, a zinc-dependent enzyme. Therefore, low zinc intake or zinc deficiency could impair absorption of food pteroylpolyglutamates and decrease folate bioavailability. Conversely, some studies and many derivative sources have suggested that folic acid may reduce zinc absorption and impair zinc utilization in individuals, particularly with high folate doses in those with marginal zinc status.[442-444] However, Butterworth and Tamura[445] reviewed the mixed findings in the research literature, as of 1989, and concluded that the "weight of current evidence favors the view that daily supplements of 5 to 15 mg folic acid do not have significant adverse effects on Zn nutriture in healthy nonpregnant subjects." Subsequently, in a trial involving 12 men (age 20-34) fed low-zinc diets (3.5 mg/day), Kauwell et al.[446] found that administration of folic acid at 800 µg/day, a relatively high dose, for 25 days did not alter zinc status, nor did zinc intake impair folate utilization.

HERB-NUTRIENT INTERACTION

Coffee

Coffee *(Caffea arabica, Caffea canephora, Caffea robusta)*.

In a randomized, placebo-controlled study, Strandhagen et al.[447] found that administration of folic acid decreases the homocysteine-increasing effect normally associated with coffee prepared by the filter method.

The 453 citations for this monograph, as well as additional reference literature, are located under Folic Acid on the CD at the back of the book.

Vitamin A (Retinol)

Nutrient Names: Vitamin A, retinol.
Synonym: Preformed vitamin A.
Related Substances: Retinol (retinaldehyde); retinoic acid; retinyl esters, such as retinyl acetate, retinyl palmitate, and retinyl propionate; all-trans dehydroretinol, vitamin A2; beta-carotene (provitamin A) and other provitamin A carotenoids: alpha-carotene, cryptoxanthin, lutein, lycopene, zeaxanthin.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Antacids ⊕⊕	Vitamin A coadministration exerts cytoprotective effect and enhances healing of gastric ulcers.	Coadminister.
Anthelmintic drugs ⊕⊕⊕	Vitamin A deficiencies are also associated with increased risk of parasitic infections. Combining anthelmintic agents with increased vitamin A intake can reduce symptoms of intestinal parasites while supporting epithelial integrity and immune response, especially when combined with increased fat intake.	Coadminister vitamin A and/or beta-carotene supplements/foods with accompanying lipid intake. Follow with improved nutrient intake (quality and quantity) to reduce susceptibility.
Chemotherapy Cytotoxic Agents ✗/⊕✗/⊕⊕	Chemotherapeutic agents interact with vitamin A in various ways, from adjunctive vitamin A for nutritive support and amelioration of adverse drug effects to cotherapy using retinoids as chemotherapeutic agents. Pattern of interaction varies depending on patient characteristics, form of cancer, and agents involved. Risk of interference with cytotoxic action through antioxidant effects contentious, but evidence inconclusive and likely not uniform for all agents, conditions, or patients.	Coadministration appropriate in some cases. Retinoid use requires close monitoring by experienced clinicians collaborating an integrative strategy, particularly given significant risk of toxicity. Multiple nutrients providing a network effect are preferred when antioxidants deemed appropriate.
Cholestyramine, colestipol Bile acid sequestrants ≈≈≈/◇	By reducing fat absorption, bile acid sequestrants tend to reduce absorption and assimilation of vitamin A and other fat-soluble nutrients. Significant adverse effects on vitamin A absorption appear less likely than for other nutrients, although may depend on agent used, diet and supplemental intake, and patient characteristics. Available research inconclusive and limited by subject population characteristics, duration, and scope; further research warranted.	Concurrent supplementation with multivitamin providing modest levels of A, D, E, and K with folate, carotenoids, and mixed tocopherols can counter potential adverse effects with little risk and minimal expense.
Colchicine ≈≈≈	Colchicine may impair vitamin A absorption and can interfere with retinol homeostasis by blocking release of retinol–retinol binding protein (RBP).	Coadminister vitamin A, beta-carotene, and other potentially affected nutrients.
Corticosteroids, oral ◇/⊕/✗	Exogenous steroid administration may cause transient increases in levels vitamin A and retinol-binding protein (RBP), whereas extended use may reduce levels of vitamin A and metabolites in plasma and tissues. Concomitant use may enhance drug efficacy by mobilizing hepatic stores and elevating plasma concentrations, particularly in very-low-birth-weight (VLBW) neonates with bronchopulmonary dysplasia. Further research into protective and synergistic effects of coadministration warranted.	Supplement during and after extended steroid administration. Monitor vitamin A and RBP levels.
HMG-CoA reductase inhibitors (statins) ◇◇	Statin therapy may elevate serum retinol levels, possibly by altering liver function; clinical implications unclear and research preliminary. Clinical trials warranted.	Caution advised with retinol intake during statin therapy. Monitoring (or alternatives to statins) appropriate with compromised liver function.
Medroxyprogesterone ◇◇/◇≈≈/⊕✗	Medroxyprogesterone, as injectable contraceptive or oral hormone replacement therapy (HRT), may elevate serum retinol levels, possibly RBP. Clinical significance, with possible underlying alteration in vitamin A function, is unclear, but serum carotenoids may decrease because of competition and altering vitamin A transport. Response likely to depend on multiple factors, including diet and patient characteristics. Further research warranted.	Conservative practice suggests avoiding retinol administration at high doses unless otherwise indicated. Carotenoid support may be indicated. Monitor with compromised liver function.
Methyltestosterone ◇≈≈/≈≈	Single case report indicates that methyltestosterone may impair visual function by altering serum levels and metabolism of vitamin A and beta-carotene. This minimal evidence may represent an atypical pharmacogenomic response but suggests the need for further investigation, including potential benefit of nutrient supplementation.	Discontinuation of drug therapy indicated on appearance of adverse effects.
Mineral oil ✗/≈≈≈	Mineral oil may interfere with or otherwise alter absorption of many nutrients, especially with simultaneous intake and extended use. Mixed evidence suggests that impact on various nutrients may vary, possibly elevating serum retinol levels and decreasing beta-carotene levels. Further research warranted; timing, dosage, duration, diet, and other factors likely influence clinical significance.	Separate intake of mineral oil from meals, and supplement administration. Avoid extended use of mineral oil internally.
Neomycin ≈≈≈	Oral neomycin, particularly high doses over extended periods, may impair vitamin A absorption and could contribute to depletion pattern. Preliminary evidence suggests further research warranted to assess clinical significance.	Coadminister vitamin A and/or beta-carotene with high-dose internal neomycin use of 2 days or longer.
Oral contraceptives (OCs) ◇◇/⊕/✗	OCs (exogenous estrogen and progestin formulations) associated with increased serum levels of vitamin A, at least in part due to increased hepatic synthesis of RBP and elevated export of RBP-retinol complex; lower carotenoid	Conservative practice suggests avoiding retinol administration at high doses unless otherwise indicated. Carotenoid support may be indicated. Monitor with compromised liver function.

Continued

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
	levels may result from competition and alterations of vitamin A transport. Clinical implications of this apparent drug effect on nutrient function uncertain, but further research warranted to investigate this emerging pattern of evidence.	
Orlistat ≈≈≈	Orlistat may interfere with absorption of vitamin A and other fat-soluble nutrients. Mixed evidence suggests that impact on various nutrients may vary, with findings ranging from no observed effect to depletion despite concurrent supplementation. Further research warranted; timing, dosage, duration, diet, and other factors likely influence clinical significance.	Concurrent supplementation with multivitamin providing modest levels of vitamins A, D, E, and K with carotenoids and mixed tocopherols may counter possible depletion pattern with little risk and minimal expense.
Retinoids ✗✗✗	Concomitant use of supplemental vitamin A and pharmaceutical retinoids not formally investigated, and evidence of clinical significance lacking. Nevertheless, "consensus" considers additive effect inevitable and inherently risky. This conclusion may be reasonable, but clinical trials providing conclusive findings are unlikely.	Avoid supplementation of more than 5000 IU vitamin A during retinoid therapy.
Tetracycline antibiotics ✗✗/✗✗✗	Concurrent use of vitamin A/retinoids and tetracycline antibiotics associated with severe adverse effects, particularly headaches and pseudotumor cerebri (benign intracranial hypertension). Consensus exists on clinical significance of risk of interaction and contraindication against concurrent use. Effects may be sudden and severe.	Avoid concomitant retinoids, including vitamin A at doses above 10,000 IU/day, during antibiotic therapy employing tetracyclines. Discontinue use immediately if symptoms appear.

Note: See also Beta-Carotene monograph.

NUTRIENT DESCRIPTION

This monograph reviews interactions issues relating to and deriving from intake of retinol and other forms of preformed vitamin A and the metabolic processes of these substances within physiological/healthy, dysfunctional, and pathological processes and states. The monograph for beta-carotene focuses on interactions issues involving intake, assimilation, and metabolic processes that constitute provitamin A activity and affect retinol and its metabolic activity. Interactions with some pharmaceutical agents inherently involve both substances and their respective class of related substances.

Chemistry and Forms

Vitamin A is a generic term used to describe the class of compounds that exhibit the biological activity of retinol. The two main sources of vitamin A in foods are retinol and the provitamin A carotenoids. *Retinol* (an alcohol), *retinal* (an aldehyde), and *retinoic acid* are collectively known as "retinoids"; they naturally occur only in animal products and can be classified as "preformed vitamin A." Some structurally related synthetic analogs (e.g., tretinoin) are also considered retinoids and may exhibit significant, partial, or no retinol-like activity.

Carotenoids are a class of related compounds found exclusively in plants (fruits, vegetables, algae, phytoplankton) and animals that feed directly on high-carotenoid plant sources, such as krill, small saltwater and freshwater crustaceans that accumulate astaxanthin from phytoplankton. Approximately 600 carotenoids have been identified thus far. Beta-carotene, alpha-carotene, lutein, lycopene, cryptoxanthin, and zeaxanthin are principal among those specifically classified as "provitamin A carotenoids"; they are so named because humans can metabolically convert them into retinol. Bonds within beta-carotene are cleaved to form all-*trans* retinol (and possibly retinal); divergent theories exist regarding the site of this cleavage, the products, and their proportion, although molecular structures suggest that one molecule of beta-carotene would result in two molecules of retinol. It is unreasonable, however, to equate the predicted retinol yields of the various provitamin A carotenoids, then add these to provide units of "vitamin A equivalents," because in non–vitamin A–deficient humans, only a small proportion of provitamin A carotenoids are actually converted to retinol or retinal.

The dietary supplement labeling convention of stating provitamin A carotenoid content in units of "retinol equivalents" (REs) or international units (IUs) of vitamin A activity has led to a widespread misperception among the lay public and many medical professionals alike, that such supplements contain potentially toxic levels of vitamin A. Potential toxicity of carotenoids such as synthetic beta-carotene in smokers is another issue, unique to beta-carotene, and unrelated to issues of vitamin A toxicity (see section on beta-carotene and other provitamin A carotenoids).

Physiology and Function

In 1913, vitamin A was the first vitamin to be isolated, thus the nomenclature "A". Researchers initially focused on its key role in vision, particularly in preventing night blindness and xerophthalmia. In 1929, Moore demonstrated that beta-carotene was converted to vitamin A, and 2 years later the chemical structures of both vitamin A and beta-carotene were determined.

Vitamin A is readily absorbed in the duodenum and jejunum in the presence of gastric secretions, bile salts, pancreatic and intestinal lipase, protein, and dietary fat. More than 90% of all dietary retinol is in the form of esters, usually retinyl palmitate. These esters must be hydrolyzed in the intestinal lumen by pancreatic enzymes and within the brush border of the intestinal epithelial cells before absorption. Retinol can be absorbed from a micelle in the presence of bile salts or a nonionic detergent. Retinol is absorbed by diffusion when present in high doses, but at low doses its transport across intestinal epithelial cells is mediated by cellular *retinol-binding protein* (RBP). In average doses, retinol is almost entirely absorbed, with peak concentrations in 4 hours. Retinol is absorbed two to five times more efficiently than beta-carotene, the bioavailability and absorption of which are also influenced by multiple factors, including the amount of carotenoid in the diet, interactions with other carotenoids, dietary fat and fiber, nutritional deficiencies of zinc and protein, and other disease states.

Excess retinol is converted to retinyl esters again and stored in the liver. Retinol binds to RBP, which serves as the carrier associated with vitamin A transport in the blood. When the amount of vitamin A exceeds the capacity of RBP to bind to it, the excess retinol binds to lipoproteins, and in this form it has toxic effects. The liver holds 90% (or more) of the body's vitamin A stores, which typically approximate 2 years' requirement for an adult; consequently, it generally does not need to be consumed daily. The lungs and kidneys also store retinol in small amounts. Retinol in storage has a half-life of 50 to 100 days. Vitamin A is present in breast milk. Vitamin A metabolites are eliminated in the bile and urine. When large amounts of retinol are ingested, a portion can be excreted in the feces, independent of biliary absorption and excretion.

Vitamin A is a key micronutrient needed to combat infection and maintain immunity and epithelial cell differentiation and turnover. Retinol and retinoic acid are necessary for maintenance of the structural and functional integrity of epithelial tissue and the immune system, cellular differentiation and proliferation, bone growth, gonadal (testicular and ovarian) function, and embryonic development. Vitamin A also acts as a cofactor in numerous biochemical reactions. A single effect or mechanism cannot account for the diverse vitamin A actions on the immune system.

Retinal is essential for the normal function of the retina, particularly visual adaptation to darkness. Both retinyl esters and beta-carotene from the diet are converted to retinal (11-*cis* isomer). Retinal is combined with the protein opsin to form rhodopsin in the rods of the retina and iodopsin in the cones. Light hitting the retina causes visual excitation and changes the *cis* configuration into the all-*trans* form of retinaldehyde. The rods are particularly sensitive to vitamin A deficiency. When in low supply, the all-*trans* form generated during the light reaction cannot be converted back to the active rhodopsin. Retinal can be also converted to retinoic acid, the form of vitamin A most directly involved in gene transcription. Approximately 20% to 35% of the retinol in food sources (e.g., cod and other fish liver oils) is in the *cis* configuration, whereas virtually all the vitamin A in supplements and vitamin A–fortified foods (e.g., dairy products) is in the all-*trans* configuration. Some evidence suggests that the *cis* configuration may be essential to certain visual and brain functions, at least in certain individuals.

A small amount of beta-carotene is converted into vitamin A in the body, but beta-carotene and the other carotenoids act independently from vitamin A as antioxidants. Only 30% to 50% of the more than 600 known carotenoids are thought to be converted into vitamin A by the body, with alpha-carotene, beta-carotene, and cryptoxanthin the most widely distributed of the provitamin A carotenoids.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

In conventional practice, supplemental vitamin A is generally thought to have no established therapeutic uses other than correcting frank deficiencies. The evidence for efficacy from administration of exogenous vitamin A (as retinol) is often considered "mixed" and "preliminary." However, both natural and synthetic retinoids have been used as pharmacological agents to treat dermatological disorders, with their action most likely deriving from their effect on the transcription of skin growth factors and their receptors. Acitretin (and previously etretinate) has been employed in the treatment of psoriasis, and tretinoin (Retin-A) and isotretinoin (Accutane) are typically used to treat severe cases of acne vulgaris; tretinoin is also used cosmetically to reduce signs of skin aging. Most oncology uses of retinoids involve retinoic acid, including 13-*cis*, 9-*cis*, and all-*trans* forms.

Historical/Ethnomedicine Precedent

Vitamin A (retinol) is not used historically as an isolated nutrient.

Possible Uses

Acne vulgaris, acute promyelocytic leukemia, alcohol withdrawal support, Alzheimer's disease, anemia (associated with deficiency), autism (*cis*-containing fish liver–derived form only), blepharitis, breast cancer, bronchitis, burns, cataracts, celiac disease, cervical dysplasia, childhood diseases, colorectal cancer, conjunctivitis, Crohn's disease (associated with deficiency), cystic fibrosis, diabetes mellitus, diabetic retinopathy (in combination with selenium, vitamins C and E), diarrhea, diverticulitis, eczema, fibrocystic breast disease, food poisoning, gastritis, glaucoma, goiter, hemorrhoids, human immunodeficiency virus and acquired immunodeficiency syndrome (HIV/AIDS) support, hypothyroidism, ichthyosis (noninflammatory skin peeling), immune function, intestinal parasites, iron deficiency anemia (with iron), keratosis follicularis (Darier's disease), leukoplakia, lichen planus pigmentosus, lung cancer, menorrhagia, mucopolysaccharidosis (Hurler syndrome), myocardial infarction, myeloproliferative disorders, night blindness (nyctalopia), osteoarthritis, osteoporosis, peptic ulcer, peritonitis, pityriasis rubra pilaris, premenstrual syndrome, psoriasis, respiratory syncytial virus (RSV), retinitis pigmentosa, retinopathy (in combination with selenium, vitamins C and E), rosacea, roundworms, rubeola (measles, severe cases, with deficiency, especially to reduce measles mortality in developing countries), seborrhea, sickle cell anemia, skin cancer, sprains and strains (associated with deficiency), surgery (preparation and recovery), tuberculosis, ulcerative colitis, urinary tract infection, varicella (chickenpox), vaginitis, warts, wound healing, xerophthalmia (classic manifestation of vitamin A deficiency).

Vitamin A deficiency is widespread, in association with general malnutrition, in developing countries, particularly among young children. Frank deficiencies are generally considered uncommon in developed countries, especially in adults, but marginal intake and deficiency status are known to occur with inadequate and poor-quality diet, especially in children and elderly persons. Furthermore, individuals who restrict their dietary intake of liver, dairy products, and vegetables rich in beta-carotene increase their risk of developing vitamin A deficiency. Chronic consumption of alcohol can deplete liver stores of vitamin A, which can be further complicated by alcohol-induced liver damage. Chronic consumption of alcohol and acetaminophen can greatly increase the hepatotoxicity of vitamin A supplements (but not of provitamin A carotenoid supplements).

Special Populations

Extremely low-birth-weight infants (≤1 kg [2.2 lb]) are at high risk of a deficiency at birth. Individuals with vitamin A deficiency caused by abnormal storage and transport conditions, including abetalipoproteinemia, diabetes mellitus, fever, hyperthyroidism, cystic fibrosis (with liver involvement), liver disease, and protein deficiency.

Deficiency Symptoms

Blindness, defective tooth and bone formation, diarrhea, diminished immune function, dry skin, increased susceptibility to respiratory and urinary tract infections, loss of appetite, metaplasia and keratinization of respiratory tract cells and other systems/organs, night blindness (nyctalopia), papular eruptions, reduced synthesis of steroid hormones, visual impairment, xerophthalmia.

Dietary Sources

Free retinol is not generally found in foods.

The richest readily available dietary source of vitamin A is fish liver oil, especially cod liver oil. In particular, all-*trans* dehydroretinol, previously known as vitamin A_2, is a vitamin A–related compound found in freshwater fish flesh and liver and, to a lesser extent, in some marine fish; it is estimated to have 40% to 50% of the vitamin A activity of all-*trans* retinol. Likewise, *cis* isomers of retinol, exhibiting up to 75% relative activity of all-*trans* retinol, can account for up to 35% of preformed vitamin A measured in fish liver oils. Oily fish such as herring, pilchards, tuna, and sardines are considered rich sources. *Retinyl palmitate*, a precursor and storage form of retinol, is found in foods from animal sources and is, along with the acetate ester, the most common form in dietary supplements. Good food sources of vitamin A include liver, kidney, butter, egg yolk, whole milk and cream, whole-milk yogurt, and fortified skim milk. Cod liver oil and halibut fish oil contain high levels of vitamin A and have been used therapeutically.

Carotenoid sources are reviewed in the Beta-carotene monograph.

Nutrient Preparations Available

Many supplements provide a combination of retinol and beta-carotene. Some individuals appear to be able to absorb water-soluble forms of vitamin A supplements better than fat-soluble vitamin A, particularly those with compromised biliary function.

Dosage Forms Available

Capsule, liquid, tablet.

Source Materials for Nutrient Preparations

The primary forms of preformed vitamin A (retinol) in supplements are the vitamin A esters retinyl palmitate and retinyl acetate. Vitamin A can be produced by extraction from fish liver oil, although the more common process is synthesis from beta-ionone.

Dosage Range

One international unit (1 IU) of beta-carotene is equivalent to 1 IU of vitamin A; 1 mg (1000 micrograms [μg]) of beta-carotene is equivalent to 500 μg of vitamin A.

Nutrient values of preformed vitamin A and provitamin A carotenoids are often combined into a single numerical value designating functional vitamin A activity. Originally, the internationally accepted values were international units, with 1 IU being defined as 0.30 μg of all-*trans* retinol, or 0.60 μg of all-*trans* beta-carotene. Although the system of retinol equivalents has become the accepted standard, these earlier are still found in many food composition tables and scientific publications.

Strong evidence for lower bioavailability of beta-carotene than previous estimates led to revision of the values for the biological activity of various forms of vitamin A and carotenoids. On the basis of rodent studies, the other provitamin A carotenoids have an estimated 50% of the growth-promoting activity of beta-carotene. Although further research has revealed greater diversity in bioavailability, absorption, and differential biological activity, the initial proportional estimates resulted in units of expression for vitamin A activity called *retinol equivalents* (REs). Retinol equivalents are now used as the internationally accepted units for vitamin A activity and can be summarized as follows:

1000 REs = 1 mg all-trans retinol
= 6 mg all-trans beta-carotene
= 12 mg other provitamin A carotenoids
= 3330 IU vitamin A (retinol)
= 10,000 IU carotene

However, differences in equivalency when converting beta-carotene to retinol has produced persistent confusion between IU and RE. Calculating total vitamin A activity using the RE system reduces the contribution of provitamin A compared with the IU system. The resultant formula for interconversion follows:

RE = IU retinol/3.33 + IU beta-carotene/10.0
= μg retinol
= μg beta-carotene/6 + μg other provitamin A carotenoids/12

Continued uncertainty about the meaning of bioavailability of carotenoids, shortcomings in methods for determining bioavailability and absorption, and emerging knowledge of numerous factors in individual variability reveal fundamental inadequacies and inaccuracy in current systems for evaluating and comparing various forms of vitamin A, particularly those from dietary intake of carotenoid-containing foods. Given the wide range of reported conversion ratios of beta-carotene to vitamin A in humans, including the ratio of 6:1 for beta-carotene and 12:1 for alpha-carotene and cryptoxanthin devised by the World Health Organization (WHO), it appears prudent to consider all such approaches as, at best, providing only an average estimate that is not applicable to all diets or individuals. Furthermore, isomerization remains a largely unaddressed issue in quantifying provitamin A activity in processed forms of plant products.

Adult

Dietary: 2333 IU/day for women and 3000 IU/day for men, from dietary sources of both vitamin A and beta-carotene, will generally be adequate to support normal gene expression, immune function, and vision. Breast-feeding women: 4000 to 4333 IU (1200-1300 μg) daily.

Supplemental/Maintenance: 2500 IU of vitamin A as retinol, or 5000 IU of vitamin A, total, with at least 50% in the form of beta-carotene.

Pharmacological/Therapeutic: 25,000 IU (7500 μg) of vitamin A daily is typically used. Doses of 100,000 to 400,000 IU/day have been used for limited periods in the treatment of certain conditions with professional supervision. A maximum of 15,000 IU/day may be more appropriate for individuals over age 65 and those with liver disease outside the context of professional supervision.

Toxic: Doses greater than 50,000 IU/day have resulted in toxicity. Adverse effects may occur in adults at intake levels above 25,000 IU (7500 μg) daily, with higher levels, at or above 100,000 IU/day, more likely to result in cumulative toxicity. Pregnant women (or those who could become pregnant during or shortly after extended supplementation) should not exceed 10,000 IU (3000 μg) daily because of the risk of birth defects, less if foods fortified with vitamin A are consumed to a significant degree with any regularity.

Pediatric (<18 years)
Dietary and Supplemental (combined):
Infants, birth to 6 months: 1333 IU (400 μg), or retinol equivalent (RE) (AI, adequate intake).
Infants 7 to 12 months: 1667 IU (500 μg), or retinol equivalent (RE) (AI)
Children, 1 to 3 years: 1000 IU (300 μg)/day (AI)
Children, 4 to 8 years: 1333 IU (400 μg)/day (RDA)
Children, 9 to 13 years: 2000 IU (600 μg)/day (RDA)
Adolescents, females, 14 to 18 years: 2333 IU (700 μg)/day
Adolescents, male, 14 to 18 years: 3000 IU (900 μg)/day (RDA)

Note: Supplementation often advised for children 6 months to 5 years of age (unless diet known to provide adequate intake)

Pharmacological/Therapeutic: 10,000 IU or greater daily for a child is considered high-dose therapy
Toxic: 10,000 IU (3000 μg) daily

Laboratory Values

Plasma retinol: levels less than 1.05 mmol/L indicate deficiency.

Note: Plasma retinol levels are maintained at the expense of liver stores of vitamin A. Thus, a decline in plasma retinol levels appears only when vitamin A deficiency is progressed to a severe degree.

Liver vitamin A content (biopsy): Levels less than 0.07 mmol/g indicate deficiency.

Note: Liver biopsy provides an accurate assessment of body stores of vitamin A.

SAFETY PROFILE

Overview

Vitamin A toxicity is relatively rare. Hypervitaminosis A is caused by excessive intake of preformed vitamin A and has never been attributed to consumption of carotenoids. Preformed vitamin A is rapidly absorbed and slowly cleared from the body. The risk of developing hypervitaminosis A is derived from total cumulative vitamin A intake rather than a specific daily dosage level, and dosage levels necessary to induce hypervitaminosis A vary significantly among individuals. Thus, vitamin A toxicity can occur in two forms: acute and chronic; that is, toxicity may result acutely from high-dose exposure over a short time, or chronically from lower intake.

Acute hypervitaminosis A results from ingestion of a very high dose of vitamin A over a brief period. Typical symptoms include bulging fontanels in infants and headache in adults, nausea, vomiting, fever, vertigo, and visual disorientation. Peeling of the skin may also occur. Chronic hypervitaminosis A is more common than the acute form and results from continued ingestion of high doses for months or even years. Symptoms include anorexia, dry itchy skin, alopecia, increased intracranial pressure, fatigue, irritability, somnolence, pronounced craniotabes (congenital cranial osteoporosis) and occipital edema, skin desquamation, fissuring of the lips, pain in the legs and forearms, neurological disturbances, and lethargy. Elevated blood lipids are also common. Furthermore, because vitamin A is fat soluble, excesses tend to accumulate in fatty tissues.

Doses up to 25,000 units (U) per day of vitamin A are generally regarded as safe, although toxicity has been associated with doses as low as 20,000 IU/day. Alleged toxicity at this lower dose has occurred in persons with liver dysfunction caused by drugs, chronic alcohol intake, viral hepatitis, aging, or protein-calorie malnutrition. Most cases of toxicity in nonpregnant females result from more than 200,000 IU/day supplementation for at least 6 to 8 months. Although widely discussed, the teratogenic risks of vitamin A intake appear to occur rarely; however, the teratogenic risk associated with ingestion of the synthetic retinoids (e.g., all-*trans* and 13-*cis* retinoic acid) during pregnancy appears to be much higher.

Reports of adverse effects are associated with doses and durations as low as 20,000 IU/day supplementation for 4 to 6 months. However, doses as high as 500,000 to 1 million IU/day over several years have not caused adverse effects in many people.

Nutrient Adverse Effects

General Adverse Effects

Typical symptoms, especially in children, include drowsiness, fatigue, irritability, vomiting, and bulging of the fontanel. In adults, headaches, dry itchy or scaly skin, brittle nails, alopecia, fatigue, anorexia, diarrhea, gingivitis, cheilosis, bone pain, hepatosplenomegaly, abnormal liver function, and visual disturbances have been reported. Severe cases of hypervitaminosis A may result in hemorrhage, liver damage, and coma.[1]

Generally, discontinuation of vitamin A intake causes symptoms to disappear within a few days with no permanent repercussions, although permanent liver injury has been reported.

Findings from several recent prospective studies suggest that long-term intake of preformed vitamin A in excess of 1500 μg (5000 IU) per day are associated with decreased bone mineral density (BMD) and increased risk of osteoporotic fracture in older men and women, particularly a greater risk of hip fractures in women.[2-6] However, because vitamin D deficiency (defined as a serum 25-hydroxyvitamin D level <20 mg/mL) appears to be relatively common in the general population (particularly older age groups), because vitamin A may antagonize the effects of vitamin D,[7] and because vitamin D status was not investigated in any of these reports, the role (if any) of vitamin D status in the higher fracture risk associated with higher intakes of vitamin A is unclear.

Adverse Effects Among Specific Populations

Lower dosage levels are generally recommended in elderly individuals because of increased risk of compromised liver function and attendant increased risk of toxicity, as well as potentially elevated risk of osteoporosis. Individuals with liver disease or diabetes may also have diminished ability to release vitamin A stored in the liver and therefore an elevated risk of toxic accumulation. Individuals with a genetic predisposition to hypercholesterolemia may also be more susceptible to toxicity at lower doses.

Pregnancy and Nursing

The greatest concerns about toxicity are the embryotoxic effects that may occur during early pregnancy. Large doses of vitamin A and most of the retinoids can interfere with normal fetal cell development and cause birth defects, although this is usually observed with other retinoids (compounds related to vitamin A, such as retinoic acid), rather than for vitamin A itself. Thus, excessive dietary intake of vitamin A has been associated with birth defects in humans in fewer than 20 reported cases over the past 30 years.[8,9] Other studies combining human and animal data suggest that up to 30,000 U/day is safe in pregnancy.[10] Nevertheless, until more conclusive, large-scale data are available, most experts suggest limiting vitamin A intake from food and supplements combined to 10,000 U during pregnancy. This standard recommendation of a 10,000 IU safe limit became institutionalized after the 1995 *New England Journal of Medicine* report on vitamin A–related teratogenicity.[11]

However, a subsequent report by Mastroiacovo et al.[12] observed only three major malformations among several hundred women exposed to 10,000 to 300,000 IU (median exposure of 50,000 IU) per day, a typical rate of occurrence regardless of vitamin A intake. Furthermore, congenital malformations were lacking in any of the 120 infants exposed to maternal intakes of vitamin A greater than 50,000 IU/day, and this high-exposure group actually demonstrated a 50% decreased risk for malformations, compared with infants not exposed to vitamin A, and a risk level lower than those exposed to midlevel doses (10,000–40,000 IU/day).[12] Other research has found a beneficial effect of vitamin A supplements in reducing free-radical–induced lipid peroxidation associated with third-trimester pregnancy–induced hypertension,[13] thus demonstrating this vitamin's antioxidant activity in an important clinical situation.

In a randomized clinical trial, Fawzi et al.[14] found that a multivitamin supplement reduced death and prolonged HIV-free survival significantly among children born to women with low maternal immunological or nutritional status. Vitamin A alone, however, was associated with increased risk of HIV transmission from mother to child while nursing. Further research is inappropriate, but prudence advises limited use of vitamin A by HIV-infected women who are nursing or susceptible to pregnancy.

Contraindications

Retinol is contraindicated in patients with compromised liver, hepatitis, or any liver disease. High alcohol intake can induce vitamin A deficiency, but ethanol and retinol may interact to increase oxidative stress and the risk of hepatotoxicity.[15]

Precautions and Warnings

High doses (>10,000 IU/day) of supplemental retinol are contraindicated in women who are or might become pregnant. This upper level may be reduced to 1500 μg (5000 IU) of vitamin A per day if foods fortified with preformed vitamin A constitute a significant component of their diet.

High doses should not be administered to older men and women, especially those with decreased BMD and corresponding increased risk of osteoporotic fractures.

At high dosage levels, especially outside the context of broad-based antioxidant nutrient networks, both vitamin A and synthetic beta-carotene have the potential to elevate triglycerides and increase oxidative stress and thereby increase risk of death from heart disease, particularly in smokers. Supplementation with synthetic all-*trans* beta-carotene has also been associated with an increased risk of lung cancer in smokers. Notably, however, retinoid therapy in former smokers, using 9-*cis*-retinoic acid, reverses loss of retinoic acid receptor-beta expression in the bronchial epithelium and may help prevent lung cancer.[16]

INTERACTIONS REVIEW

Strategic Considerations

Vitamin A is generally used in supporting healthy function and treating disorders of the tissues for which it has the greatest affinity: eyes and vision, skin and mucous membranes, cell regeneration and immune function. Both animal and plant foods can serve as dietary sources of vitamin A, but only the preformed vitamin A (primarily retinyl esters and retinol) can contribute to toxicity from excessive dietary intake.

As a nutritional supplement or as a pharmaceutical agent, retinol is primarily administered for its pharmacological activity and not as an antioxidant, as might be a primary intended function of beta-carotene and other carotenoids. In general, retinoids, whether synthetic or natural in origin, should be considered as prescription drugs because their typical use in high doses will usually override normal physiological regulatory mechanisms, thus introducing the risk of accumulation, toxicity, and adverse effects. Apart from application in supporting development and immune function in infants and children, vitamin A has largely been displaced by synthetic retinoids in conventional practice.

Vitamin A continues to play a limited role in oncology therapeutics. In some cases, particularly involving squamous tumors, up to 1 million units/day emulsified vitamin A (the preferred form because of lower hepatic accumulation) is administered daily until significant cheilosis develops, then lowered to 100,000 IU/day and gradually increased again. With such use, experienced physicians follow the blood retinol level, pushing it to the upper limit of normal, and take care to monitor hepatic enzymes, symptoms, and skeletal metabolism and adjust as needed to prevent bone loss. It is important to remain aware that liver damage may result from long-term use of 25,000 IU nonemulsified A, especially in conjunction with chemotherapeutic agents such as tamoxifen. Within conventional oncology practice, all-*trans* retinoic acid (ATRA), combined with chemotherapy, has become standard treatment for promyelocytic leukemia over the past 10 years. In contrast to such uses within conventional pharmacology, retinol and its esters are really the only "nutrient" forms of vitamin A.

NUTRIENT-DRUG INTERACTIONS

Antacids

Aluminum carbonate gel (Basajel), aluminum hydroxide (Alternagel, Amphojel); combination drugs: aluminum hydroxide, magnesium carbonate, alginic acid, and sodium bicarbonate (Gaviscon Extra Strength Tablets, Gaviscon Regular Strength Liquid, Gaviscon Extra Strength Liquid); aluminum hydroxide and magnesium hydroxide (Advanced Formula Di-Gel Tablets, co-magaldrox, Di-Gel, Gelusil, Maalox, Maalox Plus, Mylanta, Wingel); aluminum hydroxide, magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); calcium carbonate (Titralac, Tums); magnesium hydroxide (Phillips' Milk of Magnesia MOM); combination drugs: magnesium hydroxide

and calcium carbonate (Calcium Rich Rolaids); magnesium hydroxide, aluminum hydroxide, calcium carbonate, and simethicone (Tempo Tablets); magnesium trisilicate and aluminum hydroxide (Adcomag trisil, Foamicon); magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); combination drug: sodium bicarbonate, aspirin, and citric acid (Alka-Seltzer).

Interaction Type and Significance
⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability: **2. Probable**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action
Vitamin A provides nutritive support for tissue regeneration within the context of suppression of irritative gastric secretions by antacids.

Research
Patty et al.[17] investigated the combined effects of vitamin A and antacids on ulcer healing in a multiclinical, multicenter, randomized, prospective trial involving 60 patients with chronic gastric ulcer divided into three groups; they also studied the basal and maximal gastric secretory responses of 12 patients. For 4 weeks, subjects in the first group were treated with antacids only, in the second group with antacids plus vitamin A (50,000 IU orally three times daily), and in the third group the combination of antacids, vitamin A, and cyproheptadine (4 mg orally three times daily). Endoscopic analysis and planimetric measurement of ulcer sizes revealed a significant pattern of enhanced healing associated with concomitant use of vitamin A. Gastric ulcers were completely healed in 15 of 40 individuals who received vitamin A. The reduction in ulcer size was greater in the group receiving vitamin A plus antacids after both 2 and 4 weeks of use. Furthermore, vitamin A (given in doses of 100,000 IU intramuscularly) decreased neither basal nor maximal gastric secretory responses. These findings demonstrate a cytoprotective effect of vitamin A and suggest that coadministration with vitamin A and antacids may be more effective than antacids alone in healing ulcers.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Patients with gastric ulcers being treated with antacid medications may derive enhanced clinical outcomes through coadministration of vitamin A. Further research is warranted to determine safe and effective dosage levels, define parameters for establishing appropriate treatment period, and shape clinical guidelines for phased withdrawal of antacids on resolution of ulcerations. Concomitant administration of nutrients adversely affected by suppression of gastric acidity, such as vitamin B_{12}, folic acid, beta-carotene, and vitamin D, may also be warranted depending on the actions of the particular agent used, duration of use, and patient characteristics. It is not known whether similar synergy might exist between vitamin A and H_2 blockers and/or proton pump inhibitors. The relationship between vitamin A supplementation and *Helicobacter pylori* infection has also not yet been systematically investigated.

Anthelmintic Drugs

Albendazole (Zentel), levamisole (Ergamisol), praziquantel (Biltricide).

Interaction Type and Significance
⊕⊕⊕ **Beneficial or Supportive Interaction, Not Requiring Professional Management**

Probability: **2. Probable**
Evidence Base: ● **Consensus**

Effect and Mechanism of Action
Helminth infections, particularly roundworms, can interfere with vitamin A absorption, partly through their effect on intestinal epithelial cells, thus depleting body stores of vitamin A. Vitamin A deficiencies are also associated with increased risk of parasitic infections. Increased intake of vitamin A sources, whether through diet or supplementation, can counter this adverse effect of intestinal parasites and can be further enhanced by coadministration of anthelmintic agents. Enhanced vitamin A status may then help prevent or reduce symptoms associated with intestinal worms, especially roundworm. Furthermore, vitamin A supplementation has often been suggested for its physiological role in maintaining epithelial integrity, its ability to stimulate specific and nonspecific immune functions, and its beneficial effects on diarrhea. Absorption of vitamin A can also be supported by increasing levels of dietary fat intake, because both retinoids and beta-carotene are fat soluble.

Research
Depressed iron status and serum retinol have been associated with infections involving intestinal helminths, particularly *Ascaris lumbricoides* and hookworm, in South Asian and African children.[18] Deworming can contribute significantly to the prevention of morbidity and mortality associated with vitamin A deficiency among children in rural communities where intestinal helminth infection is prevalent.[19]

Jalal et al.[20] studied the effect of food sources of beta-carotene, increased dietary fat, and *A. lumbricoides* infection on serum retinol concentrations in children, 3 to 6 years of age, in Sumatra, Indonesia. Some children were administered levamisole for deworming before the feeding period; others were untreated and remained infected. Incorporation of beta-carotene sources (primarily as red sweet potatoes) into the diet significantly increased serum retinol concentrations, to the greatest degree when meals contained both additional beta-carotene sources and extra fat and the children had been dewormed. Adding more fat to the meal and deworming the children caused a rise in serum retinol similar to that observed when the diet included additional beta-carotene. Furthermore, the combined effects of fat and deworming were additive to the effects of additional beta-carotene sources. When the meal contained additional beta-carotene sources, added fat further improved serum retinol concentrations, but only with low-grade *A. lumbricoides* infection.

In a study involving 977 Kenyan children, Mwaniki et al.[21] found that the combination of multi-micronutrient supplementation, including 1000 µg (3300 IU) vitamin A, and multihelminth chemotherapy, using albendazole and praziquantel, reduced egg output of *Schistosoma mansoni*, a species of trematode blood flukes, and increased serum retinol, regardless of initial serum retinol.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Increasing vitamin A or beta-carotene intake through beta-carotene–rich dietary sources and administration of supplements, especially with additional dietary fat intake, can reduce susceptibility to and adverse outcomes from intestinal

helminth infections and work synergistically with anthelmintics to eradicate such infections. Health care professionals treating such infections or supporting preventive measures in at-risk populations can improve clinical outcomes by increasing dietary sources of vitamin A, through plant foods rich in beta-carotene and other nutrients, or through administration of broad-based nutritional supplements. Dosing levels for supplements would be based on intake needs and safety restrictions, as determined by age, weight, and other relevant factors.

Chemotherapy (Cytotoxic Agents)

Evidence: Cisplatin (*cis*-diaminedichloroplatinum, CDDP; Platinol, Platinol-AQ), cyclophosphamide (Cytoxan, Endoxana, Neosar, Procytox), docetaxel (Taxotere), fluorouracil (5-FU; Adrucil, Efudex, Efudix, Fluoroplex), methotrexate (Folex, Maxtrex, Rheumatrex), paclitaxel (Paxene, Taxol), tamoxifen (Nolvadex).
See also Tamoxifen later.

Effect and Mechanism of Action

Vitamin A has been used concurrently with chemotherapy or other forms of oncological care in many ways, and the patterns of interaction involved are not characterized by a singular or consistent mechanism of action or therapeutic strategy. All forms of cytotoxic chemotherapy are fundamentally aimed at killing dividing cells, but each class of agents clearly has different modes of action. For example, cyclophosphamide (Cytoxan) is an alkylating agent, 5-FU is an antimetabolite, and taxanes are mitosis disruptors that bind the mitotic spindle structures. Vitamin A (as retinol or retinyl esters) has its own antioxidant activity, although it is generally considered not as potent as that of the provitamin A carotenoids, which have a larger electron cloud of conjugated double bonds to utilize. In oncology, however, retinol/retinoid activities more likely are related to cell signaling (through retinoid-responsive elements of nuclear DNA), which involves cellular/tissue differentiation and induction of apoptosis.

Vitamin A with Chemotherapy in Treatment of Late-Stage Breast Cancer. An additive or synergistic effect has been reported and is presumed to be the underlying effect of concomitant use.

Antioxidants and Chemotherapy. Oxygen radicals have increasingly come under investigation as highly toxic stressors contributing to the causes of many diseases, including many forms of cancer. Vitamin A is among the nutrients well known as antioxidant agents. Antioxidants protect the body against cellular oxidative damage and thus some of the adverse effects induced by cisplatin and other cytotoxic drugs. Many nutritionally oriented health care professionals consider the oxidative damage caused by chemotherapy to be a particularly troublesome adverse effect given that evidence increasingly points to oxidative damage as a contributing factor in the causation of many cancers. However, many oncologists reason that antioxidants might be contraindicated with some agents or during some phases of chemotherapy because many chemotherapeutic agents attack cancer cells by inducing oxidative damage. For example, activation of cyclophosphamide requires hepatic oxidation, a process with which antioxidant nutrients could theoretically interfere. However, no substantial clinical research in humans has yet emerged to support this speculation or to warrant considering antioxidants as inherently contraindicated during chemotherapy.

Research

Sacks et al.[22] have conducted a number of experiments into the effects of retinoids on cancer cells, directly and in conjunction with chemotherapeutic agents. In 1990 they demonstrated that beta-ATRA inhibits macrocellular growth of a multicellular tumor spheroid model for squamous carcinoma, but allows for continuing DNA synthesis and cell cycle progression, with these two effects reconciled by a cell death effect. In 1995 these investigators used eight squamous carcinoma cell lines and reported that retinoic acid worked synergistically with chemotherapy to modulate cell growth and proliferation.[23] Although suggesting the clinical value of vitamin A as a component of integrative oncological therapeutics, such research typically evolves from nutrient administration to cotherapies using retinoids as pharmacological agents.

In a randomized controlled trial involving 100 women with late-stage metastatic breast cancer, Israel et al.[24] found that postmenopausal women experienced enhanced remission rates, duration of response, and projected survival, compared with controls, when administered 350,000 to 500,000 IU of vitamin A daily (according to body weight, given indefinitely) with their chemotherapy. Serum retinol levels were significantly increased only in the subgroup of postmenopausal women given high-dose vitamin A. Premenopausal women did not demonstrate significant elevations of serum retinol levels or significantly improved outcomes from the combined therapy.

The interactions between chemotherapeutic agents and antioxidant nutrients display similar patterns but also diversity in usage, action, and attention by researchers. The issue of antioxidants in oncology remains controversial, with conjecture on both sides and a slowly emerging body of clinically based evidence. In general, clinicians and researchers most familiar with antioxidants consistently emphasize the importance of using antioxidants in clusters capable of creating an antioxidant network, as a means of averting the potential for individual nutrients to act as pro-oxidants under conditions of high oxidative stress, particularly in individuals with multiple biochemical stressors and compromised physiology; higher doses are often recommended as more efficacious than lower doses. Furthermore, high-quality randomized trials that control for the antioxidant contribution of diet, which may well confound the contribution of supplements, have not been performed and this key issue of study design not adequately addressed by those with "conclusive" findings.

Animal research indicates that vitamin A may enhance antitumor effect of 5-fluorouracil.[25]

Besides no research linking antioxidant vitamins to reduced cyclophosphamide effectiveness in cancer treatment, Ghosh and Das[26] found that vitamin A supplementation *enhanced* the therapeutic action of cyclophosphamide in mice with vitamin A deficiency. Preliminary studies on humans undergoing chemotherapy with cyclophosphamide have indicated promise of increased survival rates when supplemented with antioxidant nutrients, including vitamin A. Nevertheless, although antioxidants might have many benefits as cotherapies, evidence as to their effectiveness in patients taking

cyclophosphamide is inconclusive.[27-30] On the other hand, no conclusive evidence has confirmed concerns of a potential adverse interaction resulting from antioxidant coadministration interfering with activation of cyclophosphamide (since it requires oxidation in the liver) and its effectiveness.[31] Thus, such concern remains speculative at this time.

A variety of studies, primarily in vitro and animal, have found vitamins A, C, and E; *N*-acetylcysteine; and other antioxidants to increase the effectiveness of and reduce adverse effects of chemotherapy in several types of cancer.[27,32-43] In a review of 71 scientific papers, Prasad et al.[44] found no evidence to support the proposition that antioxidants interfere with the therapeutic effect of chemotherapy. To the contrary, the data suggest that such combinations would do more to increase efficacy. The authors express caution, but their review indicates a low risk that these antioxidants prevent the therapeutic activity of chemotherapy, and more likely that antioxidants enhance the action of chemotherapeutic agents. Simone et al.[45a-b] arrived at parallel conclusions in a similar review of 280 peer-reviewed papers. Prasad et al.[45c] conclude the following:

> Antioxidants such as retinoids, vitamin E, vitamin C and carotenoids inhibit the growth of cancer cells. These antioxidants individually, and in combination, enhance the effects of x-irradiation, chemotherapeutic agents, and certain biological response modifiers such as hyperthermia, sodium butyrate and interferon, on cancer cells. Antioxidants individually protect normal cells against some of the toxicities produced by these therapeutic agents. Therefore, the fear of oncologists and radiation therapists that these antioxidants may protect cancer cells against free radicals that are generated by these agents is unfounded. It should be pointed out that other antioxidants such as sulfhydryl compounds will protect cancer cells at least against radiation damage. This is not true for any of the proposed antioxidant vitamins and carotenoids.

Several researchers have offered the seemingly paradoxical conclusion that the appropriate administration of antioxidant inhibitors and free-radical–generating compounds may be a useful strategy in the treatment of solid tumors. However, reports at the 1999 American Society of Cell Biology annual meeting suggested that vitamin A and E–deficient mice were less susceptible to brain tumor progression than non–vitamin-deficient control animals. Salignik et al.[46] suggested that suppression of free radicals by the antioxidant vitamins may suppress apoptosis (programmed cell death). After reviewing the relationship between chemotherapy and antioxidants, Weijl et al.[38] rebuffed warnings to avoid antioxidants during chemotherapy, but also determined that no substantive evidence supported the use of antioxidants to provide relief from the adverse side effects of chemotherapy. Although most preclinical evidence and the limited clinical evidence suggest a greater likelihood of benefit than harm from coadministration of antioxidants with radiotherapy and chemotherapy to treat human cancer, existing evidence is just beginning to answer the question,[46a] and large, well-designed clinical trials are needed for definitive answers. This question is important to public health because most mainstream medical and radiation oncology practitioners routinely proscribe concurrent use of antioxidant supplements, but many cancer patients use them covertly, based on the available information, accessible through the internet and other sources. Diet and antioxidant content vary among cancer patients, which confounds clinical trial design and has not been adequately addressed.

Interactions from coadministration of antioxidants and nutrients other than vitamin A are reviewed in the monographs of those nutrients.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The use of high doses of vitamin A to complement conventional chemotherapy offers significant potential for clinical benefit. The levels of vitamin A administered as part of the French research reviewed are much higher than levels generally considered toxic.

Physicians prescribing chemotherapy for breast cancer may want to discuss with patients the potential therapeutic value of adding vitamin A to their treatment regimen. Close supervision and regular monitoring of serum retinol levels, hepatic enzymes, and symptoms (e.g., cheilosis, headache) are required for proper dosing of vitamin A at high levels and for evaluation of efficacy, potential adverse effects, and the disease process itself.

The use of vitamin A as a chemotherapeutic agent, alone or in combination with conventional chemotherapy, involves potential risks and requires supervision by health care professionals experienced in both conventional pharmacology and nutritional therapeutics, preferably collaborating in a multidisciplinary approach to integrative oncology care. Likewise, practitioners who judiciously use antioxidants during chemotherapy or other conventional cancer care are advised to question patients about self-prescribing of antioxidants. Such concomitant use could be problematic and contraindicated, beneficial and appropriate, or both, for certain patients taking individualized and evolving dosage levels at coordinated intervals and durations. In almost all cases the administration of multiple antioxidants, such as mixed tocopherols, vitamin C, *N*-acetylcysteine, parenteral glutathione, coenzyme Q10, and proanthocyanadins, is more likely to be appropriate, safe, and effective than single agents in high doses.

High doses of vitamin A carry significant potential risks of toxicity, particularly with extended use. As noted previously, some physicians experienced in nutritional therapeutics and integrative oncology have employed dosage levels of up to 1 million units per day, using emulsified vitamin A for short periods, typically followed by reductions to 100,000 IU/day. Development of significant cheilosis can be used as a physiological monitor for toxicity and the need to reduce dosage levels until it resolves, then consider dose escalation again, based on clinical status and response.

Because the emulsified form of vitamin A is water soluble, it is absorbed directly into the lymphatics of the small intestine, thus obviating the need for micelle formation by bile salts and avoiding immediate processing by the liver ("first pass" metabolism of food components that form micelles and are transported through the portal vein to the liver). This allows larger amounts of vitamin A to reach the peripheral tissues and decreases hepatic accumulation.

Women who could become pregnant should avoid vitamin A doses greater than 10,000 IU (3000 µg) per day because it can be teratogenic, even though typical chemotherapeutic agents present significant risks for causing birth defects, particularly in the first trimester of gestation. Generally, for pharmacological action rather than supplementation support, vitamin A doses up to 25,000 IU (7500 µg) per day are considered safe for postmenopausal women and males. Nevertheless, the risk of liver damage should always be considered when administering retinoids, especially in patients with compromised liver function or chronic infection with hepatitis B or C or who are regularly ingesting hepatic toxins such as alcohol or large doses of acetaminophen. Likewise, it is also important to monitor skeletal metabolism, optimize vitamin D status by monitoring the 25-hydroxyvitamin D blood level, and adjust vitamin A dosage and serum retinol levels as appropriate to prevent bone loss.

Cholestyramine, Colestipol, and Related Bile Acid Sequestrants

Evidence: Cholestyramine (LoCholest, Prevalite, Questran), colestipol (Colestid).
Extrapolated, based on similar properties: Colesevelam (WelChol).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability:
3. Possible

Evidence Base:
◉ **Emerging** and/or
▽ **Mixed**

Effect and Mechanism of Action

Absorption of dietary (and supplemental) sources of vitamin A requires bile salts and the presence of lipids. Bile acid sequestrants, such as cholestyramine and colestipol, decrease lipid digestion and absorption. In the process, they also reduce absorption of the fat-soluble vitamins (e.g., vitamin A) and other nutrients.[47-51] Vitamin A (and beta-carotene) may also increase triglyceride levels.

Research

The general consensus over the past 40 years is that drugs that alter fat absorption and bile function will disrupt absorption and assimilation of fat-soluble nutrients. However, the evidence on the degree of such impairment, the nutrients affected, and the clinical significance is mixed, inconclusive, and still emerging. Early research by Longneck and Basu and later by West and Lloyd[52] informed several review articles that posited a general impairment of absorption of vitamin A and fat-soluble nutrients by bile acid sequestrants and other antilipidemic agents. Subsequent human trials have investigated the significance of these effects on nutrients for various medications in different patient populations.

West and Lloyd[52] (1975) studied the effects of cholestyramine (mean dosage, 0·6 g/kg/day) on 18 children with familial hypercholesterolemia over 1 to 2½ years. In addition to a major reduction in serum folate concentration and red blood cell (RBC) folate, these researchers also noted "a significant decrease in the mean serum concentrations of vitamins A and E and of inorganic phosphorus over the first two years of treatment, although values remain within the normal range." They concluded that "routine administration of fat-soluble vitamins appears unnecessary but it is prudent to measure prothrombin time [to assess vitamin K status] and serum vitamins A and E at intervals."[52]

In a study of type IIa hyperlipoproteinemic patients, Probstfield et al.[53] observed that serum total carotenoid levels fell by 30% after administration of colestipol (30 g/day) for 6 months, most likely from decreased absorption of carotenoids by bile acid sequestrant administration, but that serum vitamin A levels were not significantly altered.

In 1987, Knodel and Talbert[50] reported that "large doses of cholestyramine (>32 g/day) may be associated with malabsorption of fat-soluble vitamins," but concluded that impaired absorption of vitamins D and K presented the most significant clinical risk with long-term therapy, with bone loss and bleeding disorders being the potential adverse outcomes.

Tonstad et al.[54] investigated the effects of colestipol granules (10 g/day) and low-fat diet in an 8-week, double blind, placebo-controlled trial, followed by open treatment for 44 to 52 weeks, on low-density lipoprotein (LDL) cholesterol levels in 37 boys and 29 girls, age 10 to 16 years, with familial hypercholesterolemia. Serum concentrations of vitamins A and D, as well as other relevant nutrient parameters, were not affected significantly in the colestipol group, even though levels of serum folate, vitamin E, and carotenoids were significantly reduced. Thus, although these researchers did not suggest a need for compensatory enhancement of fat-soluble nutrients in general or vitamin A in particular, they did recommended supplementation with folate and "possibly vitamin D." They also noted the high degree of noncompliance among the adolescents in the study.

This trend toward a significant interaction raises serious questions given the ongoing debate on the correlation between nutrient status, particularly antioxidants, and long-term risk of coronary heart disease. Most importantly, with limited research and no follow-up investigation of long-term effects (i.e., decades) of such drug-induced nutrient depletion patterns on nutrient status, healthy cardiovascular function, and ultimate outcomes, the data are suggestive but inconclusive in regard to benefit versus risk.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although not always necessary, multivitamin/mineral supplementation with vitamin A and other affected nutrients can provide a safe and inexpensive means of avoiding adverse effects from these medications without interfering with (and perhaps enhancing) the therapeutic goal of supporting healthy cardiovascular function and reducing risk. Vitamin A and other fat-soluble nutrients (as well as folic acid and many medications) should be taken 1 hour before or 4 to 6 hours after bile acid sequestrants for optimal absorption. It may be more effective to coadminister water-miscible vitamin A to patients undergoing long-term bile acid sequestrant therapy. Patient characteristics will influence the need for compensatory nutrient administration, particularly age, typical diet, digestive function, comorbid conditions, and pharmacogenomic response to the medication.

Colchicine

Colchicine

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability:
4. Plausible or **2. Probable**

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Oral colchicine may impair absorption of vitamin A and other nutrients.[55,56] Colchicine also blocks hepatic release of retinol-RBP and thereby impairs upregulation of serum retinol and interferes with serum retinol homeostasis.

Research

Race et al.[55] reported that oral colchicine can induce intestinal malabsorption, affecting beta-carotene and other nutrients.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing colchicine for an extended period can suggest to patients the likely benefit of supplementing

with a high-potency multivitamin/mineral supplement to compensate for potential drug-induced depletion of vitamin A, beta-carotene, and other nutrients. Further research through well-designed human trials is warranted to determine the severity, frequency, and clinical implications of this probable interaction and to identify characteristics of individuals most susceptible to clinically significant adverse effects.

Corticosteroids, Oral

Betamethasone (Celestone), cortisone (Cortone), dexamethasone (Decadron), fludrocortisone (Florinef), hydrocortisone (Cortef), methylprednisolone (Medrol) prednisolone (Delta-Cortef, Orapred, Pediapred, Prelone), prednisone (Deltasone, Liquid Pred, Meticorten, Orasone), triamcinolone (Aristocort).

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**
⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**
✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability: **4. Plausible**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Extended use of oral corticosteroids can impair immune function and wound healing. The nutritive effect of vitamin A on immune function and tissue regeneration could prevent and support recovery from such adverse drug effects. Evidence indicates that oral corticosteroids may deplete tissue levels of vitamin A. However, some oral steroids may stimulate transient increases in plasma concentrations of vitamin A and RBP in some circumstances.

Research

Hunt et al.[57] observed that administration of topical or internal vitamin A reversed the inhibitory effect of cortisone on healing of open wounds and improved wound healing in 8 of 10 patients receiving corticosteroid therapy. Theoretically, concomitant vitamin A supplementation might interfere with the therapeutic action of corticosteroids in some patients, but evidence is lacking.[58]

Steroidal anti-inflammatory drugs may contribute to depletion of vitamin A. Using adult male rats, Atukorala et al.[59] found that the administration of large doses of corticosterone resulted in a rapid loss of vitamin A from the plasma, liver, adrenals, and thymus. Of the organs studied, the thymus appeared to be the most sensitive to treatment. Subsequent coadministration of vitamin A with corticosterone reversed the steroid-mediated depression of vitamin A levels in plasma and tissue. Also using a rat model, Georgieff et al.[60] found significant reductions in liver and lung tissue concentrations of vitamin A, retinol, and individual retinyl esters in animals treated with dexamethasone, including those assessed as "vitamin A sufficient" at the onset and demonstrating transient elevations in serum retinol levels in response to the drug.

In a prospective cohort study involving very-low-birthweight (VLBW) neonates with bronchopulmonary dysplasia (BPD), Shenai et al.[61] investigated the effects of a 7-day course of dexamethasone to test the hypothesis that vitamin A status is critical for the therapy's beneficial pulmonary response. They measured plasma concentrations of vitamin A and RBP at baseline, then during and after dexamethasone treatment, and graded pulmonary response to dexamethasone daily. A "significant, yet short-term, increase in plasma concentrations of both vitamin A and RBP was observed in most infants treated with dexamethasone." Also, "plasma vitamin A and RBP responses to dexamethasone tended to be higher in infants with a positive pulmonary response than in those with a negative response. Accounting for gender, a vitamin A response with each 10.0 microg/dL increment in plasma vitamin A concentration was associated with a 60% increase in the odds favoring a positive pulmonary response to dexamethasone." They attributed the observed increase in plasma concentrations of both vitamin A and RBP to endogenous mobilization of hepatic vitamin A stores and concluded their findings "suggest that the beneficial pulmonary response to dexamethasone in infants with BPD is influenced, at least in part, by the vitamin A status."[61] Potential synergy derived from coadministration of vitamin A was not investigated in relation to this research but may warrant investigation, given the evidence that vitamin A and its active metabolites are important to premature infants in general and support healthy respiratory epithelial differentiation and growth in particular.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing oral corticosteroids, especially for extended periods, are advised to consider coadministration of or subsequent supplementation with vitamin A. Daily doses of up to 25,000 IU (7500 µg) of vitamin A are considered safe for men and postmenopausal women for limited periods. However, women who may become pregnant should restrict their daily intake of vitamin A to less than 5000 IU (1500 µg) in supplemental form. Alternatively, when beta-carotene is used as the supplemental source, daily doses of 25,000 IU (15 mg), or even as high as 100,000 IU (60 mg), are considered safe, except in smokers (see Beta-carotene monograph). The temporary elevations of serum levels reported in the literature may not be problematic and may be beneficial in some patients but could be inappropriate for others, especially those with compromised liver function. Whenever administering vitamin A, especially in doses over 50,000 IU/day, it is important to monitor serum levels for inappropriate excess and to advise patients to report headaches or other signs of toxicity promptly. Likewise, with drugs such as steroids, it is equally important to be alert for depleted vitamin A status.

HMG-CoA Reductase Inhibitors (Statins)

Atorvastatin (Lipitor), fluvastatin (Lescol, Lescol XL), lovastatin (Altocor, Altoprev, Mevacor), combination drug: lovastatin and niacin (Advicor), pravastatin (Pravachol), rosuvastatin (Crestor), simvastatin (Zocor); combination drug: simvastatin and extended-release nicotinic acid (Niaspan).

Interaction Type and Significance

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

Probability: **4. Plausible**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

The 3-hydroxy-3-methylglutaryl–coenzyme A (HMG-CoA) reductase inhibitors may increase serum retinol levels. The question of how HMG-CoA reductase inhibition might alter liver regulation of vitamin A has not been investigated.

Research

Muggeo et al.[62] observed a pattern of elevation in serum retinol levels over 2 years of therapy in 37 hypercholesterolemic patients treated with diet modification and HMG-CoA reductase inhibitors.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Pending further research with well-designed clinical trials of sufficient size, physicians prescribing HMG-CoA reductase inhibitors should monitor blood levels of vitamin A in patients also taking this nutrient, particularly those with compromised liver function, and consider alternatives to statins in compromised patients. Furthermore, regular monitoring of liver function, especially enzyme levels, is important for prudent management of all patients taking statin drugs. Coadministration of coenzyme Q10 is also appropriate to prevent adverse effects upon endogenous coenzyme Q10 synthesis by HMG-CoA reductase inhibition.

Medroxyprogesterone

Conjugated equine estrogens and medroxyprogesterone (Premelle cycle 5, Prempro); medroxyprogesterone, oral (Cycrin, Provera); Medroxyprogesterone, injection (Depot medroxyprogesterone acetate, DMPA; Depo-Provera, Depo-subQ Provera 104); progestin and estrogen injectable: estradiol cypionate and medroxyprogesterone acetate (Cyclofem, Lunelle).

See also Oral Contraceptives below.

Interaction Type and Significance

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

Probability: **3. Possible** or **2. Probable**

Evidence Base: ◉◉ **Emerging**

Effect and Mechanism of Action

Medroxyprogesterone acetate (MPA) use is associated with elevations in serum retinol levels. Exogenous estrogen and progestin increase hepatic synthesis of RBP, thus increasing the export of RBP-retinol complex in the blood.

Research

Numerous clinical trials have investigated the effect of medroxyprogesterone administration, whether for contraception or in menopausal hormone replacement therapy (HRT), on blood levels of vitamin A and its metabolites as well as other nutrients. Most studies report increased serum retinol levels, with 40% mean increases in some trials; one study also noted RBP elevations.[63-67] In 12 nonlactating healthy Thai women, Amatayakul et al.[63] found no significant changes in levels of several nutrients, including vitamin A serum levels, before and with daily coadministration of a vitamin-mineral formulation that included vitamin A and beta-carotene, in association with 1 year of MDA use as an injectable contraceptive (150 mg intramuscularly every 90 days). In a subsequent study on the effect of 1 year of oral contraceptive (OC) use on liver vitamin A storage, as assessed by the relative dose response (RDR) test, these researchers reported that daily (one capsule) or periodic (two capsules 7 days per month) multivitamin supplementation, including 1700 µg vitamin A per capsule, did not significantly influence vitamin A serum values. However, the RDR test after 13 cycles was elevated in one woman who had taken OCs and the periodic multivitamin supplement; it reverted to normal after supplementation with vitamin A.[65]

Given the inadequate nutritional intake or compromised nutrient status of the women in some of these studies, the researchers have interpreted the phenomena of elevated serum retinol as beneficial. However, in the study of Nigerian women, whose diet is typically high in carotenoids, Wien and Ojo[68] reported that serum carotene was lower in OC users (combination estrogen-progestogen) than in groups using intrauterine device (IUD) or injectable progestogen. These researchers concluded that "more detailed study of plasma transport forms of vitamin A is needed to determine if the very high serum vitamin A levels seen in some OC users in this population are potentially harmful."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing medroxyprogesterone for contraception or menopausal HRT should consider monitoring blood levels of vitamin A, particularly in patients with compromised liver function. vitamin A supplementation may need to be avoided in some patients; in others it might be indicated, depending on patient characteristics and response to the medication. Enhanced carotenoid intake (diet, supplementation) may be beneficial. Dietary intake of preformed vitamin A and provitamin A carotenoids, nutritional status, age and menstrual status, dose, form, and therapeutic intent all influence how much medroxyprogesterone alters vitamin A levels and function and whether this is beneficial, adverse, or insignificant.

Methyltestosterone

Methyltestosterone (Android, Methitest, Testred, Virilon); combination drug: methyltestosterone and esterified estrogens (Estratest, Estratest HS).

Related but evidence lacking for extrapolation: Fluoxymesterone (Halotestin); testolactone (testolacton; HSDB 3255, SQ 9538; Fludestrin, Teolit, Teslac, Teslak); testosterone cypionate.

Interaction Type and Significance

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability: **6. Unkown**

Evidence Base: ☐ **Inadequate**

Effect and Mechanism of Action

The mechanism involved in the following report is not known.[69] Also, no research has focused on this potential interaction, its mechanisms, susceptibility factors, or clinical implications.

Report

Nisbett et al.[69] reported the case of a 59-year-old man with a 3-month history of night blindness and a 9-month history of steatorrhea subsequent to his initiation of therapy with methyltestosterone. Low serum levels of carotene (0.1 mmol/L) and vitamin A were accompanied by numerous changes in visual

function. The symptoms and the biochemical and electrophysiological abnormalities resolved within 9 months of the discontinuation of methyltestosterone.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Although this report may represent an anomalous phenomenon, it still suggests a need for further research. Physicians prescribing methyltestosterone (an anabolic steroid, not testosterone replacement) may find it prudent to assess patients for vitamin A status and recommend concomitant supplementation with vitamin A and/or beta-carotene as indicated.

Mineral Oil

Agoral, Kondremul Plain, Liquid Parafin, Milkinol, Neo-Cultol, Petrogalar Plain.

Interaction Type and Significance
✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**
≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **4. Plausible**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action
Mineral oil, as a lipid solvent, may absorb many substances and interfere with normal absorption of retinol, beta-carotene, and other nutrients.

Research
Some disagreement exists, but most research has found that mineral oil can interfere with the absorption of, and thus contribute to a depletion of, many nutrients, including beta-carotene, calcium, phosphorus, potassium, and vitamins A, D, K, and E. One study involving 25 children with chronic constipation found that a short course of mineral oil can reduce serum levels of beta-carotene while elevating serum retinol levels modestly.[70]

Nutritional Therapeutics, Clinical Concerns, and Adaptations
As a preventive and protective measure, health care professionals are advised to recommend regular use of a multivitamin supplement to patients using mineral oil for any extended period. Malabsorption of fat-soluble vitamins caused by ingestion of mineral oil can be minimized by administering mineral oil on an empty stomach or taking vitamin or mineral supplements at least 2 hours before or after the mineral oil. In general, internal use of mineral oil should be limited to less than 1 week.

Neomycin

Neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin); combination drugs: Adcortyl with Graneodin, Betnovate-N, Dermovate-NN, Gregoderm, Synalar N, Tri-Adcortyl, Trimovate.

Interaction Type and Significance
≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **2. Probable**
Evidence Base: ●●● **Consensus** or ○ **Preliminary**

Effect and Mechanism of Action
Oral neomycin impairs absorption of vitamin A, especially in large doses.[48,56]

Research
In a rat model, Favaro et al.[71] observed that neomycin reduced the bioavailability of vitamin A by approximately 13% in both vitamin A–deficient and normal animals. In a double-blind trial involving five healthy male subjects, Jacobson et al.[72] observed a significantly reduced increase in plasma vitamin A levels in all study subjects subsequent to consuming a standard meal containing vitamin A (300,000 IU) when followed by neomycin sulfate (2 g) versus placebo.

The significance of this interaction on daily supplementation of vitamin A has not undergone further research and remains unknown. Nevertheless, this interaction hypothesis has largely settled into the status of consensus, even though evidence from clinical trials is minimal.

Nutritional Therapeutics, Clinical Concerns, and Adaptations
Physicians prescribing neomycin internally for more than 2 to 3 days can advise patients of the probable benefit of supplementing with vitamin A (25,000 IU or 7.5 mg daily) or beta-carotene (25,000 IU or 15 mg daily). Individuals using neomycin topically will not experience problems related to malabsorption; likewise, adverse effects are unlikely to result from a single dose of oral neomycin as part of surgery preparation.

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCept 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).
See also Medroxyprogesterone earlier.

Interaction Type and Significance
◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**
⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**
✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

Probability: **3. Possible** or **2. Probable**
Evidence Base: ◉◉ **Emerging**

Effect and Mechanism of Action
Oral contraceptive use has been associated with increased blood levels of vitamin A (and copper).[73-75] Exogenous

estrogen and progestin increase hepatic synthesis of retinol-binding protein (RBP), thus increasing the export of RBP-retinol complex in the blood.

Research

Several studies have reported an association between the use of OCs and increased serum levels of vitamin A.[75,76,77] Horwitt et al.[78] found that women using OCs had the lowest average levels of carotenoids corresponding to the highest average levels of vitamin A in the serum, and that estrogens seemed to increase the rate of conversion of carotene to vitamin A. The clinical implications of this potential interaction are uncertain at this time.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing exogenous estrogen and progestins for contraception may consider monitoring blood levels of vitamin A in patients, particularly in individuals with compromised liver function. Vitamin A supplementation may need to be avoided in some women; in others it might be indicated, depending on patient characteristics and response to the medication. Enhanced carotenoid intake (diet, supplementation) may be beneficial. Dietary intake of preformed vitamin A and provitamin A carotenoids, nutritional status, age and menstrual status, dose, form, and therapeutic intent all affect the degree to which OC administration alters vitamin A levels and function and whether this is beneficial, adverse, or insignificant.

Orlistat (Xenical)

Orlistat (alli, Xenical)

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability:
3. Possible (short term) or
4. Plausible (long term)

Evidence Base:
◉◉ **Emerging**

Effect and Mechanism of Action

As a gastrointestinal (GI) lipase inhibitor that reduces dietary fat absorption, orlistat can reduce the absorption of vitamin A and other fat-soluble nutrients.

Research

Melia et al.[79] reported that orlistat had no significant short-term effect on blood levels of vitamin A in a small, open-label, placebo-controlled, randomized, two-way crossover study involving 12 healthy volunteers. Each participant received a single oral dose of 25,000 IU vitamin A, followed 24 hours later by a single oral dose of 400 IU vitamin E, on two separate occasions during oral administration of 120 mg orlistat or placebo three times daily for 9 days. A washout period of at least 2 weeks separated the two treatments. Based on subsequent analysis of serum concentrations of retinol, no significant effect was found on absorption of vitamin A during oral administration of 120 mg orlistat or placebo, although absorption of vitamin E was reduced significantly (by ~43% on C_{max} and ~60% on AUC). In a multicenter, randomized, double-blind, parallel-group clinical trial involving 676 obese male and female subjects, Van Gaal et al.[79a] examined dose parameters, tolerability, and effects of orlistat over 6 months. Mean levels of vitamins A, D, and E and beta-carotene remained within the clinical reference ranges in all treatment groups and rarely required supplementation.

In a year-long multicenter study assessing the efficacy and tolerability of orlistat (120 mg three times daily) on weight loss in 228 obese adult patients Finer et al.[80] coadministered vitamins A, D, and E to a small proportion of subjects "to maintain normal plasma levels of fat-soluble vitamins" and concluded that "fat-soluble vitamin supplements may be required during chronic therapy." In a clinical trial involving seventeen obese African-American and Caucasian adolescents receiving orlistat, 120 mg three times daily, McDuffie et al.[81] observed several significant nutrient depletion patterns despite coadministration of a daily multivitamin supplement containing vitamin A (5000 IU), vitamin D (400 IU), vitamin E (300 IU), and vitamin K (25 µg). However, during 3 to 6 months of orlistat treatment, acute absorption of retinol was not significantly altered, and serum levels of vitamin A did not change significantly. In contrast, mean vitamin D levels were significantly reduced compared with baseline after 1 month of orlistat, despite multivitamin supplementation, and alpha-tocopherol absorption was significantly reduced, although serum levels were not significantly altered.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although alpha-tocopherol, vitamin D, and beta-carotene status may be adversely affected by orlistat, the emerging evidence indicates it does not impact absorption enough to deplete serum retinol levels to a clinically significant degree, at least not in most patients over periods up to 12 months. The average hepatic storage of vitamin A can prevent deficiency for 2 years with no vitamin A intake and may significantly confound attempts to assess such interactions. Nevertheless, physicians prescribing orlistat may find it prudent to monitor relevant nutrient status, as well as suggest regular use of a multivitamin containing low to moderate dosages levels of vitamin A and other fat-soluble nutrients, when treating patients likely deficient in such nutrients and for whom extended use (>1 year) increases the risk of cumulative adverse effects.

Retinoids

Acitretin (Soriatane), bexarotene (Targretin); etretinate (Tegison), isotretinoin (13-*cis* retinoic acid; Accutane), tretinoin (all-*trans* retinoic acid, ATRA; Atragen, Avita, Renova, Retin-A, Vesanoid, Vitinoin).

Interaction Type and Significance

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

Probability:
2. Probable or
1. Certain

Evidence Base:
●●● **Consensus** (extrapolated);
☐ **Inadequate** (direct)

Effect and Mechanism of Action

Tretinoin and other pharmaceutical retinoids are modified versions of the vitamin A molecule. For example, isotretinoin is an isomer of all-*trans* retinoic acid (ATRA), a metabolite of retinol. A high dose intake of any retinoid (e.g., >50,000 IU daily) can result in accumulation and toxicity. An additive effect is predicted from concurrent intake of pharmaceutical retinoids and vitamin A supplements, based on structural similarities and known toxicities.

Research

Clinical research into interactions between and combined toxicity of retinol and retinoids has generally been avoided, regarded as unethical because of the apparently self-evident risk of clinically significant adverse effects. However, clinical trials do provide evidence of the impact of exogenous retinol sources on internal levels.

Rollman and Vahlquist[82] administered oral isotretinoin (0.5 mg/kg/day) for 3 months to 17 patients with severe acne vulgaris, then continued isotretinoin at a higher dose (0.75 mg/kg/day) to a subset of eight patients for an additional 3 months. After 3 months of therapy, epidermal retinol content increased by 53%, whereas dehydroretinol decreased by 79%. The researchers concluded that isotretinoin therapy interferes with the endogenous vitamin A metabolism in the skin. In a subsequent trial by this team involving 22 subjects with severe acne, administration of isotretinoin (1 mg/kg/day) for 4 months produced a marked increase in retinol and a decrease in dehydroretinol content in the skin.[83]

Clinical Implications and Adaptations

Even though no studies have confirmed adverse interactions, the structural similarities between and significant toxicities of both pharmaceutical retinoids and naturally occurring forms of vitamin A warrant caution. Consequently, supplementation of vitamin A by anyone using Accutane or related substances should be undertaken only under the supervision of an appropriately trained health care professional. These concerns are amplified for women of childbearing age because the risk of birth defects inherent to either substance is increased by their simultaneous use.

Physicians prescribing retinoids are advised to ask patients about use of vitamin supplements. Conservative practice suggests avoidance of supplemental vitamin A (particularly >10,000 IU/day) while taking Accutane or other retinoids. Most multivitamin formulations will be within the range generally considered as safe. Nevertheless, patients should watch for signs of toxicity. Headache is a common adverse effect associated with vitamin A toxicity; bone pain, dry scaly skin, and hair loss are other potential symptoms.

Some retinol is metabolized into retinoic acid, but in the absence of retinol deficiency, minimal beta-carotene (or alpha-carotene) is metabolized into retinol. Thus, current knowledge indicates that beta-carotene supplementation introduces no known risk of contributing to cumulative retinol toxicity through an additive interaction.

Tetracycline Antibiotics

Evidence: Minocycline (Dynacin, Minocin, Vectrin).
Extrapolated: Demeclocycline (Declomycin), doxycycline (Atridox, Doryx, Doxy, Monodox, Periostat, Vibramycin, Vibra-Tabs), oxytetracycline (Terramycin), tetracycline (Achromycin, Actisite, Apo-Tetra, Economycin, Novo-Tetra, Nu-Tetra, Sumycin, Tetrachel, Tetracyn); combination drugs: chlortetracycline, demeclocycline, and tetracycline (Deteclo); bismuth, metronidazole, and tetracycline (Helidac).

Evidence Base:
◉◉◉ **Consensus** (extrapolated);
● **Preliminary** (direct)

Effect and Mechanism of Action

Benign intracranial hypertension and pseudotumor cerebri (PTC) have been associated with both hypervitaminosis A and tetracycline use independently. Vitamin A may potentiate the development of intracranial hypertension when taken in combination with tetracycline antibiotics. The development of severe headaches and PTC (or benign intracranial hypertension) have been associated with such concurrent use.[84,85]

Reports

Use of retinoids, particularly Accutane, has been associated with a number of cases of pseudotumor cerebri, some of which involved concomitant use of tetracyclines. First described by Gerber et al.[86] in 1954, PTC or benign intracranial hypertension has long been associated with vitamin A administration.[87,88] PTC occurs in 30% to 50% of patients with hypervitaminosis A and has been associated with isotretinoin therapy and etretinate in particular.[85,89–91] Combination therapy with tetracyclines may increase the risk of occurrence. Typical symptoms include papilledema, vision problems, nausea, and severe headaches. However, three specific criteria constitute its clinical characterization: (1) neurological and ocular symptoms and signs of increased intracranial pressure, which may include headache, nausea, transient visual obscurations, sixth-nerve palsies, and papilledema; (2) radiologically demonstrable normal or small cerebral ventricles; and (3) elevated cerebrospinal fluid (CSF) pressure.[92,93]

Moskowitz et al.[94] published a case report describing a 16-year-old girl who developed headaches and double vision after starting treatment for acne with vitamin A and minocycline; these adverse effects resolved once the compounds were discontinued. Further research is warranted to determine whether the symptoms could have been caused by an interaction between vitamin A and the drug.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Despite minimal direct evidence, conservative practice warrants avoidance of concomitant treatment with tetracycline antibiotics and vitamin A, based on functional equivalence of vitamin A and pharmaceutical retinoids and standard contraindications against coadministration of tetracyclines and such agents. Physicians prescribing antibiotics, particularly tetracyclines, need to ask patients about supplement use, particularly self-administration of vitamin A; tetracycline antibiotics and vitamin A are both used for acne vulgaris. Patients should be advised to limit supplemental retinol to 10,000 IU or less and to watch for signs of toxicity. Headache is a common adverse effect associated with vitamin A toxicity, as are bone pain, dry scaly skin, and hair loss.

Erythromycin can serve as an effective alternative to the tetracycline family and is less likely to produce serious adverse interactions, when antibiotic therapy is considered imperative.

Current knowledge indicates that in the absence of retinol deficiency, minimal beta-carotene (or alpha-carotene) is metabolized into retinol. Thus, beta-carotene supplementation does not contribute to cumulative retinol toxicity, although evidence of its efficacy in treating acne vulgaris is relatively

weak compared with that supporting the use of retinol and related substances.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Antibiotics

Concomitant use of vitamin A with antibiotics has been proposed as efficacious in the treatment of shigellosis. Compromised nutritional status can play a significant role in susceptibility to many infections, and vitamin A is well known for its ability to reduce risk and assist treatment of many viral and bacterial infections. The use of vitamin A with antibiotic therapy represents an area of potential synergy in integrative therapeutics. However, systematic research is only beginning, and a wide range of clinical trials will be necessary before substantive conclusions can be made on nutritional synergies in antibiotic-treated bacterial infections.

In a randomized, double-blind, controlled clinical trial involving 83 children in Bangladesh, age 1 to 7 years, with acute shigellosis but no clinical signs of vitamin A deficiency, Hossain et al.[95] investigated the efficacy of a single, large oral dose of vitamin A. Nalidixic acid (55 mg/kg/day, every 6 hours), or an alternative determined by sensitivity test, was administered to all subjects. Of these, 42 received a single oral dose of 200,000 IU of water-miscible vitamin A as retinyl palmitate plus 25 IU of vitamin E; the 41 subjects in the control group received 25 IU of vitamin E. Subjects were evaluated after 5 days for evidence of "bacteriological cure." The researchers concluded that a single oral dose of 200,000 IU vitamin A can hasten clinical cure in acute shigellosis, can reduce its severity by promoting repair of the colonic mucosa and stimulating the immune system, and was especially relevant for children in areas with widespread vitamin A deficiency.

Salam et al.[96] criticized the previous study's design and the interpretation of the findings, emphasizing that the antibiotic used did not provide adequate antimicrobial treatment for most of the patients. They stated that the original authors' conclusions were not supported by the data, and that the potential clinical benefit of adjuvant vitamin A administration could not be proved without significant changes in study design and further research.

See also Tetracycline Antibiotics and Neomycin sections.

Anticonvulsant Medications, Including Phenobarbital, Phenytoin, and Valproic Acid

Evidence: Carbamazepine (Carbatrol, Tegretol), divalproex semisodium, divalproex sodium (Depakote), ethosuximide (Zarontin), phenobarbital (phenobarbitone; Luminal, Solfoton), phenytoin (diphenylhydantoin; Dilantin, Phenytek), sodium valproate (Depacon), valproic acid (Depakene, Depakene Syrup), valproate semisodium.

Extrapolated, based on similar properties: Clonazepam (Klonopin), clorazepate (Tranxene), ethotoin (Peganone), felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), gabapentin (Neurontin), lamotrigine (Lamictal), levetiracetam (Keppra), mephobarbital (Mebaral), methsuximide (Celontin), oxcarbazepine (Trileptal), pentobarbital (Nembutal), piracetam (Nootropyl), primidone (Mysoline), topiramate (Topamax), trimethadione (Tridione), vigabatrin (Sabril), zonisamide (Zonegran).

Conventional practice regards both vitamin A and anticonvulsant drugs as carrying significant risks of teratogenic adverse effects, especially when taken in high doses during pregnancy, although the mechanism involved has thus far eluded researchers. Preliminary evidence suggests that anticonvulsant medications can significantly alter endogenous retinoid metabolism in several ways. In particular, numerous studies have found that antiepileptic drugs (AEDs) alter endogenous retinoid concentrations, and that this effect could provide a possible mechanism for the pattern of teratogenesis observed with anticonvulsant therapy.

Although birth defects have been presented as a significant risk of high levels of vitamin A intake, other research indicates that supplemental vitamin A might prevent birth defects in children born to women receiving multiple-anticonvulsant therapy. All-*trans* retinoic acid (ATRA) and other vitamin A metabolites significantly influence embryonic development (e.g., growth, differentiation, morphogenesis), and imbalances in vitamin A status, both excess and deficiency, have been associated with teratogenic effects. Thus, medications such as AEDs that disrupt healthy levels of plasma retinoids could result in adverse effects, which could vary depending on the pathophysiology of the patient's underlying disorder(s), the medications and dosage levels being used, as well as the clinical response, nutritional status, general state of health, and other characteristics of the mother.

Evidence indicates that the toxicity of anticonvulsant drugs, and most likely some of their teratogenic effect, may be related to low blood levels of vitamin A. Nau et al.[97] measured plasma levels of retinol and its oxidative metabolites all-*trans*, 13-*cis*, and 13-*cis*-4-oxo retinoic acid in 75 infants and children treated with various AEDs for seizures and in 29 untreated controls of comparable age. Retinol levels increased with age, whereas the concentrations of retinoic acid compounds did not exhibit age dependency. Valproic acid monotherapy increased retinol levels in the young age group, and a trend toward increased retinol concentrations was seen in all other patient groups. The authors also noted significant declines in plasma levels of 13-*cis* and 13-*cis*-4-oxo retinoic acid in all patient groups treated with phenytoin, phenobarbital, carbamazepine, and ethosuximide, in combination with valproic acid, to levels below one third and one tenth of corresponding control values, respectively. Only minor changes were observed with ATRA, except in one patient group treated with valproic acid plus ethosuximide who demonstrated increased levels of this retinoid.

The available research does not conclusively answer whether coadministration of anticonvulsants and vitamin A inherently results in adverse effects or increases the risk of birth defects when taken during pregnancy. Because both retinoids and AEDs are highly associated with teratogenicity, clinical trials adding retinoid to AEDs in pregnant epileptic women are unlikely and inadvisable. Ultimately, characterization of these interactions remains important for understanding pharmacology and physiology, but it does little to change the recommendations of clinicians for their female patients of childbearing age; that is, neither anticonvulsants nor moderate to high doses of vitamin A should be considered as safe during pregnancy; and alternative therapeutic strategies of lesser toxicity are required.

Furthermore, these cautions need to be extended because of "off-label" prescribing of medications broadly classified as "anticonvulsants." These medications may be more often prescribed for pain, insomnia, anxiety, migraines, postherpetic neuralgia, and conditions other than seizure disorders. For example, up to 90% of gabapentin (Neurontin) is prescribed for off-label purposes, which are aggressively promoted

by drug manufacturers and marketers. Such off-label use, however, is generally for conditions with less serious consequences than uncontrolled seizure disorders, and thus continued medication use during pregnancy is less likely to occur for such conditions.

Arachidonic Acid Cascade Inhibitors

5,8,11,14-Eicosatetraenoic acid, curcumin, indomethacin, 1-phenyl-3-pyrazolidone (phenidone), nordihydroguaiaretic acid (NDGA).

Based on the findings of previous in vivo research Spingarn et al.[98] conducted in vitro studies on the potential synergistic effects of combining 13-*cis* retinoic acid (a retinoid, Accutane) and arachidonic acid cascade inhibitors (AACIs) on growth of head and neck squamous cell carcinoma (HNSCC). First, they investigated the effects of several AACIs (indomethacin, curcumin, phenidone, nordihydroguaiaretic acid, and 5,8,11,14-eicosatetraenoic acid) and 13-*cis* retinoic acid on the growth of two HNSCC cell lines and found that AACIs caused dose-dependent growth inhibition of both cell lines. When they combined these substances with 13-*cis* retinoic acid, they found that, except for indomethacin, they were able to inhibit HNSCC cell growth at lower concentrations of these drugs.

Although provocative and encouraging, this initial research has not yet matured to the level necessary for practical implementation in a clinical setting. Furthermore, because this research involved 13-*cis* retinoic acid, rather than a standard supplemental form of vitamin A, any extrapolation to such forms of vitamin A are not directly supported by the available evidence. Oncologists might consider discussing the potential benefit of such experimental adjunctive treatment options with patients. Such coadministration would necessitate close monitoring in conjunction with health care professionals trained and experienced in nutritional therapeutics, preferably within the context of a coordinated integrative care facility. Further research is warranted.

Methotrexate

Methotrexate (Folex, Maxtrex, Rheumatrex).

Vitamin A plays an important role in the function of healthy skin and proper function of the immune system. Both vitamin A and methotrexate are used in the treatment of psoriasis; methotrexate is also used against many other conditions, including malignant tumors. Nakagawa et al.[25] found that coadministration of methotrexate and retinyl palmitate enhanced antitumor activity in mice bearing ascites sarcoma 180 or P388 leukemia.

These preliminary findings suggest potential value in further study using well-designed research. Physicians prescribing methotrexate might consider coadministration of vitamin A within the context of close supervision and regular monitoring by health care professionals experienced in both conventional pharmacology and nutritional therapeutics.

Tamoxifen

Tamoxifen (Nolvadex).

Tamoxifen is an estrogen antagonist, specific for estrogen-driven cancers, and not a form of cytotoxic chemotherapy per se. Thus it needs to be treated separately from the agents discussed earlier under chemotherapy.

Some clinical oncologists experienced in the treatment of breast cancer patients with integrative therapeutics have used high-dose emulsified vitamin A in conjunction with tamoxifen. This form of vitamin A is significantly less likely to produce as much hepatic retinyl ester accumulation, with dosage levels as high as 1 million U/day administered until significant cheilosis developed, then cut to 100,000 IU/day and gradually increased again. Close monitoring of the blood retinol level is essential, especially since it is typically pushed to or slightly beyond the upper limit of normal. Likewise, it is necessary to monitor skeletal metabolism and adjust vitamin A intake as needed to prevent bone loss. In an anecdotal report, one patient developed liver damage from long-term use of 25,000 IU nonemulsified vitamin A along with tamoxifen.[99] Further research into efficacy, safety, and factors influencing individual appropriateness is warranted through well-designed clinical trials, preferably within the context of integrative oncology care involving health care professionals trained and experienced in conventional pharmacology and nutritional therapeutics.

Thioridazine

Thioridazine (Mellaril).

Curtis and Swicord[100] stated that patients taking thioridazine exhibited elevated plasma vitamin A concentrations compared with individuals not using the medication. The clinical implications of this reported phenomenon, as well as its frequency and patterns of individual susceptibility, remain to be investigated. Well-designed clinical trials and thorough documentation of case reports are needed to determine whether this potential interaction might result in clinically significant effects. Pending such evidence, physicians prescribing thioridazine, and possibly other phenothiazines, are advised to ask patients about supplement intake, educate regarding signs and symptoms of vitamin A toxicity, and monitor those individuals for whom concurrent use appears appropriate but risky.

Warfarin and Related Oral Vitamin K Antagonist Anticoagulants

Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar), warfarin (Coumadin, Marevan, Warfilone).

Vitamin A may increase the anticoagulant effects of warfarin or related anticoagulant medications. Physicians are advised to ask all patients about supplement intake, and vitamin A dosage should be noted. Despite minimal corroborating evidence, doses of vitamin A greater than 750 μg (2500 IU) have been reported to induce a hypoprothrombinemic response.[101] Long-term use of vitamin A or use of high doses may lead to an increased risk of bleeding for those taking anticoagulant medications, particularly warfarin.

The clinical significance and frequency of occurrence of this possible interaction are uncertain, even with several case reports. Physicians prescribing warfarin need to be aware of the risk of altered treatment effect when vitamin A is coadministered and closely monitor such patients for increased effects. International normalized ratio (INR) levels and prothrombin time (PT) need to be checked with greater frequency during the first 2 weeks after either starting or stopping vitamin A, particularly at high doses, to verify that the risk of bleeding or clotting (as reflected by the INR value) is not being affected by the nutrient. In general, it is important always to monitor PT twice weekly when medications, supplements, and diet are changed; this is the safest and most reliable method of compensating for unexpected or idiosyncratic interactions in patients undergoing treatment with coumarin derivatives.

NUTRIENT-NUTRIENT INTERACTIONS

Calcium

Because growing evidence indicates that excessive vitamin A intake may promote bone loss, the concomitant increase of calcium intake in conjunction with vitamin D support (through diet, supplements, and sunlight, titrating to blood level of 25-hydroxyvitamin D) is to be encouraged with high-dose administration of retinoids more than briefly.

Iron

Vitamin A deficiency may exacerbate iron deficiency anemia. Research involving anemic children indicates that concomitant intake of iron and vitamin A supplements enhances treatment of iron deficiency more effectively than iron supplementation alone.[102] Suharno et al.[103] reported similar findings in research involving treatment of pregnant women with "nutritional anemia" in West Java, Indonesia. Vitamin A supplementation can also improve iron status in populations, especially children, when poor nutritional status, including iron deficiency, is related to helminthiasis, as discussed earlier.[18] Conversely, Muñoz et al.[104] found that supplementation with iron and zinc improved indicators of vitamin A status in Mexican preschoolers.

Vitamin D

Vitamin A may antagonize the action of vitamin D.[7]

Vitamin E

Large doses of vitamin E can interfere with the absorption of vitamin A.

Zinc

Zinc deficiency appears to interfere with vitamin A metabolism through several mechanisms, including its absorption, transport, and utilization. Zinc binds with the transporter protein RBP, which is then able to transport vitamin A from liver stores to cells and tissues of numerous organs. Consequently, zinc deficiency results in decreased synthesis of RBP, thus affecting transport of retinol to target tissues. Zinc deficiency results in decreased activity of retinyl-palmitate esterase, the hepatic enzyme that releases retinol from retinyl palmitate, its storage form. Zinc is also required for retinol dehydrogenase, the enzyme involved in the oxidative conversion of retinol into retinal.[1,105]

As noted, Muñoz et al.[104] found that administration of zinc and iron improved indicators of vitamin A status in Mexican preschoolers. However, most human studies have shown only a weak link between vitamin A and zinc status. Thus far, animal and human studies have not conclusively differentiated responses related to zinc deficiency from generalized protein-energy deficiency. In disease states in which liver function is severely compromised and both zinc and vitamin A metabolism and transport are impaired, serum zinc and vitamin A concentrations tend to be positively correlated. More research is warranted to understand further the apparent synergy between these two nutrients, its mechanisms, and contextual influences, particularly individual variations and coexisting, moderate to severe, zinc and vitamin A deficiencies.

The 108 citations for this monograph, as well as additional reference literature, are located under Vitamin A (Retinol) on the CD at the back of the book.

Vitamin B_1 (Thiamine)

Nutrient Name: Vitamin B_1, thiamine.
Synonyms: Thiamin, thiamine.
Related Substances: Aneurine hydrochloride, thiamine hydrochloride, thiaminium chloride hydrochloride; benfotiamine; tetrahydrofurfuryl disulfide (TTFD).

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Antacids ≈≈≈	Antacids interfere with the absorption of thiamine and other nutrients.	Separate intake of thiamine sources and antacids by at least 2 hours.
Antibiotics ≈≈≈	Repeated or protracted administration of broad-spectrum antibiotics can destroy beneficial intestinal flora and disrupt healthy gut ecology, including production of B vitamins. Mechanism is widely recognized, but clinical significance and long-term implications are just beginning to be acknowledged and understood.	Administration of diverse probiotic is judicious after significant antibiotic therapy. Multivitamin supplementation may be indicated if deficient.
Fluorouracil (5-FU) Antimetabolite chemotherapeutic agents ◇◇/⊕✗/◇≈≈	Fluorouracil interferes with conversion of thiamine to thiamine pyrophosphate as a means of inhibiting DNA and RNA synthesis and tumor cell proliferation. Mechanism and probability of this interaction are axiomatic, and its clinical significance is fundamental to use as chemotherapeutic strategy.	Thiamine restriction and depletion essential, but intermittent dietary enhancement or supplementation may be appropriate. Supervision and monitoring critical.
Furosemide Loop diuretics ≈≈≈/☼/◇	Furosemide and other loop diuretics can increase urinary thiamine excretion and induce thiamine depletion, which can contribute to cardiac insufficiency and aggravate congestive heart failure. With mechanism and prevalence of this adverse effect reaching consensus, so has appreciation of its profound clinical significance and long-term implications. Changes in medical practice are emerging.	Coadminister with diuresis longer than 1 month. Monitor for deficiency symptoms.
Nortriptyline Tricyclic antidepressants (TCAs) ≈≈≈/⊕⊕⊕	Response improved with coadministration of antidepressants, including nortriptyline and TCAs, and B vitamins, particularly thiamine. Mechanism undetermined: prevention of nutrient depletion or promotion of active synergistic effect, or both. Evidence preliminary but with strong positive trend. Clinical significance and individual patient factors still undefined.	B-complex coadministration judicious and considered safe, especially with probable deficiency.
Oral contraceptives (OCs) ≈≈≈/☼	Variable decreases in levels of thiamine and other nutrients associated with OC use. Clinical significance controversial; evidence mixed.	B-complex coadministration judicious and considered safe, especially with probable deficiency.
Phenytoin Anticonvulsant medications ≈≈≈/☼	Phenytoin interferes with thiamine function, particularly in brain, CNS, and CSF. Antiepileptic drugs may deplete thiamine (and folate), and supplementation may enhance therapeutic effect.	Coadminister with anticonvulsant therapy longer than 1 month. Monitor for deficiency symptoms.
Scopolamine ⊕⊕/☼	Scopolamine may interfere with CNS functions of thiamine, particularly involving acetylcholine. Preliminary evidence of reduced adverse effects with thiamine coadministration. Clinical significance probable.	Coadminister; may require high doses under supervision.
Stavudine Reverse-transcriptase inhibitor (nucleoside) antiretroviral agents ≈≈≈/☼	Thiamine used to counter severe lactic acidosis associated with stavudine, alone or with HAART protocols, particularly in patients with genetic susceptibility or preexisting vitamin deficiency. Evidence from anecdotal reports, but pattern consistent.	Preventive B-complex coadministration prudent. Intravenous thiamine administration indicated in critical cases. Close supervision, monitoring.
Tetracycline Tetracycline antibiotics ◇◇	Thiamine and other B-complex vitamins may interfere with tetracycline pharmacokinetics. Concomitant intake may significantly impair bioavailability. Evidence minimal but not controversial.	Avoid thiamine and B vitamins. If necessary, separate intake by 4 hours.

CNS, Central nervous system; *CSF*, cerebrospinal fluid; *HAART*, highly active antiretroviral therapy.

NUTRIENT DESCRIPTION

Chemistry and Forms

In 1926, thiamine was the first B vitamin isolated, as a crystalline, water-soluble, yellowish white powder with a salty, slightly nutty taste. By 1936 it had been synthesized and its chemical structure determined. This substance is heat and oxygen stable in its dry form, heat and alkali reactive in solution, and stabilized by acid.

Physiology and Function

Thiamine uptake by active transport is highest in the jejunum and ileum, with both passive diffusion and active, carrier-mediated transport. Throughout the small intestine, and generally by cells in various organs, absorption is mediated by a saturable, high-affinity transport system, and once absorbed, thiamine is primarily transported in the serum bound to albumin. In humans, thiamine can be synthesized in the large intestine as *thiamine pyrophosphate* (TPP). Too large a molecule to be absorbed across the intestinal mucosa, TPP requires the use of an enzyme to cleave the smaller thiamine molecule out of the compound. Skeletal muscle, heart, liver, kidneys, and the brain are sites of particularly high concentrations, although only small amounts of thiamine (30-70 mg) are typically stored in the body.

Thiamine is required for all tissues as a coenzyme in the metabolism of carbohydrates and branched-chain amino acids, particularly in the tricarboxylic acid (TCA) cycle and pentose phosphate shunt. Thiamine needs to be phosphorylated to become metabolically active, and thiamine diphosphate is its active form. Thiamine diphosphate is a cofactor for several important enzymes involved in the biosynthesis of neurotransmitters and various cell constituents, for the

production of reducing equivalents used in oxidative stress responses, and for the biosyntheses of pentoses (e.g., ribose, deoxyribose) used as nucleic acid precursors. When it combines with two molecules of phosphoric acid, thiamine will form TPP. Functioning as a co-carboxylase, TPP is required for the oxidative decarboxylation of pyruvate to form active acetate and acetyl coenzyme A. It is also required for the oxidative decarboxylation of other alpha keto acids such as α-ketoglutaric acid and the 2-keto-carboxylates derived from the amino acids methionine, threonine, leucine, isoleucine, and valine. TPP is also involved as a coenzyme for the transketolase reaction, which functions for the pentose monophosphate shunt pathway. With a specific role in neurophysiology separate from its coenzyme function, TPP works at the nerve cell membrane to allow displacement so that sodium ions can freely cross the membrane. Although thiamine is needed for the metabolism of carbohydrates, fat, and protein, it is especially central to carbohydrate metabolism in the brain. In addition to providing TPP, thiamine becomes part of thiamine triphosphate, which appears to have an important function in brain cell viability. Thiamine is also required in acetylcholine and fatty acid synthesis.

Research is ongoing into the genetic and biochemical factors contributing to interindividual differences in susceptibility to development of disorders related to thiamine deficiency, as well as the differential vulnerabilities of various tissues and cell types.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Thiamine deficiency manifests primarily as disorders of the nervous, cardiovascular, muscular, and gastrointestinal systems. Deficiency symptoms include: fatigue, weight loss, depression, irritability, memory loss, mental confusion, heart palpitations, tachycardia, anorexia, indigestion, edema, neuritis, neuropathies, paresthesia, hyporeflexia (especially of legs), defective muscular coordination, muscular weakness, and sore muscles (especially calves).

Historical/Ethnomedicine Precedent

Beriberi, the classic thiamine deficiency disease.

Possible Uses

Alcoholism, Alzheimer's disease, anxiety, atherosclerosis, canker sores, chronic dieting, congestive heart failure (CHF), Crohn's disease, depression, diabetes mellitus, dysmenorrhea, fibromyalgia, glaucoma, hepatitis, human immunodeficiency virus and acquired immunodeficiency syndrome (HIV/AIDS) support, insomnia, Kearns-Sayre syndrome, Leigh's disease, minor injuries, mosquito repellant, multiple sclerosis, neuropathy (especially benfotiamine), roundworms, sciatica, sensory neuropathy (diabetic), trigeminal neuralgia, Wernicke-Korsakoff syndrome; diets consisting primarily of highly processed, refined foods; treatment of thiamine deficiency–related disorders, including cardiovascular (wet) beriberi, nervous (dry) beriberi, Wernicke's encephalopathy syndrome, and peripheral neuritis associated with pellagra (vitamin B_3 deficiency); alcoholic patients with altered sensorium; various genetic metabolic disorders, such as thiamine-responsive megaloblastic anemia.

Dietary Sources

Pork, liver, chicken, fish, beef, wheat germ, dried yeast, cereal products, lentils, potatoes, brewer's yeast, rice polishings, most whole-grain cereals (especially wheat, oats, and rice), all seeds and nuts, beans (especially soybeans), milk and milk products, vegetables such as beets, green leafy vegetables.

Most plant and animal foods contain some thiamine, but the richest dietary sources are brewer's yeast and organ meats.

Thiamine deficiency is one of the most common nutritional deficiency patterns in modernized societies. Almost half the U.S. population consumes less than half the recommended daily allowance (RDA) of thiamine, according to the U.S. Department of Agriculture. Although whole grains may be rich in thiamine, processing of grains significantly reduces their thiamine content. Likewise, because thiamine is water soluble and heat sensitive, cooking largely results in the loss or destruction of this vitamin, especially when chlorinated water is used.

Clinical signs of thiamine deficiency primarily involve the nervous, cardiovascular, muscular, and gastrointestinal systems. Adults have the following symptoms:

- Mental confusion, anorexia, muscle weakness, calf muscle tenderness, ataxia, indigestion, constipation, tachycardia with palpitations.
- *Wet beriberi:* edema starting in the feet and progressing upward into the legs, trunk, and face, eventually resulting in death from cardiac enlargement and CHF.
- *Dry beriberi:* worsened polyneuritis in early stages (particularly peripheral neuritis), difficulty walking, and muscle wasting, especially atrophy of the legs.

The distinction between wet (cardiovascular) and dry (neuritic) manifestations of beriberi usually relates to the duration and severity of the deficiency, the degree of physical exertion, and the caloric intake. The wet or edematous condition results from severe physical exertion and high carbohydrate intake. The dry or polyneuritic form stems from relative inactivity with caloric restrictions during the chronic deficiency.

Wernicke-Korsakoff syndrome is the classical manifestation of central nervous system (CNS) deficiency of thiamine caused by alcoholism. Patients present with impaired memory and cognitive function, irritability, and nystagmus caused by weakness in the sixth cranial nerve; coma is a common end state. Vitamin B_1 is necessary for the metabolism of alcohol, but alcohol interferes with its absorption, making malnourished alcoholics often severely thiamine deficient. Alcoholics given intravenous (IV) glucose without thiamine are at high risk of developing Wernicke-Korsakoff syndrome and sustain permanent neurological damage, because the glucose, which also requires thiamine for its metabolism, rapidly depletes remaining tissue levels of brain thiamine. For this reason, an IV "cocktail" of glucose, thiamine, and a narcotic antagonist is typically administered in emergency rooms to unconscious patients who present with unconsciousness of unknown etiology.

Infant symptoms appear suddenly and severely, involving cardiac failure and cyanosis.

The etiology of thiamine deficiency can be traced to an exclusive diet of milled, nonenriched rice or wheat, raw fish consumption (microbial thiaminases), large amounts of tea, alcoholism (impaired absorption and storage, poor nutrition, increased thiamine utilization), use of loop diuretics, and several inborn errors of metabolism.

Special Populations

Individuals with alcoholism, anorexia, CHF, Crohn's disease, folate deficiency, malabsorption syndrome, and multiple sclerosis are at increased risk of developing thiamine deficiency, as are those undergoing long-term diuretic therapy, hemodialysis, or peritoneal dialysis.

Alcoholic individuals frequently develop a deficiency of thiamine because the vitamin is a necessary cofactor in the metabolism of alcohol. Because many alcoholics tend to eat less and drink more, and usually their alcohol-based drinks are low in thiamine, they frequently develop a thiamine deficiency. In hospitals it is routine for alcoholics to receive intramuscular (IM) injections of thiamine on admission.

Elderly persons demonstrate a general decline in thiamine levels that is apparently related more to age than to coexisting illness or health status. This increased susceptibility enhances the risk for adverse effects of drug-induced depletion, especially in regard to cardiovascular health and cognitive stability.[1]

Nutrient Preparations Available

Thiamine, water soluble. *Thiamine hydrochloride* is generally considered the preferred supplemental form of thiamine. Thiamine mononitrate is also available. Thiamine supplementation is usually provided in vitamin B–complex formulations, in most multivitamin preparations, and in vitamin-enriched foods, such as breakfast cereals.

Benfotiamine is a lipid-soluble form of thiamine developed and patented in Japan, now widely used in neuropathy therapies.

Dosage Forms Available

Capsule, liquid, tablet, effervescent tablet; liposomal spray. Parenteral form may be administered by IM or slow IV injection.

Source Materials for Nutrient Preparations

Synthesized.

Dosage Range

The RDA for thiamine varies slightly with gender and life stage.

Men (> 19 years): 1.2 mg/day
Women (> 19 years): 1.1 mg/day
Pregnancy and breastfeeding (any age): 1.4 mg/day

Adults

Supplemental/Maintenance: Dependent on dietary intake, usually 1 to 2 mg/day. A paper on the "ideal" daily thiamine intake reported that the healthiest people consumed more than 9 mg/day.[2]
Pharmacological/Therapeutic: 1.5 to 200 mg/day. In research studies, therapeutic dosage for most conditions ranges from 10 to 100 mg/day, in divided doses. In clinical practice, 200 to 600 mg/day may be given, and some clinicians have used oral dosages as high as 8 g/day, in divided doses, for a variety of metabolic disorders.
Thiamine deficiency (beriberi): 5 to 30 mg per dose, intramuscularly (IM) or intravenously (IV), three times daily (if critically ill); then orally 5 to 30 mg/day in single or divided doses, three times daily for 1 month.
Wernicke's encephalopathy: 100 mg IV initially, then 50 to 100 mg/day IM or IV until consuming a consistently balanced and nutritious diet.
Toxic: There is no defined upper limit (UL) for thiamine because of its relative safety.

Pediatric (<18 years)

Supplemental/Maintenance:
Infants: 0.3 to 0.5 mg/day
Children: 0.5 to 1 mg/day
Pharmacologic/Therapeutic, for thiamine deficiency (beriberi): 10 to 25 mg per dose, IM or IV, daily (if critically ill), or 10 to 50 mg per dose orally every day for 2 weeks, then 5 to 10 mg per dose orally daily for 1 month.
Toxic: No toxic intake level known to date.

SAFETY PROFILE

Overview

Thiamine is generally considered virtually nontoxic, even in very high doses orally. Being water soluble, thiamine excretion is rapid; the vitamin is not stored in the body, and accumulation to toxic levels is highly improbable using oral intake. No adverse effects associated with thiamine intake from food sources or nutritional supplements have been reported. Rare occurrences of adverse effects of thiamine have been documented, although they appear to be largely associated with allergic reactions to thiamine injections.

Nutrient Adverse Effects

General Adverse Effects

Adverse effects are theoretically possible but rare with oral supplemental thiamine intake. Oral doses greater than 200 mg have been reported to cause drowsiness in some individuals. In a study of 989 patients, 100 mg/day IV thiamine hydrochloride resulted in a burning effect at the injection site in 11 subjects and pruritus in one.[3]

Large doses of vitamin B_1 over an extended period may cause imbalance among various B vitamins.

Administration of IV or IM thiamine warrants caution because anaphylactic or allergic reaction infrequently occurs. Allergic reactions to thiamine injections are rare (<1%) but can be severe and include cardiovascular collapse and death, angioedema, paresthesia, warmth, and rash.

Adverse Effects Among Specific Populations

High oral intakes might have some unknown potential for adverse reactions in select, metabolically compromised populations because of pharmacogenomic susceptibility, but such data are only recently under consideration.

Pregnancy and Nursing

A review of the medical literature reveals no substantial reports of adverse effects related to fetal development during pregnancy or to breast-fed infants.

Infants and Children

A review of the medical literature reveals no substantial reports of adverse effects specifically related to the use of thiamine in infants and children.

Contraindications

No contraindications are known to date, except hypersensitivity to thiamine or to any component of any compound formulation. Some clinicians and researchers are proposing that cancer patients undergoing chemotherapy may benefit from restricted thiamine intake during treatment.

Precautions and Warnings

Use with caution with parenteral administration, especially with IV administration.

Laboratory Values

Whole-blood thiamine: Level less than 70 nmol/L indicates deficiency.
Erythrocyte transketolase (EKTA): Low activity of EKTA (< 5 U/mmol hemoglobin) indicates deficiency, as does increase in EKTA (> 16 U/mmol) after stimulation by the addition of TPP.
Therapeutic reference range: 1.6-4.0 mg/dL.

INTERACTIONS REVIEW

Strategic Considerations

Thiamine plays a critical role in a range of metabolic processes, especially the Krebs cycle and adenosine triphosphate (ATP) synthesis. Vitamin B_1 depletion by diet, lifestyle, or medications increases several risk factors, especially for the cardiovascular and nervous systems. Although thiamine is central to metabolic vitality and cardiovascular health, the use of loop diuretics increases the risk of clinically significant thiamine depletion. However, adverse effects caused by drug depletion can be safely and effectively treated with thiamine supplementation, while further supporting healthy cardiac function. Thiamine intake during chemotherapy is challenging, and personalized integrative care may clarify paradoxical data. In other, simpler situations, the potential for adverse effects from unintentional depletion of thiamine by pharmacological agents can be corrected through supplementation at typical therapeutic levels.

NUTRIENT-DRUG INTERACTIONS

Antacids, Including Aluminum Hydroxide and Magnesium Trisilicate

Aluminum carbonate gel (Basajel), aluminum hydroxide (Alternagel, Amphojel); combination drugs: aluminum hydroxide, magnesium carbonate, alginic acid, and sodium bicarbonate (Gaviscon Extra Strength Tablets, Gaviscon Regular Strength Liquid, Gaviscon Extra Strength Liquid); aluminum hydroxide and magnesium hydroxide (Advanced Formula Di-Gel Tablets, co-magaldrox, Di-Gel, Gelusil, Maalox, Maalox Plus, Mylanta, Wingel); aluminum hydroxide, magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); calcium carbonate (Titralac, Tums), magnesium hydroxide (Phillips' Milk of Magnesia MOM); combination drugs: magnesium hydroxide and calcium carbonate (Calcium Rich Rolaids); magnesium hydroxide, aluminum hydroxide, calcium carbonate, and simethicone (Tempo Tablets); magnesium trisilicate and aluminum hydroxide (Adcomag trisil, Foamicon); magnesium trisilicate, alginic acid, and sodium bicarbonate (Alenic Alka, Gaviscon Regular Strength Tablets); combination drug: sodium bicarbonate, aspirin, and citric acid (Alka-Seltzer).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability:
3. Possible

Evidence Base:
○ **Preliminary**

Effect and Mechanism of Action

Antacids interfere with the absorption of many nutrients, including thiamine. Thiamine is alkali reactive in solution and stabilized by acid. Thiamine absorption in the human small intestinal brush-border membrane vesicle is pH dependent.[4] In particular, aluminum-based antacids may lower thiamine absorption.

Report

Majoor and de Vries[5] described a patient who developed cardiac beriberi with polyneuritis after chronic use of large amounts of magnesium trisilicate.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The adverse effect on absorption of thiamine can be reduced by separating antacid use by at least 2 hours from intake of thiamine supplements or foods relied on as primary thiamine dietary sources.

Antibiotics and Antimicrobial Agents (Systemic)

Aminoglycoside antibiotics: Amikacin (Amikin), gentamicin (G-mycin, Garamycin, Jenamicin), kanamycin (Kantrex), neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin), netilmicin (Netromycin), paromomycin (monomycin; Humatin), streptomycin, tobramycin (AKTob, Nebcin, TOBI, TOBI Solution, TobraDex, Tobrex).
Beta-lactam antibiotics: Methicillin (Staphcillin); aztreonam (Azactam injection); carbapenem antibiotics: meropenem (Merrem I.V.); combination drug: imipenem and cilastatin (Primaxin I.M., Primaxin I.V.); penicillin antibiotics: amoxicillin (Amoxicot, Amoxil, Moxilin, Trimox, Wymox); combination drug: amoxicillin and clavulanic acid (Augmentin, Augmentin XR, Clavulin); ampicillin (Amficot, Omnipen, Principen, Totacillin); combination drug: ampicillin and sulbactam (Unisyn); bacampicillin (Spectrobid), carbenicillin (Geocillin), cloxacillin (Cloxapen), dicloxacillin (Dynapen, Dycill), mezlocillin (Mezlin), nafcillin (Unipen), oxacillin (Bactocill), penicillin G (Bicillin C-R, Bicillin L-A, Pfizerpen, Truxcillin), penicillin V (Beepen-VK, Betapen-VK, Ledercillin VK, Pen-Vee K, Robicillin VK, Suspen, Truxcillin VK, V-Cillin K, Veetids), piperacillin (Pipracil); combination drug: piperacillin and tazobactam (Zosyn); ticarcillin (Ticar); combination drug: ticarcillin and clavulanate (Timentin).
Cephalosporin antibiotics: Cefaclor (Ceclor), cefadroxil (Duricef), cefamandole (Mandol), cefazolin (Ancef, Kefzol), cefdinir (Omnicef), cefepime (Maxipime), cefixime (Suprax), cefoperazone (Cefobid), cefotaxime (Claforan), cefotetan (Cefotan), cefoxitin (Mefoxin), cefpodoxime (Vantin), cefprozil (Cefzil), ceftazidime (Ceptaz, Fortaz, Tazicef, Tazidime), ceftibuten (Cedax), ceftizoxime (Cefizox), ceftriaxone (Rocephin), cefuroxime (Ceftin, Kefurox, Zinacef), cephalexin (Keflex, Keftab), cephapirin (Cefadyl), cephradine (Anspor, Velocef), imipenem combination drug: imipenem and cilastatin (Primaxin I.M., Primaxin I.V.); loracarbef (Lorabid), meropenem (Merrem I.V.).
Fluoroquinolone (4-Quinolone) antibiotics: Cinoxacin (Cinobac, Pulvules), ciprofloxacin (Ciloxan, Cipro), enoxacin (Penetrex), gatifloxacin (Tequin), levofloxacin (Levaquin), lomefloxacin (Maxaquin), moxifloxacin (Avelox), nalidixic acid (Neggram), norfloxacin (Noroxin), ofloxacin (Floxin, Ocuflox), sparfloxacin (Zagam), trovafloxacin (alatrofloxacin; Trovan).
Macrolide antibiotics: Azithromycin (Zithromax), clarithromycin (Biaxin), dirithromycin (Dynabac), erythromycin oral (EES, EryPed, Ery-Tab, PCE Dispertab, Pediazole), troleandomycin (Tao).

Sulfonamide antibiotics: Sodium sulfacetamide (AK-Sulf, Bleph-10, Sodium Sulamyd), sulfamethoxazole (Gantanol), sulfanilamide (AVC), sulfasalazine (salazosulfapyridine, salicylazosulfapyridine, suphasalazine; Apo-Sulfasalazine, Azulfidine, Azulfidine EN-Tabs, PMS-Sulfasalazine, Salazopyrin, Salazopyrin EN-Tabs, SAS), sulfisoxazole (Gantrisin); combination drug: sulfamethoxazole and trimethoprim (cotrimoxazole, co-trimoxazole, SXT, TMP-SMX, TMP-sulfa; Bactrim, Bactrim DS, Cotrim, Septra, Septra DS, Sulfatrim, Uroplus); triple sulfa (Sultrin Triple Sulfa).

Chemotherapy, cytotoxic antibiotics: Bleomycin (Blenoxane), dactinomycin (Actinomycin D, Cosmegen, Cosmegen Lyovac), mitomycin (Mutamycin), plicamycin (Mithracin).

Miscellaneous antibiotics: Bacitracin (Caci-IM), chloramphenicol (Chloromycetin), chlorhexidine (Peridex), colistimethate (Coly-Mycin M), dapsone (DDS, diaminodiphenylsulphone; Aczone Gel, Avlosulfon), furazolidone (Furoxone), lincomycin (Lincocin), linezolid (Zyvox), nitrofurantoin (Macrobid, Macrodantin), oral clindamycin (Cleocin), trimethoprim (Proloprim, Trimpex), vancomycin (Vancocin).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: **3. Possible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

The B vitamins, including thiamine, are produced in appreciable amounts by probiotic microorganisms as part of their synergistic role within the healthy intestinal microecology.

Research

Repeated or chronic use of antimicrobial agents can deplete or functionally eliminate these beneficial flora and contribute to depleted status of thiamine and other important nutrients.[6,7]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The severity of disruption to the intestinal microecology will vary depending on many factors, including an individual's diet, medical history, health status, and co-morbid conditions. Potential adverse effects of antibiotics on thiamine status can be safely and effectively prevented or reversed through supplementation with thiamine and related nutrients at standard supplemental levels, along with replenishment of flora through consumption of high doses of vigorous and variegated probiotic microorganisms. Duration of such restorative nutritional therapy depends on the individual's health status as well as the dosage, duration, and type of antibiotic medications(s) being administered. Individuals not undergoing diuretic therapy, suffering from alcoholism, or characterized by other high-risk factors will generally not require, although they may benefit from, increased thiamine supplementation during or after a single course of antibiotics; a short course of probiotic therapy is still recommended as supportive in such circumstances.

Fluorouracil and Related Antimetabolite Chemotherapeutic Agents

Evidence: Fluorouracil (5-FU; Adrucil, Efudex, Efudix, Fluoroplex).

Extrapolated, based on similar properties: Agalsidase beta (Fabrazyme), capecitabine (Xeloda), cladribine (Leustatin), cytarabine (ara-C; Cytosar-U, DepoCyt, Tarabine PFS), floxuridine (FUDR), fludarabine (Fludara), gemcitabine (Gemzar), lometrexol (T64), mercaptopurine (6-mercaptopurine, 6-MP, NSC 755; Purinethol), methotrexate (Folex, Maxtrex, Rheumatrex), pentostatin (Nipent), pemetrexed (Alimta), raltitrexed (ZD-1694; Tomudex), thioguanine (6-thioguanine, 6-TG, 2-amino-6-mercaptopurine; Lanvis, Tabloid), ZD9331.

Effect and Mechanism of Action

Fluorouracil is an antimetabolite of the pyrimidine analog type. In the form of its active metabolite, 5-FU inhibits the conversion of thiamine to TPP and inhibits DNA and RNA synthesis. The cofactor of transketolase, TPP promotes nucleic acid ribose synthesis and tumor cell proliferation through the non-oxidative transketolase (TK) pathway.[8-10]

Research

The research on the role of thiamine during chemotherapy is complex and seemingly contradictory, but an emerging consensus may clarify clinical options for integrative therapies within a strategic framework. Thiamine deficiency frequently occurs in patients with advanced cancer, particularly within the context of drug-induced nutrient depletion, and therefore thiamine supplementation has often been used for nutritional support.[9] In vitro research and clinical observations suggest that fluoropyrimidines may increase cellular thiamine metabolism and depletion.[10-12] This has raised concern of possible thiamine deficiency and indicated a potential beneficial role for increased dietary intake and supplementation of thiamine.[13] Lactic acidosis caused by thiamine deficiency is known to complicate chemotherapy and radiotherapy of malignant tumors. However, clinical and experimental data demonstrate both increased thiamine utilization by tumor cells and thiamine's interference with certain types of anti-neoplastic chemotherapy.[13] In particular, metabolic control analyses predict that, by supporting a high rate of nucleic acid ribose synthesis, thiamine and other stimulators of transketolase enzyme synthesis contribute to tumor cell survival, chemotherapy resistance, and cancer cell proliferation.[13-15] Both human and animal studies support these hypotheses.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Scientific research and clinical experience suggest that no static and generic protocol is possible for thiamine support or restriction in patients undergoing antineoplastic chemotherapy, especially involving 5-FU. Integrating the findings of the research literature into a clinical context requires an individualized and evolving approach to the therapeutic process, tactical emphases, and the patient's general health status. Ultimately,

it is critical to determine whether the benefits of thiamine administration outweigh the risks of tumor proliferation and how such determination may shift through the course of treatment. Some researchers and clinicians have also suggested administration of transketolase inhibitors as a complementary tactic in treating some oncology patients. Thus, the evidence supports a flexible strategy involving phased restriction of thiamine intake during chemotherapy, followed by compensatory dietary enhancement and/or thiamine supplementation as a reasonable conservative approach, with the particulars of such implementation ultimately dependent on the prior history, emerging needs, and evolving response of the individual patient.

Intercurrent thiamine supplementation may be clinically appropriate for some patients at critical stages in their therapeutic regimen if thiamine depletion presents an overriding concern for patient survival and well-being. Implementation of such an approach to integrative personalized care requires active collaboration by health care professionals trained and experienced in both conventional pharmacology and nutritional therapeutics. When tumor-bearing patients receive thiamine-containing supplements, it would seem prudent to use RDA levels of thiamine (1-2 mg/day) and avoid higher doses (10-100 or more mg/day) of thiamine, unless the patient has cardiac, neurological, or musculoskeletal symptoms consistent with severe thiamine deficiency and promptly ameliorated by a therapeutic trial of higher-dose thiamine administration. Once corrected, a return to RDA-level supplementation and encouraging dietary intake of thiamine-rich foods, such as brewer's/nutritional yeast, would seem appropriate in view of the data on thiamine's potential to enhance tumor growth. In patients with recurrent or metastatic malignant disease, even with no evidence of tumor on scans and physical examination after treatment, micrometastatic disease is probable, and in the absence of a life-threatening deficiency syndrome, it would seem prudent to avoid high levels of thiamine administration (as well as niacin/niacinamide, shown to support growth of new blood vessels—angiogenesis—on which tumor growth and metastasis depend).

Furosemide and Related Loop Diuretics

Evidence: Furosemide (Lasix).
Extrapolated, based on similar properties: Bumetanide (Bumex), ethacrynic acid (Edecrin), torsemide (Demadex).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**
◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **1. Certain**
Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Several studies have suggested that loop diuretics, especially furosemide (Lasix), can cause thiamine depletion due to increased urinary excretion, contributing to cardiac insufficiency in patients with CHF.[16-21] Further research has indicated that the compromised thiamine status of individuals with CHF may be caused by altered metabolism, rather than simple deficiency, of thiamine. In a study of the diuretic effects of single IV doses of furosemide on six healthy volunteers, Rieck et al.[22] observed a doubling of thiamine excretion rate, along with the expected increased urine volume and sodium excretion. Another study examined cardiac function and status of select nutrients in 30 patients with idiopathic dilated cardiomyopathy using diuretics, compared with a similar number of healthy control individuals. Measuring the activity of erythrocytic transketolase and the effect of TPP, da Cunha et al.[22a] determined the presence of thiamine deficiency in 33% of the patients with heart disease (vs. 10% of controls).

Even though all loop diuretics work by inhibiting sodium and chloride reabsorption in the thick ascending limb of Henle's loop, no conclusive research on the effects of other loop diuretics on thiamine has been published. However, CHF is characteristic of wet beriberi, caused by thiamine deficiency. Patients receiving furosemide are likely to have compromised kidney function, decreased metabolic function associated with aging, malnourishment, alcoholism and other lifestyle factors, and other variables aggravating thiamine depletion, deficiency, and dysregulation.[17-19,23]

Research

As noted earlier, numerous studies have determined that thiamine depletion is a common phenomenon among patients undergoing loop diuretic therapy. For example, an investigation of 38 sequential patients in a cardiology clinic assessed thiamine status by in vitro erythrocyte transketolase activity assay and dietary intake of thiamine. Thiamine deficiency was found in 21% of the patients and evidence of risk for dietary thiamine inadequacy in 25%.[19]

A small pilot study in 1991 examined the effects of long-term furosemide therapy (80-240 mg for 3-14 months) in hospitalized patients with CHF to determine the occurrence of clinically significant thiamine deficiency caused by urinary loss.[17] Elevated levels of thiamine pyrophosphate effect (TPPE), indicating thiamine deficiency, were found in 21 of 23 furosemide-treated patients and in 2 of 16 age-matched controls. Biochemical evidence of thiamine deficiency tended to be more common among patients with poor left ventricular ejection fractions (LVEF). A 7-day course of IV thiamine, 100 mg twice daily, lowered TPPE levels to normal in six of the subjects, indicating normal thiamine utilization capacity, and improved LVEF in four of five patients, as demonstrated by echocardiography. These preliminary findings suggest that long-term furosemide therapy may be associated with clinically significant thiamine deficiency, presumed to result from urinary loss, and contribute to impaired cardiac performance in patients with CHF. Further, this apparent drug-induced depletion pattern responded to appropriate thiamine administration within an inpatient setting.

In 1995 the same research team conducted a double-blind, placebo-controlled trial in which they initially randomized 30 subjects to 1 week of either IV thiamine (200 mg/day) or placebo within inpatient care.[18] In the second phase, all individuals were discharged and given oral thiamine (200 mg/day) for 6 weeks. After the initial IV thiamine, thiamine status normalized, and LVEF increased significantly in those who received IV thiamine, in contrast to no measurable response in thiamine status among those given IV placebo. After the 7-week intervention, the 27 remaining subjects showed 22% improvement in LVEF. The researchers concluded that cardiac function in CHF patients may be exacerbated by thiamine depletion attributable to long-term furosemide therapy; thiamine supplementation or systematic dietary enhancement may avert or correct this adverse effect and its probable sequelae in patients with moderate to severe CHF.

Although there is consensus on an association between loop diuretic therapy and compromised thiamine status, conclusive evidence is lacking to confirm a consistent causal relationship. Using high-pressure liquid chromatography (HPLC) to assess blood thiamine and thiamine ester concentrations in erythrocytes of 41 elderly patients with CHF treated with furosemide (and a control group), a Swedish team found reduced thiamine diphosphate (TPP), the storage form of thiamine, but not thiamine phosphate (TP). The researchers concluded that the observed change in CHF patients taking furosemide was most likely not an expression of a thiamine deficiency, but rather of altered thiamine metabolism not yet explained.[24]

Zenuk et al.[25] investigated the thiamine status of 32 patients with CHF who received either 40 to 80 mg or 80 mg or more of furosemide daily. Using erythrocyte transketolase enzyme activity and the degree of TPPE, these researchers found that 96% (24 of 25) of those receiving the higher diuretic dose demonstrated biochemical evidence of severe thiamine deficiency, as did 57% (4 of 7) of patients taking 40 mg furosemide daily. No other clinical variables showed a significant association with thiamine status.

Thus, collectively, the body of evidence suggests that thiamine deficiency occurs in a substantial proportion of CHF patients being treated with furosemide.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Long-term diuretic administration remains a central pharmacological therapy of heart insufficiency and hypertension in conventional practice. However, loop diuretics can aggravate the high-risk status inherent to many conditions for which these medications are prescribed, especially among hospitalized or chronic care elderly patients. Thiamine supplements should be considered in patients undergoing sustained diuresis, particularly when dietary deficiency may be present. Investigating the risk posed by diuretic use for subclinical thiamine deficiency in elderly patients, Swiss researchers suggested that low-dose thiamine supplementation may help prevent the development of subclinical wet beriberi in such patients.[20] Pending conclusive evidence to the contrary, patients taking furosemide, and possibly other loop diuretics, would most likely benefit from thiamine support of 100 mg per day, orally.

Nortriptyline and Related Tricyclic Antidepressants

Evidence: Nortriptyline (Aventyl, Pamelor).
Extrapolated, based on similar properties: Amitriptyline (Elavil); combination drug: amitriptyline and perphenazine (Triavil, Etrafon, Triptazine); amoxapine (Asendin), clomipramine (Anafranil), desipramine (Norpramin, Pertofrane), doxepin (Adapin, Sinequan), imipramine (Janimine, Tofranil), nortriptyline (Aventyl, Pamelor), protriptyline (Vivactil), trimipramine (Surmontil).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

⊕⊕⊕ **Beneficial or Supportive Interaction, Not Requiring Professional Management**

Probability: **3. Possible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

The mechanism of action involved in the proposed interactions between nortriptyline and thiamine, or more exactly B-vitamin complex, is uncertain at this time, and various explanations are available. Interference with nutrient metabolism of other drug-induced depletion effects may be corrected by supplementation. A synergistic interaction between the antidepressant and the nutrient(s) may also be contributing to improved outcome measures.[26] Further research to determine the mechanism(s) of action could clarify the physiological processes and help refine integrative therapies to enhance clinical outcomes.

Research

A 1992 study involving 14 institutionalized geriatric patients with impaired cognitive function undergoing treatment for depression is the primary evidence for augmentation of nortriptyline therapy using supplemental B-vitamin complex. In this 4-week, randomized, placebo-controlled, double-blind trial, the elderly inpatients were administered open tricyclic antidepressant (TCA) treatment (nortriptyline titrated to doses yielding blood levels of 50-150 ng/mL) along with vitamins B_1, B_2, and B_6 (each 10 mg/day). The researchers reported that "the active vitamin group demonstrated significantly better B_2 and B_6 status on enzyme activity coefficients and trends toward greater improvement in scores on ratings of depression and cognitive function, as well as in serum nortriptyline levels compared with placebo-treated subjects."[27]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The coadministration of thiamine, as part of a B-vitamin complex formula at customary dosage levels, offers reasonable potential for enhancing treatment of depression (especially with cognitive dysfunction) with nortriptyline, or other TCAs, particularly in elderly of other patients who have restricted mobility or who are living in institutionalized care settings, at increased risk of inadequate and inconsistent nutrient intake.

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).
Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCep. 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging**

Effect and Mechanism of Action

The use of oral contraceptives (OCs) may be associated with altered metabolism of many nutrients and increased susceptibility to depletion in some women, particularly vitamins B_1, B_2, B_3, B_6, B_{12}, and C, as well as folic acid, manganese, magnesium, and zinc.[28]

Research

Researchers have observed slight to moderate decreases in thiamine levels in some women taking OCs.[29-32] Evidence is still insufficient to confirm consistent patterns of nutritional deficiencies resulting from OC.[33,34] Although thiamine levels have not been consistently lower in women taking OCs compared with controls, urinary thiamine levels are higher in women using OCs who also take supplemental thiamine.[35]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The clinical implications of this probable interaction are uncertain at this time. Further research focusing on variable susceptibility to thiamine depletion, particularly such factors as pharmacogenomic variables, dietary intake, age, and concomitant medications and health conditions, could further define conditions of increased risk and elucidate approaches for optimal correction with nutritional therapies. Pending such evidence, coadministration with customary supplemental daily doses of thiamine, particularly in a B-complex formulation to address parallel depletion effects, would safely and effectively reduce risks of adverse effects.

Phenytoin and Related Anticonvulsant Medications

Evidence: Phenytoin (diphenylhydantoin; Dilantin, Phenytek). Extrapolated, based on similar properties: Carbamazepine (Carbatrol, Tegretol), clonazepam (Klonopin), clorazepate (Tranxene), divalproex semisodium, divalproex sodium (Depakote), ethosuximide (Zarontin), ethotoin (Peganone), felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), levetiracetam (Keppra), mephenytoin, mephobarbital (Mebaral), methsuximide (Celontin), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), phenobarbital (phenobarbitone; Luminal, Solfoton), piracetam (Nootropyl), primidone (Mysoline), sodium valproate (Depacon), topiramate (Topamax), trimethadione (Tridione), valproate semisodium, valproic acid (Depakene, Depakene Syrup), vigabatrin (Sabril), zonisamide (Zonegran).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **1. Certain**

Evidence Base: ●●● **Consensus**

Effect and Mechanism of Action

In their study of phenytoin's effects on the in vivo kinetics of thiamine in rat nervous tissues, Patrini et al.[36] reported that phenytoin appeared to interfere mainly with thiamine and thiamine monophosphate (TMP) uptake, thiamine pyrophosphate (TPP) dephosphorylation to TMP, and TPP turnover times, and that these effects were particularly prominent in the cerebellum and brainstem of chronically treated animals.

Research

The research team led by M.I. Botez in Montreal has contributed significantly to our understanding of the effects of phenytoin on thiamine in humans. In a 1982 study, Botez et al.[37] determined by microbiological assay a statistically significant difference between whole-blood thiamine and cerebrospinal fluid (CSF) thiamine levels in comparing samples from 23 control subjects and 11 phenytoin-treated epileptic patients. Similar studies of 157 epileptic patients observed low levels of folate and thiamine in the blood and CSF, associated with phenytoin therapy.[38] In a subsequent clinical trial this research team conducted a clinical trial investigating the effects of thiamine and folate on verbal and nonverbal intelligence quotient (IQ) testing in 72 epileptic patients receiving phenytoin alone or in combination with phenobarbital for more than 4 years. They noted that 31% had subnormal blood thiamine levels and 30% had low folate at baseline assessment, and that such vitamin deficiencies were independent phenomena. After a 6-month, randomized, double blind trial, they found that thiamine (50 mg/day) improved neuropsychological functions in both verbal and nonverbal IQ testing. In particular, higher scores were recorded on the block design, digit symbol, similarities, and digit span subtests. The researchers concluded that, in epileptic patients chronically treated with phenytoin, thiamine supplementation improves neuropsychological functions, such as visuospatial analysis, visuomotor speed, and verbal abstracting ability.[39]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Individuals undergoing anticonvulsant therapy, particularly using phenytoin, will most likely benefit from coadministration of 50 to 100 mg of oral thiamine daily. Such corrective nutrient therapy seems prudent, especially given that vitamin B_1 has no known toxicity. All currently available evidence indicates that such coadministration is safe and can be undertaken without close supervision or specific monitoring. Nevertheless, individuals using any anticonvulsant medication should consult with their prescribing physician and a health care professional experienced in nutritional therapeutics before introducing any significant levels of supplementation into their therapeutic regimen.

Scopolamine

Scopolamine

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Thiamine is involved in the presynaptic release of acetylcholine and exerts a cholinomimetic effect in the central nervous system. Thiamine binds to nicotinic receptors and may exhibit anticholinesterase activity. Scopolamine exerts an anticholinergic effect.[40]

Research

A small human study investigated the effects of pharmacological doses of thiamine on the cognitive deficits typically associated with scopolamine therapy. In this randomized, double-blind, placebo-controlled, double-crossover clinical trial with 13 healthy subjects, the group receiving 5 g thiamine

orally (with scopolamine, 0.007 mg/kg IM) demonstrated significantly reduced adverse effects of scopolamine compared with the placebo group. Improvements were measured in P3 latency, spectral components of electroencephalography, and memory recall.[40]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Patients undergoing scopolamine therapy will most likely benefit from oral thiamine coadministration, generally 2 to 4 g/day. Such supportive nutrient therapy probably will have significant clinical benefit and generally is considered to present negligible risk. The available research has been conducted with higher doses and close supervision (in a research setting with healthy patients). Pending further research into specific doses and response patterns with patient populations prescribed scopolamine for typical medical conditions, close supervision and regular monitoring are advisable, preferably within an integrative care setting providing for collaboration between the prescribing physician and a health care professional experienced in nutritional therapeutics.

Stavudine and Related Reverse-Transcriptase Inhibitor (Nucleoside) Antiretroviral Agents

Evidence: Stavudine (d4T, Zerit).
Extrapolated, based on similar properties: Abacavir (Ziagen), didanosine (ddI, dideoxyinosine; Videx); dideoxycytidine (ddC, zalcitabine; Hivid), lamivudine (3TC, Epivir), stavudine (D4T; Zerit), tenofovir (Viread), zidovudine (azidothymidine, AZT, ZDV, zidothymidine; Retrovir); combination drugs: zidovudine and lamivudine (Combivir); abacavir, lamivudine, and zidovudine (Trizivir).

Interaction Type and Significance

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**
☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **3. Possible**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

With expanded use of stavudine and similar medications, often with highly active antiretroviral therapy (HAART) protocols, severe lactic acidosis has been increasingly reported as a severe and potentially fatal complication of HIV treatment.[41-45] Defects in the gene on the X chromosome encoding the E1 peptide of the E1 subunit (pyruvate decarboxylase), which binds TPP, can contribute to increased susceptibility to lethal lactic acidosis.[46]

Reports

Two case reports provide the evidence supporting thiamine therapy to reduce risk of or respond to adverse effects of stavudine. Schramm et al.[47] reported the case of a 30-year-old woman with AIDS and nucleoside analog–induced lactic acidosis that exacerbated shortly after introducing total parenteral nutrition and reversed within hours after treatment with IV thiamine. A 2001 paper described an asymptomatic HIV-infected woman treated with HAART (stavudine, lamivudine, and indinavir) for 1 year who demonstrated an "impressively rapid response (within a few hours)" to 100 mg IV thiamine.[48]

Preexisting vitamin deficiency appears to be an important cofactor in the susceptibility to this unpredictable adverse reaction to therapy in patients with HIV infection.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Lactic acidosis induced by stavudine or similar nucleoside analog medications for HIV infection is a serious and often life-threatening condition, and such patients are usually already hospitalized or under close supervision by their prescribing physician. The available reports involved critical care and physician administration of high-dose thiamine to address both the lactic acidosis and the patient's presumed background vitamin deficiency status. The clinicians submitting these reports recommended that physicians prescribing stavudine therapy take note of the rapid response to thiamine administration, suggest that high-dose B vitamins should be given to any patient presenting with lactic acidosis under nucleoside analog treatment, and advise thiamine infusion for critical care of this potentially life-threatening complication of HIV therapy.

Supplementation with customary oral doses of a B-vitamin complex may be self-administered as a prophylactic measure by patients undergoing stavudine or other antiretroviral therapy, particularly when nutrient intake has been compromised by an inadequate or imbalanced diet. Pending further research into preventive and reactive doses of thiamine with respective modes of administration, for coadministration with stavudine or similar nucleoside analog medications, close supervision and regular monitoring are advisable when lactic acidosis is present or threatening, preferably within an integrative care setting providing for collaboration between the prescribing physician and a health care professional experienced in nutritional therapeutics.

Tetracycline and Related Tetracycline Antibiotics

Evidence: Tetracycline (Achromycin, Actisite, Apo-Tetra, Economycin, Novo-Tetra, Nu-Tetra, Sumycin, Tetrachel, Tetracyn).
Extrapolated, based on similar properties: Demeclocycline (Declomycin), doxycycline (Atridox, Doryx, Doxy, Monodox, Periostat, Vibramycin, Vibra-Tabs), minocycline (Dynacin, Minocin, Vectrin), oxytetracycline (Terramycin), tetracycline combination drugs: chlortetracycline, demeclocycline, and tetracycline (Deteclo); bismuth, metronidazole, and tetracycline (Helidac).

Interaction Type and Significance

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

Probability: **3. Possible**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Nutrient formulations containing B vitamins, including thiamine (B_1), may interfere with tetracycline pharmacokinetics.

Research

In an investigation of the effects of various nutrients on the pharmacokinetics of tetracycline hydrochloride in healthy subjects, researchers observed a significant impairment of drug bioavailability associated with concomitant oral administration of a B-complex vitamin formulation.[49]

Clinical Implications and Adaptations

Physicians prescribing tetracycline or related antibiotic medications should advise patients regularly supplementing with thiamine, alone or within a B-complex vitamin formulation, to take the nutrient(s) and the medication at least 4 hours apart from each other.

NUTRIENT-NUTRIENT INTERACTIONS

Thiaminases

Thiaminases are thiamine antagonists found in a few plants and some raw seafood. When these enzymes are ingested, in coffee, black tea, certain vegetables, and the raw flesh and viscera of certain fish and shellfish, especially carp, they can destroy dietary or supplemental thiamine. Such type I thiaminases render thiamine biologically inactive by displacing its pyrimidine methylene group with a nitrogenous base or SH-compound to eliminate the thiazole ring. Once the thiamine molecule is cleaved by a thiaminase, the body is incapable of restoring it. Thus, the ingestion of significant amounts of thiaminases can induce thiamine deficiency, even when dietary intake of thiamine may be otherwise adequate. The level of raw fish consumption by humans is rarely sufficient, even among frequent sushi eaters, to constitute a significant probability of clinically significant thiamine depletion. Thiaminases are denatured by heat, so cooking or other forms of heat treatment will render them inactive.

Chlorinated Water and Chlorogenic Acid

Chlorinated water tends to destroy thiamine, especially when heated in the cooking of grains. Chlorogenic acid, found both in decaffeinated and caffeinated coffee, also destroys thiamine.

B Vitamins and Other Synergistic Nutrients

Thiamine works synergistically with vitamin B_2 and vitamin B_3.

Ames et al.[50] suggest that combination therapy with thiamine, alpha lipoic acid, riboflavin, nicotinamide, and adequate potassium may be optimal for the initial treatment of patients with maple syrup urine disease, a rare, autosomal recessive disorder of branched-chain amino acid metabolism.

HERB-NUTRIENT INTERACTION

Horsetail

Horsetail (*Equisetum arvense*)

Equisetum arvense (horsetail) may impair thiamine absorption. This particular form of thiaminase poisoning occurs most often among farm animals where hay has been contaminated by horsetail. No cases have been reported of humans consuming *Equisetum* medicinally and experiencing clinically significant thiamine depletion or deficiency.

The 51 citations for this monograph, as well as additional reference literature, are located under Vitamin B_1 (Thiamine) on the CD at the back of the book.

Vitamin B_2 (Riboflavin)

Nutrient Name: Vitamin B_2, riboflavin.
Synonyms: 7,8-dimethyl-10-(11-o-ribityl)isoalloxazine, 7,8-dimethyl-10-(o-ribo-2,3,4,5-tetrahydroxypentyl)isoalloxazine, flavin, flavine, hepatoflavin, lactoflavin, lyochrome, ovoflavin, riboflavine, uroflavin, vitamin B_2, vitamin G.
Trade Names Include: Aquo-Flave, Beflavin, Beflavina, Béflavine, Beflavit, Berivine, Dolo-Neurotmt, Flavoxin, Ribobis, Ribobutin, Ribipea.
Related Substance: Riboflavin-5-phosphate: Alloxazine mononucleotide, coflavinase, cytoflav, flavine mononucleotide, FMN, riboflavin phosphate.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Anticonvulsant medications Barbiturates ≈≈/☼/◈≈≈	Anticonvulsant medications, especially those that induce cytochrome P450, may alter riboflavin metabolism and interfere with activity of riboflavin-related coenzymes and deplete riboflavin. Riboflavin is essential to the function of folate, MTHFR, and pyridoxine. Coadministration can mitigate adverse effects. Further research needed.	Riboflavin (and folate) coadministration may be beneficial, but interaction can vary depending on medication. Requires clinical management.
Antimalarial drugs ✗/◈◈/⊕✗/⊕	Strong evidence indicates that low riboflavin status is protective against malaria and advantageous in reducing the severity of malarial symptoms. Several antimalarial medications appear to act as riboflavin antagonists. Riboflavin intake is generally contraindicated in both prevention and treatment. However, limited research indicates that high doses of riboflavin may exert activity against *Plasmodium falciparum*. Further research needed.	Avoid concomitant riboflavin intake, as well as vitamin E, iron, and folate, except as indicated by extraordinary circumstances and then only under medical supervision.
Antiretroviral agents Nucleoside (analog) reverse-transcriptase inhibitors (NRTIs) ☼/≈≈/◈≈≈	Drug-induced mitochondrial toxicity associated with riboflavin deficiency contributes to lactic acidosis in patients treated with NRTIs. Riboflavin coadministration can prevent or reverse these and other adverse effects. Further research warranted to confirm consistent but limited evidence.	Coadministration, preferably with thiamine, can be beneficial. Supervise closely and monitor regularly.
Boric acid, borate, and boron ≈≈≈/☼	Boron, in various forms, tends to complex with riboflavin and thereby reduce absorption and increase urinary excretion. Effects are rapid, and continued use may cause riboflavin deficiency. Separation of intake can reduce gut absorption interference. Conversely, riboflavin may be used to treat acute boric acid poisoning.	Separate intake of boron/boric acid and riboflavin unless binding is intentional.
Chlorpromazine Phenothiazine antipsychotics ◈≈≈/≈≈/◈◈	Chlorpromazine and other phenothiazines can inhibit hepatic flavokinase and conversion of riboflavin to FMN and FAD. Binding and increased excretion may also occur; thus, simultaneous intake might impair activity of both agents. Interrelationships reported linking unipolar depression, low thyroxine status, deficiency of riboflavin, and folate. Riboflavin (or FAD) may protect against chlorpromazine-induced arrhythmia and mitochondrial dysfunction.	Consider coadministration of riboflavin (and folic acid), especially in unipolar depression. Separate intake. Evaluate and monitor riboflavin, FAD, and thyroxine status.
Doxorubicin Anthracyclines ◈≈≈/≈≈/☼/◈◈	Doxorubicin can inhibit the conversion to FMN and FAD but coadministration of riboflavin may not adequately counteract resulting toxic effects. Binding and increased excretion may also occur; thus, simultaneous intake might impair activity of both agents. Sunlight exposure in the presence of riboflavin may deactivate doxorubicin. Further research needed.	Coadministration, especially with coenzyme Q10, can be beneficial but may not be adequate. Separate intake. Sunlight avoidance may be prudent with coadministration. Supervise closely and monitor regularly.
Oral contraceptives (OCs) ◈≈≈/≈≈/☼	Mixed OCs may reduce levels of riboflavin (as well as B_6, folate, and B_{12}). Evidence mixed as to clinical significance of effects, but risk appears higher with high-dose hormones, high metabolic demands, poor nutritional status, and during initial months. Nutritional support may prevent or reverse adverse effects on riboflavin and related nutrients. Continued research necessary for conclusive determination of effects and susceptibility and effective clinical response.	Coadministration of a B-complex formulation can be beneficial. No adverse effects probable.
Probenecid ≈≈/≈≈≈	Probenecid can adversely affect riboflavin through several mechanisms, including impaired absorption in gastrointestinal tract, inhibited renal tubular secretion, and decreased urinary excretion. Evidence limited but generally accepted as plausible. Probable that riboflavin administration can prevent or reverse adverse drug-induced effects.	Coadminister riboflavin, especially with nutritionally compromised patients and with long-term therapy. Monitor for signs of deficiency.
Propantheline ✗/◈◈	Propantheline appears to elevate riboflavin levels by decreasing salivary flow and decreasing rate of gastric emptying and gastrointestinal motility. Minimal evidence, but low probability of significant risk due to minimal toxicity of riboflavin. Substantive research necessary for conclusive determination of effects and appropriate clinical response.	No response necessary. Patients need not avoid riboflavin in multivitamin.

Continued

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Tetracycline antibiotics Other antibiotics ✗✗/◇◇	Simultaneous intake of riboflavin and other B vitamins with tetracycline-class antibiotics can reduce absorption and bioavailability of both/all agents. Antibacterial effect on intestinal flora and gut ecology can produce secondary adverse effects on B-vitamin status and inflammatory processes.	Separate intake if concurrent administration indicated or necessary. Probiotic flora beneficial after antibiotic therapy.
Thyroid hormones ⊕⊕	Hypothyroidism and riboflavin deficiency share many characteristics. Triiodothyronine (T_3) enhances biosynthesis of FMN through the expression of riboflavin kinase. Thyroid status appears to influence activity of riboflavin (and folate) and response to tricyclic antidepressants and phenothiazines.	Coadministration may be beneficial, except with riodoric susceptibility or treatment.
Tricyclic antidepressants (TCAs) ⊕⊕/◇≈≈/≈≈	TCAs can adversely affect riboflavin activity (and increase requirements) by impairing absorption and inhibiting synthesis of FMN and FAD. Coadministration may prevent or reverse depletion as well as augment clinical response to TCAs through an additive or synergistic effect. Continued research warranted. Coadministration potentially beneficial in migraine.	Coadministration of riboflavin can be protective and may enhance clinical response, especially with deficiency. Consider B_1, B_6, B_{12}, and folic acid. Check thyroxine status. Supervise closely and monitor regularly.

MTHFR, 5,10-Methylenetetrahydrofolate reductase; *FMN*, flavin mononucleotide; *FAD*, flavin adenine dinucleotide.

NUTRIENT DESCRIPTION

Chemistry and Forms

Riboflavin names: 7,8-dimethyl-10-(11-D-ribityl)isoalloxazine, 7,8-dimethyl-10-(D-ribo-2,3,4,5-tetrahydroxypentyl)isoalloxazine, and 7,8-dimethyl-10-ribitylisoalloxazine.
Formula: $C_{17}H_{20}N_4O_6$.
Molecular weight: 376.4 daltons.
Riboflavin is stable to heat, oxidation, and acid; it is destroyed by alkali and light, especially fluorescent light. Riboflavin is partially soluble in water.
Riboflavin is a water-soluble member of the B-vitamin family. The originally termed "yellow enzyme," which became known as "flavin mononucleotide" or "riboflavin phosphate," was initially synthesized in 1935. The name "riboflavine" was initially chosen because it contained the pentose side chain ribitol, and *flavius* is Latin for "yellow," in recognition of the deep color of the crystals formed from the pure vitamin and the deep-yellow color it imparts to urine. The final "e" was later dropped on learning that it really was not an amine. In 1952 the Commission on Biochemical Nomenclature formally adopted the name *riboflavin*. At this time, riboflavin is the Approved Name for use on pharmaceutical labels in Britain.

Physiology and Function

Riboflavin plays a critical role as a component of several key metabolic substances involved in oxidation of glucose, fatty acids, and certain amino acids; reactions with several intermediaries of the Krebs cycle; activation of pyridoxine phosphate (B_6) to form pyridoxal phosphate, its biologically active form; conversion of folate to its coenzymes; conversion of tryptophan to niacin; and support of antioxidant activity through *flavin adenine dinucleotide* (FAD) and reduced glutathione. Riboflavin exerts minimal direct or intrinsic metabolic activity, and only a small portion of the total flavin pool in the human body remains as riboflavin, primarily stored in the liver. Most is converted into coenzyme derivatives *flavin mononucleotide* (FMN) and its product, the more predominant FAD, before these flavins form complexes with numerous flavoprotein dehydrogenases and oxidases. Notably, *flavokinase*, the enzyme required for the production of FAD and FMN, is regulated by thyroxin so that thyroid hormones increase the synthesis of flavin cofactors.

As flavocoenzymes, FMN and FAD participate in oxidation-reduction reactions in metabolic pathways and in energy production through the respiratory chain. The isoalloxazine ring system of riboflavin serves as the functional moiety in both FAD and FMN by acting as a two-electron acceptor in enzymatic biochemical reductions. This property enables FMN and FAD to act as cofactors for flavoproteins, the enzymes involved in oxidation-reduction reactions of organic substrates and in intermediary metabolism. FAD and FMN serve as intermediate hydrogen carriers in the mitochondrial electron transport chain, accepting hydrogen ions and transferring electrons to the cytochrome system as part of the metabolism of carbohydrates to produce adenosine triphosphate (ATP). Riboflavin aids in beta oxidation in lipid metabolism and is involved, as a coenzyme component of the dehydrogenases, in the first step in glucose metabolism.

Xanthine oxidase, nicotinamide-adenine dinucleotide phosphate (NADP)–cytochrome *c* reductase, and D- and L-amino acid oxidase are among the key riboflavin-dependent flavoenzymes. Succinic dehydrogenase, monoamine oxidase (MAO), and other flavoenzymes have FAD covalently bound to them. As a component of these flavin coenzymes, riboflavin serves as a cofactor in numerous respiratory enzymes, including glutaryl coenzyme A dehydrogenase, erythrocyte glutathione reductase, sarcosine dehydrogenase, NADH dehydrogenase, electron-transferring flavoprotein, and ETF dehydrogenase. Flavocoenzymes are also involved in the biosynthesis of niacin-containing coenzymes from tryptophan (via FAD-dependent kynurenine hydroxylase), the FMN-dependent conversion of the 5′-phosphates of vitamin B_6 to pyridoxal 5′-phosphate, the FAD-dependent dehydrogenation of 5,10-methylenetetrahydrofolate to the 5′-methyl product, and the vitamin B_{12}–dependent formation of methionine and sulfur amino metabolism.

Riboflavin participates in other self-regulatory and protective processes, particularly by facilitating destruction of reactive oxygen species and prevention of cellular oxidative injury in a range of tissues. Glutathione reductase is a FAD-containing enzyme that generates reduced glutathione, which acts as a

cofactor in the formation of glutathione peroxidases, major selenium-containing antioxidant enzymes central to the regulation of lipid peroxidation. The availability of riboflavin is also essential to maintaining the mitochondrial pool of reduced glutathione necessary to the activities of the flavoenzymes reduced nicotinamide-adenine dinucleotide phosphate (NADPH)–cytochrome P450 (CYP450) reductase and NADPH–cytochrome *b* reductase. Riboflavin may also play a role in maintaining the integrity of erythrocytes and nerve tissue. *Flavin reductase*, also known as methemoglobin reductase, is an NADPH-dependent enzyme that appears to provide protection against oxidative forms of hemeproteins, such as those involved in reperfusion injury. In this process, riboflavin acts as an antioxidant through its conversion to dihydroriboflavin, with methemoglobin reduced while riboflavin is oxidized. The dihydroriboflavin not only maintains the hemeproteins in their lower oxidation states, but also rapidly reduces higher oxidation states of hemeproteins and prevents peroxidative damage to the heme and protein groups. Moreover, because the 5,10-methylenetetrahydrofolate reductase gene product (MTHFR) is a riboflavin/FAD-dependent enzyme, riboflavin status modifies the metabolic effect of the MTHFR 677C→T polymorphism, a critical factor in regulation of plasma concentrations of total homocysteine (tHcy), coronary artery disease, and colon cancer risk. For individuals who carry the 677C→T polymorphism, improving both riboflavin and folate nutriture is protective.

Riboflavin is also required for gluconeogenesis, erythropoiesis, thyroid enzyme regulation, and the production of corticosteroids. Riboflavin is also important in deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) metabolism and can be found in high concentration in the retina.

In normal physiological settings, riboflavin is readily absorbed in the upper gastrointestinal tract, principally in the duodenum, through a saturable active transport system. The presence of food can increase absorption fourfold when riboflavin is ingested with meals rather than taken separately. The gastric environment is important because acid is responsible for releasing B_2 from noncovalent bonding in foods so that it may be absorbed. Hepatitis, cirrhosis, or biliary obstruction can also significantly impair its absorption. Riboflavin absorption is increased in hypothyroidism and decreased in hyperthyroidism. Riboflavin and a number of other water-soluble vitamins can be synthesized by the microflora that should normally populate the large intestine. Circulating riboflavin can complex with a variety of proteins, including plasma albumin. Conversion of riboflavin to its coenzymes forms (e.g., FAD) predominantly takes place in the liver, heart, and kidneys, but also to some degree in most tissues. In the body tissue, riboflavin is predominantly present as the coenzyme FAD. Riboflavin is stored in the liver to a limited extent, but hepatic reserves will only reduce to 50% of maximum storage when availability is low. Riboflavin is excreted primarily in the urine, predominantly as metabolites, with a typical half-life elimination of 66 to 84 minutes. Excess riboflavin, approximately 9%, is excreted unchanged, imparting the well-known yellow color to urine. Riboflavin crosses the placenta readily and is also excreted in breast milk.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Treatment of *ariboflavinosis* (riboflavin deficiency) is the primary application of riboflavin recognized in conventional medical practice. An emerging body of evidence supporting the efficacy of riboflavin for the prevention of migraine and ocular cataract is becoming more widely recognized but is still generally viewed as mixed. Nevertheless, clinical experience and a close review of the literature reveal a solid basis for further research through well-designed and high-powered clinical trials aimed at developing guidelines for therapeutic application. The use of riboflavin in conjunction with antiviral regimens, especially nucleoside analog reverse-transcriptase inhibitors (NNRTIs), is well established, particularly for treatment and prevention of lactic acidosis.

Riboflavin is most often administered in conjunction with other nutrients, especially B vitamins, because its physiological functions and activities as well as its depletion patterns tend to cluster, and their coadministration produces a synergistic effect.

Historical/Ethnomedicine Precedent

Vitamin B_2 (riboflavin) has not been used historically as an isolated nutrient.

Possible Uses

Anemia, anorexia, aphthous ulcers, ariboflavinosis (riboflavin deficiency), bulimia, burn recovery, burning feet syndrome, carpal tunnel syndrome, cataracts, depression, esophageal cancer (risk reduction and treatment), ethylmalonic encephalopathy, fatigue, glaucoma, human immunodeficiency virus (HIV) support, hyperhomocysteinemia, involuntary eye movement, ischemia-reperfusion injury, malaria, methemoglobinemia (congenital), migraine headache (prophylaxis), mitochondrial encephalomyopathy (MEM), multiple acyl-coenzyme A dehydrogenase deficiency, neonatal jaundice (with phototherapy), Parkinson's disease, posttransplant headache, preeclampsia, red blood cell aplasia, sickle cell anemia, sports performance enhancement, thyroid disorders.

Deficiency Symptoms

Cheilosis, glossitis, and angular stomatitis (cracking at lip corners) are classic deficiency symptoms, but both hyporiboflavinosis and ariboflavinosis can also manifest as lethargy, depression, generalized weakness, hyperemia, edema of the pharyngeal and oral mucous membranes, dermatitis (particularly seborrheic dermatitis affecting the scrotum or labia majora and nasolabial folds), photosensitivity, burning and itching of the eyes, corneal vascularization, and normochromic normocytic anemia, leukopenia, and thrombocytopenia, sometimes associated with pure erythrocyte cytoplasia of the bone marrow. These clinical signs of deficiency in humans may appear at intakes less than 0.5 to 0.6 mg per day. Isolated riboflavin deficiency is rare and usually occurs in conjunction with broader nutritional deficiency patterns, particularly involving other B vitamins and contexts associated with increased vulnerability. Symptoms of niacin and vitamin B_6 deficiency may also appear because riboflavin is necessary to their metabolic activity.

The U.S. recommended dietary (daily) allowance (RDA) for riboflavin (vitamin B_2), as revised in 1998, was established based on dosage level necessary to prevent the pathophysiological changes associated with riboflavin deficiency, not to maintain normal enzyme function, promote optimal health, or treat specific conditions.

The most common cause of insufficient riboflavin status is unbalanced, nutritionally deficient diets, particularly affecting

infants and children, elderly persons, low-income populations, and those in areas characterized by deprivation. Individuals in particular groups tend to be especially at risk for riboflavin deficiency, including chronic heavy alcohol use, people with chronic illnesses (especially chronic liver disease), patients with severe burns or sickle cell anemia, patients receiving total parenteral nutrition (TPN) with inadequate riboflavin, and gastric bypass bariatric surgery patients, if they neglect to take high-potency B-complex supplements. Impaired absorption and reduced assimilation of riboflavin can result from abnormal digestion caused by various conditions, including gastrointestinal (GI) infections or parasites, infectious enteritis, GI and biliary obstructions, chronic diarrhea, decreased GI passage time, celiac disease, tropical sprue, malignancy, and resection of the small intestine, as in management of patients with Crohn's enteritis. Infants receiving phototherapy for neonatal jaundice are also at risk for riboflavin deficiency. Inadequate thyroid hormone and cataract formation can also be associated with impaired riboflavin status. Inborn errors of metabolism affecting the formation of a flavoprotein, such as acyl-coenzyme A dehydrogenases, can cause deficiency in relatively rare cases. Children may be at increased risk of deficiency during phases of rapid growth. Riboflavin deficiency is relatively common in children with cardiac disease, especially congestive heart failure. Low milk consumption and lactose intolerance can also contribute to decreased riboflavin intake. Vegetarians tend to have depressed riboflavin levels, and vegans are considered at increased risk of riboflavin deficiency, although nutritional yeast is an excellent source for vegans. Individuals engaged in strenuous athletic activities tend to have increased riboflavin requirements and may be more susceptible to deficiency. Women using oral contraceptives tend to lower levels of riboflavin and other B vitamins. In many women, riboflavin levels tend to be lower during periods of exercise and calorie-restrictive dieting.

Dietary Sources

Even though all plant and animal cells contain riboflavin and it is widely distributed in foodstuffs, few foods provide abundant sources of this essential nutrient. The richest dietary sources of riboflavin are calf liver and other organ meats, torula (nutritional) yeast, brewer's yeast, and mushrooms. Milk products (especially yogurt), spinach, asparagus, broccoli and other leafy green vegetables, egg whites, fish roe, almonds and other nuts, legumes, sunflower seeds, whole grains (especially wild rice), wheat germ, and fortified grains can also contain significant amounts of vitamin B_2. Regular daily intake of riboflavin is important because, as with other B vitamins, vitamin B_2 is not stored in appreciable amounts. Healthy subjects restricted to a riboflavin-free diet may demonstrate symptoms of riboflavin deficiency within 7 days.[1] The requirement for riboflavin appears to be related more to nitrogen balance than to caloric intake.

The availability and stability of riboflavin vary with different food sources. Riboflavin from animal sources is better absorbed and thus exhibits higher bioavailability than from vegetable sources. Vegetarians, and vegans in particular, therefore are more susceptible to inadequate riboflavin intake. The milling and processing of grains usually result in substantial loss of riboflavin because the vitamin is concentrated in the germ and bran. Furthermore, being water soluble, the riboflavin in grains and vegetables is often leached away during cooking, unless those fluids are reused as soups and sauces. The riboflavin in milk is relatively abundant and generally stable, although it was often degraded by light exposure when distributed in clear-glass bottles.

Nutrient Preparations Available

Riboflavin and riboflavin 5′-monophosphate are the most common forms of riboflavin available in supplements. Riboflavin is rarely administered as a monotherapy or dispensed as an individual nutrient; it is almost always part of a multinutrient formulation, particularly as a component of a B-vitamin complex. In general, such coadministration is superior because vitamin B_2 is most effective in combination with vitamins B_1, B_3, and B_6.

Dosage Forms Available

Oral: Capsule, soft elastic capsule, tablet, enteric-coated tablet, extended-release tablet.
Injection: Injectable riboflavin sodium phosphate is available by prescription. Riboflavin is moderately unstable in glucose–amino acid solutions but is stabilized with addition of a lipid, typically a 3:1 mixture, in TPN admixtures.

Dosage Range

Adult

Dietary: 5 to 30 mg per day. However, a survey conducted by the U.S. Department of Agriculture estimated that daily riboflavin intake less than the RDA occurs in about a third of Americans. In the United Kingdom the average adult daily diet for men provides 2.24 mg and 1.98 mg for women.
Supplemental/Maintenance: The ideal level of riboflavin intake has not been established, but the 25 to 50 mg typically contained in nutritional supplements is generally considered more than adequate for most individuals.

In the United States the Food and Nutrition Board of the Institute of Medicine of the National Academy of Sciences recommends the following dietary reference intakes (DRIs) for riboflavin:
Men (> 18 years): 1.3 mg
Women (> 18 years): 1.1 mg
Pregnant women (any age): 1.4 mg
Lactating women (any age): 1.6 mg
Pharmacological/Therapeutic: 10 to 100 mg/day, although 400 mg/day is often administered for migraine prophylaxis.
Toxic: None established. The evidence on adverse effects has been deemed insufficient to set a tolerable upper intake level (UL) for riboflavin.

Pediatric (< 18 Years)

Dietary: 2.5 to 10 mg/day.
Infants, birth to 6 months: 0.3 mg/day (AI, adequate intake)
Infants, 7 to 12 months: 0.4 mg/day (AI)
Children, 1 to 3 years: 0.5 mg/day (RDA)
Children, 4 to 8 years: 0.6 mg/day (RDA)
Children, 9 to 13 years: 0.9 mg/day (RDA)
Adolescents, 14 to 18 years: 1.0 mg/day for females; 1.3 mg/day for males (RDA)
Supplemental/Maintenance: 0.4 to 1.8 mg/day.
Pharmacological/Therapeutic: Riboflavin is generally not administered in pharmacological doses to infants or children. Riboflavin at levels five times that in formulas for term infants is often provided in augmented preterm infant formulas (PIFs) administered enterally to very-low-birth-weight (VLBW)

infants; 5 mg three times daily has been used during phototherapy for neonatal jaundice.
Toxic: Not established.

Laboratory Values

Erythrocyte riboflavin: This test is generally not considered to provide a sensitive index. Levels below 15 μg/dL of red blood cells indicate deficiency.
Red blood cell FAD and FMN: Because these forms constitute more than 90% of riboflavin, these levels (obtained after modest hydrolysis from FAD) have been used as indicators of the cellular concentration of riboflavin in its form as coenzyme.
Urinary riboflavin: Urinary excretion of riboflavin reflects an excess of current intake beyond tissue requirements. A normal adult excretes 120 μg or more in 24 hours. Excretion of less than 100 μg daily indicates deficiency.
Erythrocyte glutathione reductase (EGR) activity coefficients: Stimulation of FAD-dependent EGR in vitro, which relies on an associated oxidation of NADPH, can be readily monitored spectrophotometrically and expressed as an activity coefficient (AC) indicating the ratio of activities in the presence and absence of added FAD. Assessment of this riboflavin-dependent enzyme provides a reliable indicator of functional riboflavin status but has known limitations, particularly in individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency.
An activity coefficient less than 1.2 is defined as "acceptable," 1.2 to 1.4 as indicating low riboflavin status, and greater than 1.4 indicating deficiency.
Capillary electrophoresis with laser-induced fluorescence detection: This test may provide an effective tool for accurate assessment of riboflavin status by allowing detection of all riboflavin vitamers below physiological concentrations.

Urinary riboflavin levels are often measured to assess compliance with medication regimens, particularly with patients being treated for alcohol dependence, mental disorders, and other conditions.

High intake levels of riboflavin are known to interfere with the accuracy of many laboratory tests, including urinalysis based on spectrometry, drugs of abuse assays, and fluorometric determinations of catecholamines and urobilinogen.

SAFETY PROFILE

Overview

Riboflavin (vitamin B_2) is generally considered to be nontoxic at typical supplemental and dietary dosage levels. Its limited intestinal absorption and water solubility make riboflavin toxicity highly improbable.

Nutrient Adverse Effects

General Adverse Effects

Beyond flavinuria, the yellow discoloration of urine, with high doses and extremely rare instances of allergic reactions, riboflavin toxicity in humans is unknown. Although indications of serious adverse effects are lacking, very high doses have reportedly caused itching, numbness, and burning or prickling sensations. Only two minor, nonspecific adverse events (diarrhea and polyuria) were reported during the 4-month course of a clinical trial involving 400 mg per day for migraine prophylaxis.[2] A potential risk from the photosensitizing properties of riboflavin has been raised, but no substantial evidence is available to confirm such a concern as clinically significant.

Mutagenicity. None has been found on testing or has otherwise been proposed or suspected.

Pregnancy and Nursing

Riboflavin is excreted in breast milk but is generally considered safe during pregnancy and lactation at usual dosage levels.

Teratogenicity. None has been reported.

Infants and Children

No pediatric adverse effects from vitamin B_2 have been established.

Contraindications

No contradictions have been established for riboflavin.

Precautions and Warnings

No warnings or precautions have been established for vitamin B_2, other than known allergy to constituents of the formulation.

INTERACTIONS REVIEW

Strategic Considerations

The administration of riboflavin as a monotherapy is atypical in conventional practice and nutritionally oriented therapeutics; its use in migraine prophylaxis represents its most well-known monotherapeutic application. Supplementation is usually unnecessary for individuals with a balanced diet and healthy lifestyle, although requirements can be increased with stresses such as poor nutritional intake (of riboflavin and other B vitamins), chronic illness, malabsorption disorders, alcohol consumption, hemodialysis, chemotherapy, or even vigorous athletic activity. The diagnosis of riboflavin deficiency is usually based on the symptoms and evidence of general undernutrition. Angular stomatitis is the most readily observable sign of emerging deficiency but frequently goes unrecognized at early stages. Diagnostic tests to confirm riboflavin deficiency are not readily available or particularly sensitive to functional depletion. In cases of frank riboflavin deficiency, high doses are typically administered orally until symptoms resolve. Impairment and deficiencies involving B vitamins are highly interdependent, and these nutrients are usually most effective when administered concomitantly. Riboflavin is generally considered to be nontoxic at typical supplemental and dietary dosage levels, with flavinuria (yellow-colored urine) being the primary side effect.

Although evidence from focused clinical trials is limited, adverse effects from coadministration appears to be improbable with most medications, given basic intake timing precautions. The major exception is individuals at high risk for malaria or being treated with antimalarial medications. Coadministration of riboflavin is particularly indicated with the several pharmaceuticals that impair riboflavin absorption and the many that inhibit conversion of riboflavin to its active coenzymes, FAD and FMN. The concomitant use of riboflavin and thiamine with the nucleoside analog reverse-transcriptase inhibitors used in HIV pharmacotherapy can prevent or reverse the uncommon but usually irreversible lactic acidosis caused by drug-induced mitochondrial toxicity and riboflavin deficiency. Coadministration with tricyclic antidepressants appears not only to counter drug-induced adverse effects but also to

enhance therapeutic response, especially in depressed patients with low folate levels, defective methylation functions, and low thyroxine levels. Less dramatically, riboflavin's lack of toxicity suggests that it can be broadly prescribed to prevent or reverse drug-induced depletion effects, even in the absence of deficiency signs, as with oral contraceptives and CYP450-inducing antiseizure medications. Riboflavin appears to be safe even in the case of the anticholinergic agent propantheline, which can elevate riboflavin levels. Concomitant administration of other B vitamins is often indicated for full effectiveness of vitamin B_2.

Tetracycline-class antibiotics, chlorpromazine and related phenothiazine antipsychotics, and boric acid are prominent among the drugs with notable pharmacokinetic interactions with riboflavin, typically involving binding that impairs absorption of both substances. Chlorpromazine and boric acid and its derivatives promote renal excretion of riboflavin. Preliminary evidence suggests that riboflavin could theoretically impair the therapeutic activity of doxorubicin, selegiline, and some sulfa drugs in individuals exposed to sunlight or other bright light.

The role of riboflavin in cardiovascular function is emerging as an area of significant scientific research, providing new data on interactions involving related medications. Research involving patients with migraine demonstrated a decreased mitochondrial phosphorylation potential between migraine attacks and suggests that decreased brain mitochondrial energy reserve between attacks is related to the activity of flavoenzymes, particularly FMN and FAD, in the electron transport chain and the production of cellular energy. The pivotal role of riboflavin in FAD, which is the cofactor for the MTHFR enzyme, as well as the role of MTHFR in the regulation of homocysteine, may bring riboflavin into equal prominence with folic acid, vitamins B_6 and B_{12}, and possibly thiamine as a key agent in remethylation processes and modulation of risks associated with hyperhomocysteinemia. The antioxidant activity of vitamin B_2 and its clinical implications have yet to be fully elucidated but are derived from its role as a component of FAD and the role of this cofactor in the production of the antioxidant peptide reduced glutathione, as well as from its conversion to dihydroriboflavin. By affecting the mitochondrial pool of reduced glutathione, riboflavin deficiency in turn affects the activities of the flavoenzymes NADPH-CYP450 reductase, NADPH–cytochrome *b* reductase, and NADPH-dependent methemoglobin reductase (i.e., flavin reductase).

Oxidative forms of hemeproteins have been implicated in reperfusion injury, and elevated riboflavin levels have been reported to provide protection against such altered hemeproteins and reperfusion injury.[3-6] Continued research into these activities and functions will provide new insight into the importance of riboflavin nutriture, suggest expanded therapeutic uses for riboflavin administration, and present new challenges for understanding both beneficial and harmful interactions with conventional medications.

NUTRIENT-DRUG INTERACTIONS

Anticonvulsant Medications and Related Barbiturates

Evidence: Carbamazepine (Carbatrol, Tegretol), divalproex semisodium, divalproex sodium (Depakote), fosphenytoin (Cerebyx, Mesantoin), mephenytoin, oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), phenobarbital (phenobarbitone; Luminol, Solfoton), phenytoin (diphenylhydantoin; Dilantin, Phenytek), primidone (Mysoline), sodium valproate (Depacon), valproate semisodium, valproic acid (Depakene, Depakote).

Similar properties but evidence lacking for extrapolation: Amobarbital (Amytal), aprobarbital (Alurate), butabarbital (Butisol), butalbital (Fiorinal, Fioricet), clonazepam (Klonopin), clorazepate (Gen-Xene, Tranxene), diazepam (Valium), ethosuximide (Zarontin), ethotoin (Peganone), felbamate (Felbatol), gabapentin (Neurontin), lamotrigine (Lamictal), levetiracetam (Keppra), mephobarbital (Mebaral), methohexital (Brevital), methsuximide (Celontin), phenetur-ide (ethylphenacemide), pentobarbital (Nembutal), secobarbital (Seconal), thiopental (Pentothal), thiopentone (Thiopental), tiagabine (Gabitril), topiramate (Topamax), trimethadione (Tridione), zonisamide (Zonegran); combination drugs: acetylsalicylic acid, codeine, butalbital, and caffeine (Fiorinal); acetaminophen, butalbital, and caffeine (Fioricet). See also Folic Acid monograph.

Effect and Mechanism of Action

Anticonvulsant medications may alter riboflavin metabolism, which could interfere with the activity of riboflavin-related coenzymes and deplete riboflavin. For example, by inducing CYP450 phenobarbital (and other enzyme-inducing antiepileptic drugs [AEDs], e.g., carbamazepine or phenytoin, and/or primidone) may increase destruction of riboflavin and thereby increase the risk of deficiency.[7] Riboflavin is the precursor for FAD, the cofactor for MTHFR, which catalyzes the formation of 5-methyltetrahydrofolate, which in turn acts as a methyl donor for homocysteine remethylation. Riboflavin is also necessary for activating vitamin B_6 to pyridoxal 5'-phosphate (PLP). Thus, the recycling of folate cofactors depends on vitamin B_6 and riboflavin.

Concurrent riboflavin administration appears to prevent or reverse these adverse effects.

Research

Although the evidence regarding the adverse impact of AEDs on folate and B_6 is abundant and consensus has emerged as to the character and significance of these interactions, the evidence regarding riboflavin has often been more indirect, associative, and inferential.

Numerous studies, primarily from the 1970s and 1980s, indicate that children undergoing anticonvulsant therapy with phenytoin (diphenylhydantoin) and related medications have exhibited subnormal riboflavin urinary excretion levels. Lewis et al.[8] found a wide range of variability in creatinine excretion of children treated with anticonvulsant drugs compared with normal, phenylketonuric and galactosemic children, 300% to 500% over 24 hours. In particular, they noted that "creatinine excretion rates were significantly more variable for children treated with anticonvulsant drugs than for normal children," and that "riboflavin-creatinine ratios determined on individual voidings were variable but adequate although total riboflavin was low."

Riboflavin, folate, and vitamin B_6 status influence the tendency toward elevated plasma total homocysteine (tHcy) concentrations often observed in patients taking AEDs. The effects of AEDs on riboflavin and other B vitamins appear to play a major role in the elevated tHcy concentrations.[9-16] In a 2003 study involving 101 patients with symptomatic, cryptogenic, or primary generalized epilepsy and 101 controls, Apeland et al.[16] investigated fasting and postmethionine loading concentrations of homocysteine (Hcy), vitamin B_2, and vitamin B_6 in patients taking AEDs. Patients receiving inducer AEDs (carbamazepine or phenytoin, phenobarbital, and/or primidone) had high plasma flavin nucleotide/riboflavin concentration ratios associated with low riboflavin concentrations, typically indicating a functional deficiency. Notably, riboflavin concentrations were positively correlated with serum folate and PLP concentrations, as well as weakly correlated with tHcy concentrations. The authors concluded that "it therefore seems reasonable to ensure an adequate intake of riboflavin in patients on inducer AEDs."[16]

In a cross-sectional design that included 423 healthy blood donors, age 19 to 69 years, Hustad et al.[17] determined that "plasma riboflavin is an independent determinant of plasma tHcy," but that the riboflavin-tHcy relationship was modified by MTHFR C677T genotype and "was essentially confined to subjects with the C677T transition of the MTHFR gene." Other data, derived from the Framingham Offspring cohort, suggest that "riboflavin status may affect homocysteine metabolism, but only in a small segment of the population who have both low folate status and are homozygotes for the MTHFR C677T mutation."[18] Subsequently, Moat et al.[19] studied B-vitamin status and plasma tHcy in 126 healthy individuals, 20 to 63 years of age (42 CC, 42 CT, and 42 TT MTHFR genotypes), at baseline and after three interventions lasting 4 months. At baseline and after nutritional intervention, lower riboflavin status was associated with increased plasma tHcy concentrations, with the mean plasma tHcy 2.6 μmol/L higher in the lowest quartile of plasma riboflavin levels compared with the highest quartile. This effect was not restricted to those with the T allele. Notably, folic acid given as a 400-μg/day supplement appeared to exacerbate a tendency toward riboflavin deficiency, as suggested by an increase in the proportion of individuals with erythrocyte glutathione reductase activation coefficient (EGRAC) of 1.4 or greater, from 52% to 65% after supplementation. These authors concluded that "folate and riboflavin interact to lower plasma tHcy, possibly by maximizing the catalytic activity of MTHFR," and that this observed effect "may be unrelated to MTHFR genotype."[19] Further research is warranted to elucidate these various factors and their clinical implications.

Overall, the limited evidence currently available is consistent with earlier findings, but research is still in preliminary phases. Nevertheless, adequately powered and well-designed clinical trials more specifically focusing on riboflavin are warranted. Pending such conclusive findings, the probability of such effects can be considered substantial given the established activity of these drugs on folate and related nutrients and the inherent interdependencies among these nutrients.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing anticonvulsant medications (including barbiturates) are advised to consider nutritional support, including riboflavin, in patients undergoing long-term therapy. Such concomitant nutrient administration is more likely to be important in children, patients with compromised nutritional status, those receiving AED polypharmacy, and patients with genetic polymorphisms adversely influencing methionine metabolism and Hcy levels, such as the C677T MTHFR mutation. Pending conclusive research, coadministration of folic acid and vitamins B_{12} and B_6 is also prudent in most cases. Close supervision and regular monitoring of both medication and Hcy levels are essential to responsible and effective clinical management of such patients.

Antimalarial Drugs

Chloroquine (Aralen, Aralen HCl), hydroxychloroquine (Plaquenil), mefloquine (Lariam), quinacrine (Atabrine, Mepacrine); combination drug: atovaquone and proguanil (Malarone).

Effect and Mechanism of Action

Scientific information on the interrelationships among riboflavin, malaria, and antimalarial drugs is complex, paradoxical, and inconclusive. Low dietary intake of riboflavin, especially to the level of deficiency, appears to be protective against malaria and advantageous in reducing the severity of malarial symptoms. Several antimalarial medications appear to act as riboflavin antagonists, which may play a significant role in their therapeutic efficacy. Quinacrine and related antimalarials impair riboflavin utilization by inhibiting the conversion of riboflavin to FMN and FAD, its active coenzyme derivatives.[20,21] The resultant diminished availability of glutathione reductase and reduced glutathione may render intraerythrocytic malaria parasite more vulnerable to oxidative stress.[22,23] Several antimalarial drugs appear to bind with and increase urinary excretion of riboflavin. Stereospecific complexes with riboflavin-binding protein (RBP) do not appear to form.[24] For example, the phenothiazine ring of chlorpromazine and the isoalloxazine ring of riboflavin exhibit a number of shared structural characteristics.[25] These similarities contribute to the tendency to bind the nutrient and promote riboflavinuria.

Conversely, and paradoxically, high doses of riboflavin may exert activity against the human malaria parasite *Plasmodium falciparum* through its action as a reducing agent and its effects on methemoglobin.[26]

Research

Research findings from animal and human studies indicate that deficient riboflavin nutriture can greatly decrease malarial parasitemia, inhibit the growth of *Plasmodium*, and mitigate the severity of malarial symptoms.[27-31] Dutta et al.,[32] who

conducted many experiments in this area, offered two hypotheses to explain this phenomenon:

It is therefore likely that the conditions which riboflavin deficiency produce have a common biochemical mechanism for their antimalarial activity—namely, they compromise the composition and integrity of membrane phospholipids. Alternatively, it is conceivable that riboflavin deficiency may selectively affect glutathione metabolism in the parasitised red blood cells, since glutathione reductase is an FAD-requiring enzyme.

More recently Akompong et al.[26] investigated the in vitro activity of riboflavin against the *P. falciparum* parasite. The human malaria parasite digests hemoglobin and polymerizes the released free heme into hemozoin, and high doses of riboflavin are used clinically to treat congenital methemoglobinemia without any adverse effects. First, the authors found that the acidic environment of food vacuoles is essential for survival of the parasite in erythrocytes, and such an environment also enhances the auto-oxidation of hemoglobin. They then released parasites from their host cells and separately analyzed hemoglobin ingested by the parasites from that remaining in the erythrocytes; isolated parasites contained elevated amounts of oxidized hemoglobin (methemoglobin) compared with levels found in normal, uninfected erythrocytes. Finally, they treated infected cells with riboflavin, as a reducing agent, for 24 hours, which decreased the parasite methemoglobin level by 55%; hemozoin production was inhibited by 50%, and the average size of the food vacuole decreased by 47%. Administration of riboflavin for 48 hours resulted in a 65% decrease in food vacuole size and inhibited asexual parasite growth in cultures. Based on these findings, the authors concluded that riboflavin is "attractive as a safe and inexpensive drug for treating malaria caused by *P. falciparum*."[26]

The exact mechanism by which riboflavin status influences malaria parasitemia has yet to be fully elucidated. Quinacrine and several drugs with known antimalarial properties, including chlorpromazine, imipramine, and amitriptyline, inhibit biosynthesis of FMN and FAD from riboflavin, most likely because of their structural similarity to riboflavin (e.g., phenothiazine ring of chlorpromazine and isoalloxazine ring of riboflavin), and increase urinary excretion of riboflavin.[20,25,32] Related in vitro research, however, indicates that quinacrine, chlorpromazine, and daunomycin do not form stereospecific complexes with RBP.[24] Furthermore, malaria parasites are known to be highly susceptible to activated oxygen species because of very limited activities of catalase and superoxide dismutase and because their plasma membranes, composed of very high amounts of phospholipids containing unsaturated fatty acids, apparently render them susceptible to the damaging effects of lipid peroxidation.[22,23,33] Thus, given the importance of riboflavin availability to glutathione reductase activity and redox capacity, the parasites may have a higher requirement for riboflavin than do host erythrocytes, and thus they may be more vulnerable to riboflavin deficiency, whether dietary or induced by competition. Consequently, in a review of these conflicting and unresolved findings, Rivlin and Dutta[34] note that "under certain circumstances, specific nutrient deficiencies, such as deprivation of vitamin E, iron, riboflavin, and folate, may prove to be beneficial for the treatment of malaria," and caution that "the indiscriminate use of vitamin supplementation, while well intended, may prove to be potentially harmful."

All the investigators who have conducted research in this area have emphasized the need for further research, through well-designed clinical trials of sufficient power, into the implications of riboflavin availability and activity for drug design and therapeutic strategy, especially given the wide prevalence of resistance to conventional antimalarial drug therapy.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians treating patients infected with malaria are advised to query patients about any nutritional supplement use and to advise that they avoid concurrent intake of riboflavin, as well as vitamin E, iron, and folate, except as indicated by some extraordinary circumstances and then only under medical supervision. Pending more conclusive research, the potential benefit from high-dose riboflavin administration deserves consideration, but pending actual clinical trials of such an intervention in malaria patients, implementation could pose a significant risk of aggravating the condition, particularly in terms of inhibiting efficacy of standard antimalarial drugs.

Antiretroviral Agents, Nucleoside (Analog) Reverse-Transcriptase Inhibitors (NRTIs or NNRTIs)

Evidence: Didanosine (ddI, dideoxyinosine; Videx), lamivudine (3TC, Epivir), stavudine (D4T, Zerit), zidovudine (azidothymidine, AZT, ZDV, zidothymidine; Retrovir).
Extrapolated, based on similar properties: Abacavir (Ziagen), dideoxycytidine (ddC, zalcitabine; Hivid), tenofovir (Viread), zidovudine combination drugs: zidovudine and lamivudine (Combivir); abacavir, lamivudine, and zidovudine (Trizivir).

Effect and Mechanism of Action

Riboflavin deficiency, even at mild levels, appears to increase the risk of nonischemic (type B) lactic acidosis, which infrequently occurs in patients treated with reverse-transcriptase anti-HIV agents. Several adverse effects associated with nucleoside reverse-transcriptase inhibitors (NRTIs) appear to derive from drug-induced mitochondrial toxicity.[35-42] Didanosine/ddI, stavudine, zidovudine/AZT, and other drugs in this class can inhibit DNA polymerase and critical DNA-related riboflavin activity, resulting in impaired mitochondrial DNA synthesis; such adverse effects may be mitigated by riboflavin coadministration.[43] Further, NRTI-induced lactic acidosis is not readily reversible after discontinuation of NRTI and is often fatal because of progressive lactic acidosis and hypotension.[44] Hepatic steatosis and fatty liver are other serious mitochondrial-related complications observed in HIV patients undergoing antiretroviral therapy.[45] These adverse effects have been reversed with riboflavin administration, with concurrent thiamine in some patients.

Research/Reports

Mild to moderate riboflavin deficiency is common among HIV-infected individuals because of compromised nutritional

status, lifestyle stressors, pregnancy, and drug-induced depletion or interference.[46] In 1998, Fouty et al.[43] achieved a major breakthrough in the pathophysiology of this NRTI-associated disorder in the cases of three patients with riboflavin deficiency who were exhibiting lactic acidosis and hepatic steatosis during antiviral treatment and responded well on restoration of normal riboflavin concentrations. In the most striking example, a 46-year-old woman with AIDS who had been on triple-antiretroviral therapy (stavudine, lamivudine, and indinavir) for 4 months was admitted with lactic acidosis, low blood urea nitrogen (BUN), and marked hepatic steatosis. The treating physicians observed that she was taking amitriptyline and suspected an actual or functional deficiency of riboflavin, which was confirmed on testing her enzyme EGRAC. The patient recovered rapidly after receiving 50 mg of riboflavin daily. Subsequently, two other HIV-infected patients on similar triple-drug therapy who had fatty liver on abdominal computed tomography (CT) and (less severe) lactic acidosis demonstrated normalization of serum lactate levels after administration of riboflavin.

In 1999, on the basis of Fouty's report, Luzzati et al.[47] treated a 35-year-old HIV-infected pregnant woman with 50 mg oral riboflavin daily after she presented with severe lactic acidosis. Blood lactate levels returned to normal within 4 days of initiating riboflavin. That patient had been undergoing antiviral therapy with stavudine and lamivudine over the previous 12 months (after previous treatment with zidovudine and zalcitabine). The authors also noted the work of Vir et al.[50] in suspecting increased risk of riboflavin deficiency with pregnancy. Later in 1999, Schramm et al.[48] described a 30-year-old female with AIDS and nucleoside analog–induced lactic acidosis that exacerbated shortly after introducing total parenteral nutrition. She demonstrated a therapeutic recovery within hours after administration of high dose thiamine.

Dalton and Rahimi[49] describe a case of type B lactic acidosis in a 51-year-old HIV-positive woman receiving three nucleotide analogs. She presented with nausea, vomiting, abdominal pain, and hepatic steatosis. Serum riboflavin levels documented a deficiency, and signs of mitochondrial toxicity were demonstrated by diffuse myopathy and pancreatitis. Immediately after treatment with 50 mg of riboflavin daily, serum BUN level, lactic acid levels, and arterial blood pH all returned to normal values, and her signs of mitochondrial toxicity improved. These authors concluded that it is "impossible to predict which patients are predisposed to the development of this syndrome," and suggested that "it may be important to screen and treat riboflavin deficiency in patients on nucleoside analogues."

Vasseur et al.[50] reported the case of a 47-year-old woman with HIV and end-stage renal disease on hemodialysis, treated with combination antiretroviral drug therapy, who developed an acute, severe lactic acidosis 24 hours after surgery for endocarditis. This patient fully recovered after administration of riboflavin, discontinuation of antiretroviral medication, and other supportive measures, including hemodialysis. The authors suggest that the timing of this complication and previous reports imply that open-heart surgery may be a risk factor for nonischemic (type B) lactic acidosis in patients taking NRTIs.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians treating patients with HIV infection are advised to test for riboflavin deficiency and initiate nutritional support with riboflavin, thiamine, and possibly other B vitamins before beginning treatment with NRTIs. Such a course of action seems warranted given the nontoxic character and low cost of the vitamin therapy and the relative severity of the potential adverse effects. Although the anecdotal case literature provides repeated examples of using a 50-mg dose, no parameters have been established for prophylactic dosage levels.

Even though the body of available evidence is limited and reliant on case reports, the pattern of deficiency-related susceptibility, drug-induced toxicity, and favorable response provides a consistent clinical reference and pharmacologically plausible rationale for preventive intervention, pending conclusive research. Well-designed trials are clearly warranted to confirm the efficacy of riboflavin for preventing and treating this serious adverse effect.

Boric Acid, Borate, and Boron

Interaction Type and Significance

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:
3. Possible or
2. Probable

Evidence Base:
☐ **Inadequate** or
○ **Preliminary** (presumed
● **Consensus**)

Effect and Mechanism of Action

Most administered forms of boron are readily converted to boric acid. Boric acid and borate can bind riboflavin, by complexing with its polyhydroxyl ribitol side chain, and displace it from plasma-binding sites. By thus increasing water solubility and urinary excretion of riboflavin, high intake levels of boric acid can potentially cause a deficiency of the nutrient, particularly in the first 24 to 48 hours after ingestion.[25]

Conversely, riboflavin increases urinary excretion of boric acid and can be used to treat boric acid poisoning.

Research

In a review of drugs that promote renal excretion of riboflavin, Pinto and Rivlin[25] discuss the mechanism involved and conclude that boric acid or borate, as typically found in nutritional supplements, eye products, and mouthwashes, can bind riboflavin and significantly impair its bioavailability. Such activity would inherently involve the binding and reduced therapeutic activity of the boric acid or related substance.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing boric acid or its derivatives, or treating a patient who is self-administering such agents, are advised to consider coadministration of riboflavin. The probability of this interaction occurring is relatively high given the known mechanisms, but the probability of a clinically significant drug-induced depletion depends on the individual's initial nutritional status, drug dosage and duration, and other factors of susceptibility or individual variability. Prudence suggests that concurrent administration of riboflavin alone or within a B-complex vitamin formulation is warranted during continued administration of boric acid or high-dose boron, with intake separated by at least 4 hours. The exact dose level at which such an effect occurs, and how it changes proportionately, has yet to be determined, especially for any given individual.

Chlorpromazine and Related Phenothiazine Antipsychotics

Evidence: Chlorpromazine (Largactil, Thorazine).
Similar properties but evidence lacking for extrapolation: Acetophenazine (Tindal), fluphenazine (Modecate, Permitil, Prolixin, Prolixin Decanoate, Prolixin Enanthate), mesoridazine (Serentil), methotrimeprazine (levomepromazine; Nozinan), pericyazine (Neuleptil), perphenazine (Trilafon); combination drug: perphenazine and amitriptyline (Etrafon, Triavil, Triptazine); prochlorperazine (Compazine, Stemetil), promazine (Sparine), promethazine (Phenergan, Promacot, Promethegan), propiomazine (Largon), thioproperazine (Majeptil), thioridazine (Mellaril), trifluoperazine (Stelazine), triflupromazine (Vesprin).

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

Probability: **2. Probable**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Chlorpromazine, a phenothiazine derivative, impairs riboflavin utilization by inhibiting the activity of hepatic flavokinase and thus the conversion of riboflavin to FMN and FAD, its active coenzyme derivatives.[20,21] The phenothiazine ring of chlorpromazine and the isoalloxazine ring of riboflavin exhibit a number of shared structural characteristics.[25] Consequently, chlorpromazine tends to bind with and increase urinary excretion of riboflavin, although stereospecific complexes with RBP do not appear to form.[24] This similarity contributes to the tendency to bind the nutrient and promote riboflavinuria. Such a mechanism of action would imply the binding and reduced therapeutic activity of the chlorpromazine or related phenothiazine drugs.

Research

Using a rat model, Pinto et al.[20] demonstrated that chlorpromazine, as well as imipramine and amitriptyline, "inhibited the incorporation of [14C]riboflavin into [14C]FAD in liver, cerebrum, cerebellum, and heart." They found that in vitro these drugs inhibited hepatic flavokinase, the first of two enzymes in the conversion of riboflavin to FAD. After 3 or 7 weeks, the effects of chlorpromazine administration, at doses comparable on a weight basis to those used clinically, impaired conversion of riboflavin to its coenzyme derivatives and interfere with riboflavin metabolism and utilization "in the animal as a whole" to a significant degree, as indicated by several standard indices of riboflavin status. The EGRAC, an FAD-containing enzyme, was elevated, indicating a riboflavin deficiency state. The urinary excretion of riboflavin was more than twice that of age- and gender-matched pair-fed control rats. Tissue levels of FMN and FAD in test animals were significantly lower than those of pair-fed controls after administration of chlorpromazine for 7 weeks, despite consumption of a diet estimated to contain 30 times the RDA. Thus the authors concluded that low doses of chlorpromazine in rats fed abundant riboflavin increase urinary riboflavin excretion and reduce hepatic flavin stores.[20] In a follow-up study, this research team confirmed that low doses of chlorpromazine increased urinary riboflavin excretion and greatly depleted FAD levels in liver, kidney, and heart, both in animals fed a normal diet and in animals fed a riboflavin-deficient diet. Notably, "brain levels of FAD by contrast were relatively resistant to both dietary riboflavin withdrawal and treatment with chlorpromazine."[51] Subsequent studies showed that urinary riboflavin excretion began to increase within 6 hours of administration of chlorpromazine.

In related research, animal studies have found that administration of riboflavin or FAD can protect against chlorpromazine-induced arrhythmia and mitochondrial dysfunction, particularly when used with coenzyme Q10.[52,53]

In a study involving 52 male and female acute psychiatric inpatients (see Tricyclic Antidepressants), Bell and colleagues[112] investigated the relationship between FAD, which is "reportedly sensitive to thyroid status and to phenothiazine and tricyclic drug exposure," and folate-dependent methylation pathways that "may play a role in the etiology and treatment of such mental disorders as major depression." Nine subjects (17%) demonstrated riboflavin deficiency on a functional red blood cell enzyme assay, thus indicating insufficient FAD activity, with only one riboflavin-deficient subject exhibiting deficiency in another B-complex vitamin, folate. Notably, all patients demonstrating riboflavin deficiency were women, who were characterized by being significantly younger than the rest of the sample, having significantly lower thyroxine levels (even when controlling for gender and covarying for age), and exhibiting "a nonsignificant trend toward more unipolar depression (44% vs 14%), but not toward bipolar or schizophrenic disorders." Moreover, "drug exposure did not show a relationship to riboflavin deficiency in this sample." The authors concluded that these "findings suggest that B_2 (FAD) activity may serve as a sensitive marker of thyroxine status in certain female psychiatric inpatients and that B_2 deficiency may play an etiological role in defects of the methylation pathways in a subset of mentally ill individuals."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing chlorpromazine or related phenothiazines to individuals for unipolar depression, schizophrenia, anxiety, porphyria, or nausea are advised to evaluate riboflavin, FAD, and thyroxine status and to consider coadministration of a B-complex formulation containing riboflavin and folate. Such nutrient supplementation may address fundamental susceptibilities in these patients while preventing drug-induced nutrient depletion patterns. Given the available information regarding potential binding of riboflavin and chlorpromazine, it would be prudent to separate intake of the nutrients and other medications by 4 hours or more.

Doxorubicin and Related Anthracycline Chemotherapy

Evidence: Doxorubicin (Adriamycin, Rubex).
Extrapolated, based on similar properties: Daunorubicin (Cerubidine, DaunoXome), epirubicin (Ellence, Pharmorubicin), idarubicin (Idamycin, Zavedos), mitoxantrone (Novantrone, Onkotrone).
Similar properties but evidence lacking for extrapolation: Doxorubicin, pegylated liposomal (Caelyx, Doxil, Myocet).

Evidence Base:
○ **Preliminary** to ◉ **Emerging**

Effect and Mechanism of Action

Doxorubicin has been shown to form a 1:1 stoichiometric complex with riboflavin, increasing urinary excretion, and competing for binding to tissue proteins.[25,54–57] Such a pharmacokinetic interaction would impair activity of both agents.

Doxorubicin can interfere with the normal metabolism and function of riboflavin by inhibiting the conversion to FMN and FAD.

Riboflavin 2',3',4',5'-tetrabutyrate (B_2-butyrate) may be effective in reducing lipid peroxidation and other toxic effects associated doxorubicin therapy.[58–60]

Riboflavin may deactivate doxorubicin (ADR) in the presence of daylight. "The inactivation of the drug results from its direct oxidation by the excited triplet riboflavin in a type I photosensitization reaction, and 3-methoxysalicyclic acid is an ADR breakdown product."[61,62]

Research

Animal models and clinical reviews indicate that Adriamycin/doxorubicin can cause riboflavin deficiency, even when dietary sources of riboflavin have been sufficient, and that such drug-induced depletion plays a role in drug toxicity and adverse effects. Pinto et al.[54,63] demonstrated that the increased levels in aldosterone associated with doxorubicin are the result of the drug's inhibition of flavin coenzyme biosynthesis. Based on findings using a rat model, these researchers concluded that flavins play a decisive role in regulating the levels of aldosterone and suggested that a doxorubicin-induced increase in serum aldosterone may play a significant role in the pathogenetic mechanisms of cardiovascular toxicity and overall muscular weakness. In related experiments, this research team found that Adriamycin intensifies depletion of reduced glutathione by riboflavin deficiency in rat lens.[63,64]

The findings indicating that the effects of light exposure on riboflavin may impair the activity of doxorubicin are preliminary and of uncertain clinical significance. Ramu et al.[62] investigated the enhancement of doxorubicin inactivation through light-excited riboflavin by histidine and other imidazole analogs. The rate of bleaching of doxorubicin by light-excited riboflavin was enhanced in the presence of histidine in a concentration-dependent manner. These researchers concluded that "in contrast to singlet oxygen, the transannular peroxide, formed by the interaction of histidine and the singlet oxygen produced by photoexcited riboflavin, is an efficient oxidizer" of doxorubicin. Based on these findings, they noted that the "presence of urocanic acid in the skin suggests that significant degradation of ADR could occur in the presence of biologically relevant concentrations of riboflavin if patients treated with ADR are exposed to sunlight."[62]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians administering doxorubicin are advised to coadminister riboflavin to prevent or reverse adverse effects of the agent on riboflavin and its coenzymes. Administration of riboflavin before, during, and after chemotherapy with anthracyclines, particularly doxorubicin, is supported by the body of scientific evidence and experienced clinicians. A daily dosage of 20 to 25 mg of riboflavin, the amounts found in many multivitamin supplements, is most likely sufficient to compensate for doxorubicin-induced deficiency; intake should be separated by 4 hours to minimize risk of binding. Riboflavin is nontoxic, even in high doses, and evidence of any interference by the nutrient on the therapeutic effect of the chemotherapy is lacking and generally considered as unlikely, apart from risk of mutual interference with absorption. Patients might be instructed to avoid significant exposure to sunlight or other sources of major light exposure. All cases inherently require close supervision and regular monitoring. Notably, riboflavin administration may not adequately counteract the toxic effects of doxorubicin related to interference with biosynthesis of FAD and FMN. Concurrent administration of coenzyme Q10 may mitigate doxorubicin cardiotoxicity and myopathy (see Coenzyme Q10 monograph).

Physicians and other health care professionals may consider reviewing the potential for such synergistic therapies with appropriate patients and provide referral information to centers specializing in such integrative approaches. Further research with large, well-designed clinical trials is needed.

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).

Effect and Mechanism of Action

Oral contraceptives (OCs), particularly in high doses in women with compromised nutriture, tend to alter levels of several nutrients, lowering some, elevating others, and producing ambiguous effects in a few. The mechanisms of such effects have yet to

be fully elucidated but almost certainly involve the physiological interrelationships among vitamin B_6, vitamin B_1, riboflavin, folate, and tryptophan, such that a deficiency in one nutrient induces alterations in the activity of others.[65] Concurrent administration of riboflavin and related nutrients appears to prevent or compensate for these adverse effects.

Research

Beginning in the mid-1970s, a series of studies and reviews reported an association between OCs and alterations in physiological levels of several nutrients, most notably depressing serum levels of vitamin B_6, but also B_{12} and riboflavin.[65-69] In a 1974 letter regarding a study by Sanpitak and Chayutimonkul[70] on OCs and riboflavin nutriture, Briggs[71] noted that the data showed "striking decreases in women taking oral contraceptives in all the water-soluble vitamins (C, B_{12}, riboflavine, B_6), no change in vitamin E, but an increase in plasma-retinol." As Wynn[66] summarized in 1975: "Biochemical evidence of co-enzyme deficiency has been reported for vitamin B_2, vitamin B_6, and folic acid." Webb[69] noted that "OC users need more pyridoxine and riboflavin is needed to oxidize pyridoxine phosphate to pyridoxal phosphate." Generally, however, summary remarks echoed this theme: "The clinical significance of these alterations is unknown." However, given the apparent need for enhanced nutriture, consumption of multivitamins was often the ensuing, tentative recommendation.

Ahmed et al.[68] investigated the effects of OCs on nutrient status through a series of animal and human studies. In 1975 they compared biochemical parameters used for assessing vitamin nutritional status in a group of women who had used low-estrogen combination OCs for 6 to 12 months with those of another group of nontreated women, initially and at one or more times in the 6 months. Among several changes relating to nutrient levels and activity, they noted a "fall in erythrocyte riboflavin concentration associated with a decrease in erythrocyte glutathione reductase activity and increase in vitro stimulation with FAD." Notably, "most of these changes were observed during the first few cycles of oral contraceptive treatment."[68]

In a 1979 cross-sectional and follow-up study, Vir and Love[72] found "no significant adverse effect" of OCs on riboflavin nutriture in 65 "young healthy women." Biochemical deficiency of riboflavin manifested in 3 of 33 women in the cross-sectional group, whereas in the follow-up group, only one developed biochemical deficiency after 3 months. Notably, "biochemical riboflavin status did not correlate with OC use," with no correlation observed "between riboflavin intake and activity coefficient of erythrocyte glutathione reductase activity (EGR)." "Most of the subjects had adequate riboflavin intake," and the authors suggested that for women "in developing countries it is possible that the combined effects of poor dietary riboflavin nutrition and OCs contribute to the further deterioration of dietary riboflavin nutrition."[72]

In 1980, Lewis and King[72a] published findings from a small clinical trial indicating that women taking OCs were responsive to riboflavin and thiamin supplementation at relatively low levels, even though deficiencies were not detectable by standard laboratory assessment. In this experiment involving 13 young women, age 19 to 25, thiamin, riboflavin, and pantothenic acid status were determined at the beginning and end of a 12-day confined study. The subjects were fed a constant formula diet containing 2.0 mg thiamin, 3.0 mg riboflavin, and 10 mg pantothenic acid on entering the metabolic unit during the first week of their menstrual cycle. The activity of erythrocyte transketolase or erythrocyte glutathione reductase (EGR) was responsive to the levels of thiamin and riboflavin fed during the study, even though use of OCs did not appear to influence the activity of these enzymes or their response to in vitro stimulation by their cofactors. In the group receiving OCs, erythrocyte transketolase and EGR stimulation by their cofactors was significantly decreased by day 12.

These studies suggest that coadministration of riboflavin may provide support against potential effects of OCs by reversing or preventing nutritional deficits, particularly in those with inadequate intake or preexisting depletion patterns.

Inconsistent findings in various reports have been attributed to differences of OC formulation or riboflavin intake, but more recent research indicates that the women, their biochemical individuality, and variable demands on their systems may play significant roles in determining the effects of OCs. Roe et al.[73] compared the riboflavin requirements of eight healthy OC users and 10 nonusers on diets prepared in a metabolic unit using a single daily menu and meal pattern. On measurement, "erythrocyte glutathione reductase assay values and urinary riboflavin excretion showed intersubject and interperiod differences but no significant group differences (OC versus non-OC)." These authors concluded that "when dietary intake is controlled, OC do not significantly influence riboflavin status," but that "riboflavin needs were related to energy requirements of the subjects." In related research not involving OCs, Belko et al.[74] investigated the riboflavin requirement of young women during periods of sedentary living and exercise determined during a 12-week metabolic study. After examining intake of calories and riboflavin, exercise effects, and EGRAC, they concluded that "healthy young women require more riboflavin to achieve biochemical normality" than the 1980 RDAs, and that "exercise increases riboflavin requirements."

Overall, the body of available evidence indicates that OC effects on riboflavin status, as with other nutrients, are significantly influenced by interindividual variability in diet, nutritional status, energy requirements, and response to OCs. Given adequate nutrient intake relative to activity levels, OCs, particularly at the lower estrogen dose levels more typical in recent years, are not likely to exert a significant adverse effect on riboflavin status in most women. In some women, levels of riboflavin and other nutrients may be adversely affected during the initial months of use, but such effects tend to diminish after the initial 3 to 6 months relative to other factors, although long-term use of estrogen-containing OCs can induce folic acid and B-vitamin deficiency. As always, individual variations in tolerance and susceptibility to adverse effects are probable. Further research is warranted through well-designed and adequately powered clinical trials.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The supplemental dose of riboflavin, 20 to 25 mg, found in most multivitamins is probably adequate to compensate for any potential deficiency resulting from OC use, although requirements can increase with significant changes in dietary intake or activity level. Coadministration of vitamin B_6, folic acid, and B_{12} is usually appropriate when nutritional support is indicated. Enhanced nutrient intake is most important in women with compromised nutritional status, lifestyle factors, or medical conditions impairing vitamin nutriture, or taking medications that tend to deplete riboflavin or interrelated nutrients.

Probenecid

Probenecid (*p*-(di-*n*-propylsulfamyl)-benzoic acid; Benemid, Parbenem, Probalan).
Related: Sulfinpyrazone (Anturane).

Interaction Type and Significance

≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, Not Requiring Professional Management**

≈≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, Not Requiring Professional Management**

Probability: 4. Plausible
Evidence Base: ○ Preliminary

Effect and Mechanism of Action

Probenecid may decrease the absorption of riboflavin from the GI tract, but it can also inhibit renal tubular secretion of riboflavin and decrease riboflavin excretion in the urine.[75-79]

Research

Although widely discussed as a probable interaction, the research findings regarding the effects of probenecid on riboflavin absorption and function are preliminary and limited in scope.

Using an in vitro cellular model system, Said et al.[80] found that uptake of riboflavin by colonic epithelial cells was not inhibited in a competitive manner by probenecid, although it was inhibited by the membrane transport inhibitor amiloride (used clinically as a potassium-sparing diuretic).

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing probenecid are advised to administer riboflavin concurrently because requirements for riboflavin may be increased by the drug's action. Risk is likely to be higher with nutritionally compromised patients and long-term therapy. Physicians should monitor closely for any signs of deficiency.

Propantheline Bromide (Pro-Banthine)

Propantheline bromide (Pro-Banthine)

Interaction Type and Significance

✗ **Potential or Theoretical Adverse Interaction of Uncertain Severity**

◇◇ **Drug-Induced Effect on Nutrient Function, Supplementation Contraindicated, Professional Management Appropriate**

Probability: **4. Plausible** or **6. Unknown**
Evidence Base: ○ **Preliminary** but ● **Consensus**

Effect and Mechanism of Action

Propantheline is an antimuscarinic (anticholinergic) agent that can significantly increase riboflavin absorption by decreasing salivary flow, rate of gastric emptying, and GI motility.[81-85]

Research

The available research investigating the effects of propantheline on riboflavin absorption lacks evidence from clinical trials, but its conclusions are generally accepted as consensus in the pharmacological literature. Nevertheless, even though this effect is apparently "probable to certain" in occurrence, its clinical significance is minimal because the capacity to absorb riboflavin from the GI tract by humans is limited, and riboflavin is generally considered nontoxic at known doses.[86-88] In most cases the effect would be minimal, and it could be beneficial in patients with compromised riboflavin nutriture. Further research would be required to determine whether this pharmacokinetic effect might diminish over time and to assess more accurately any subtle physiological effects of long-term propantheline therapy on riboflavin metabolism and its relationships with coenzymes, related nutrients, and their activities.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing propantheline can better understand the drug's actions by analyzing its effects on riboflavin. Derivative literature typically cautions patients taking propantheline to "seek medical advice." In most cases, however, no changes in clinical management are necessary as a result of these highly probable effects. In particular, avoidance of multivitamins containing typical doses of riboflavin is generally unnecessary.

Tetracyclines and Other Antibiotics

Demeclocycline (Declomycin), doxycycline (Atridox, Doryx, Doxy, Monodox, Periostat, Vibramycin, Vibra-Tabs), minocycline (Dynacin, Minocin, Vectrin), oxytetracycline (Terramycin), tetracycline (Achromycin, Actisite, Apo-Tetra, Economycin, Novo-Tetra, Nu-Tetra, Sumycin, Tetrachel, Tetracyn); combination drugs: chlortetracycline, demeclocycline, and tetracycline (Deteclo); bismuth, metronidazole, and tetracycline (Helidac).
Related: Antibiotics, all classes.

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

Probability: 2. Probable
Evidence Base: ○ Preliminary

Effect and Mechanism of Action

B vitamins, including riboflavin, may interfere with tetracycline pharmacokinetics, impairing absorption and bioavailability. Such an interaction would also impair bioavailability of the vitamins. Thus, tetracyclines can increase urinary riboflavin excretion. More broadly, riboflavin can impair the antibiotic activity of tetracyclines (as well as streptomycin, erythromycin, tyrothricin, and carbomycin) but generally does not inhibit the activity of chloramphenicol, penicillin, or neomycin.[88-90]

Extended use of tetracycline antibiotics could adversely affect bioavailability and function of riboflavin and other B-complex nutrients, both directly and indirectly. Apart from the two-way pharmacokinetic issues, the destructive impact of antimicrobial agents on gut microflora can impair production of B vitamins (as well as folate and vitamin K) and could contribute to systemic inflammatory processes and depressed immune system function.[91-100]

Research

Experiments have demonstrated inactivation of tetracycline solutions by riboflavin in vitro.[89,101] Omray and Varma[102] demonstrated that oral administration of a vitamin C and

vitamin B complex could impair absorption and reduce bioavailability of tetracycline hydrochloride through pharmacokinetic interference.

Clinical Implications and Adaptations

Physicians prescribing tetracycline or related antibiotic medications should advise patients regularly supplementing with riboflavin, alone or within a B-complex vitamin formulation, to take the nutrient(s) and the medication at least 4 hours apart from each other.

Patients treated with tetracyclines or other broad-spectrum antibiotics for an extended period or with high doses will usually benefit from a course of probiotic flora for an equivalent duration to restore intestinal microbiota. Short-term use of tetracyclines is unlikely to lead to clinically significant alterations in the GI ecology. A diet rich in leafy green vegetables and whole grains would typically provide sufficient compensation for any drug-induced decrease in nutrient intake or synthesis, although a multivitamin (taken separate from the medication) may be appropriate in patients with compromised nutritional status undergoing extended tetracycline therapy.

Thyroid Hormones

L-triiodothyronine (T_3): Cytomel, liothyronine sodium, liothyronine sodium (synthetic T_3), Triostat (injection).
Levothyroxine (T_4): Eltroxin, Levo-T, Levothroid, levothyroxine (synthetic), levoxin, Levoxyl, Synthroid, thyroxine, Unithroid.
L-Thyroxine and L-triiodothyronine ($T_4 + T_3$): Animal levothyroxine/liothyronine, Armour Thyroid, desiccated thyroid, Westhroid.
L-Thyroxine and L-triiodothyronine (synthetic $T_4 + T_3$): Euthroid, Euthyral, liotrix, Thyar, Thyrolar.
Dextrothyroxine (Choloxin).
See also Antimalarial Drugs and Tricyclic Antidepressants.

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability:
4. Plausible or
3. Possible

Evidence Base:
○ **Preliminary** to
◉ **Emerging**

Effect and Mechanism of Action

Thyroid hormone regulates the enzymatic conversion of riboflavin to FMN and FAD, its active coenzyme forms.[103] Specifically, triiodothyronine (T_3) plays a key role in the conversion of riboflavin into FMN by enhancing biosynthesis through the expression of riboflavin kinase.[104,105]

Riboflavin is necessary for thyroxine synthesis, as are niacin, pyridoxine, and iodine. Inadequate riboflavin intake can also contribute to diminished thyroid function.

Research

Although a significant body of scientific research explores the physiological functions and the relationships involving riboflavin, its coenzymes, and thyroid hormones, evidence from clinical trials directly investigating coadministration and therapeutic strategies is limited.

Using a rat model, Lee and McCormick[104] reported a "correspondence of flavokinase activity with the amount of a high-affinity flavin-binding protein quantitated immunologically in hypo-, eu-, and hyperthyroid rats [which] indicated that the thyroid response is caused by an increased amount of enzyme; moreover, the concomitant decrease in a low-affinity flavin-binding protein suggests an inactive precursor form of flavokinase." Furthermore, "FAD synthetase activity showed a similar but less pronounced trend than flavokinase."

In 1968, Rivlin et al.[106] observed that hypothyroidism has biochemical similarities to riboflavin deficiency, including lowered FAD biosynthesis, depressed basal EGR activity, and elevated EGRAC. In 1969, Rivlin and Wolf[107] reported diminished responsiveness to thyroid hormone in riboflavin-deficient rats. Croxson and Ibbertson[108] reported low serum T_3 and hypothyroidism in patients with anorexia nervosa. They noted that "a probable decrease of peripheral T_4 to T_3 conversion leads to low serum T_3 concentrations." In a clinical trail involving six hypothyroid human adults, Cimino et al.[105] demonstrated that the activity of EGR, an accessible FAD-containing enzyme, is decreased to levels comparable to those found in riboflavin deficiency, and thyroxine therapy resulted in normal EGR levels while the subjects were on a controlled dietary regimen. Subsequently, in a clinical trial of 17 adolescent girls diagnosed with anorexia nervosa, Capochichi et al.[109] found that "triiodothyronine concentrations were low and negatively correlated with plasma riboflavin concentrations." They concluded that the "low triiodothyronine concentrations observed in anorexia nervosa could alter the extent of riboflavin conversion into cofactors, thus leading to high erythrocyte riboflavin concentrations, low plasma flavin adenine dinucleotide concentrations, and high rates of ethylmalonic acid and isovalerylglycine excretion."

Notably, as discussed in reviewing interactions between riboflavin and antimalarial drugs, hypothyroidism is known to be associated with decreased susceptibility to parasitemia.[110]

Some secondary sources have suggested that synthetic thyroid medication (T_4) tends to decrease riboflavin absorption, but evidence is lacking to support this hypothesis.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians treating patients diagnosed with hypothyroidism are advised to consider concurrent nutritional support that includes riboflavin, as well as iodine, niacin, and vitamins B_6 and C, as appropriate to the patient's particular characteristics and needs. Patients receiving Synthroid or equivalent exogenous T_4 may particularly benefit from enhanced riboflavin nutriture. Further research using well-designed clinical trials is warranted to explore these potential therapeutic synergies.

Tricyclic Antidepressants (TCAs)

Evidence: Amitriptyline (Elavil), imipramine (Janimine, Tofranil), nortriptyline (Aventyl, Pamelor).
Similar properties but evidence lacking for extrapolation: Amitriptyline combination drug: amitriptyline and perphenazine (Etrafon, Triavil, Triptazine); amoxapine (Asendin), clomipramine (Anafranil), desipramine (Norpramin, Pertofrane), doxepin (Adapin, Sinequan), protriptyline (Vivactil), trimipramine (Surmontil).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

◇≈≈ **Drug-Induced Adverse Effect on Nutrient Function, Coadministration Therapeutic, with Professional Management**

≈≈ Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management

Nutrient Depletion
Probability: **3. Possible** or **2. Probable**
Evidence Base: ◉ **Emerging**

Coadministration Benefit
Probability: **4. Plausible** to **2. Probable**
Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Tricyclic antidepressants (TCAs) can decrease riboflavin absorption and inhibit the incorporation of riboflavin into FMN and FAD.[20] Consequently, the potential for riboflavin depletion and impairment of physiological functions can increase riboflavin requirements during extended therapy using these medications. Moreover, coadministration of riboflavin and other B vitamins may elevate levels of these nutrients and their metabolites and augment the therapeutic activity of TCAs and clinical outcomes from such therapy.

Research

A review of the scientific literature reveals a significant trend suggesting a probable additive or synergistic effect with TCA/riboflavin coadministration, the occurrence and degree of which are influenced by the patient's nutritional status and other individual variables.

In two clinical trials in 1992, Bell et al.[111,112] demonstrated the potential clinical advantages of coadministering riboflavin and TCAs to influence intermediates in the folate-dependent methylation pathways. In a 4-week, randomized, placebo-controlled, double-blind study involving 14 geriatric inpatients diagnosed with depression, they investigated augmentation of open TCA treatment with 10 mg each of vitamins B_1, B_2, and B_6. The "active vitamin group demonstrated significantly better B_2 and B_6 status on enzyme activity coefficients and trends toward greater improvement in scores on ratings of depression and cognitive function, as well as in serum nortriptyline levels compared with placebo-treated subjects."[111] In the second study, starting with a sample of 52 male and female acute psychiatric inpatients, they found that nine women (17% of total) exhibited "B_2 deficiency (i.e., insufficient FAD activity) on a functional red blood cell enzyme assay, but only one B_2-deficient individual showed deficiency in another B-complex vitamin (folate)." Notably, the "B_2-deficient women had significantly lower thyroxine levels, even when controlling for sex and covarying for age" and "exhibited a nonsignificant trend toward more unipolar depression (44% vs 14%), but not toward bipolar or schizophrenic disorders." Furthermore, as in the parallel trial, "drug exposure did not show a relationship to riboflavin deficiency in this sample." These researchers concluded that their "findings suggest that B_2 (FAD) activity may serve as a sensitive marker of thyroxine status in certain female psychiatric inpatients and that B_2 deficiency may play an etiological role in defects of the methylation pathways in a subset of mentally ill individuals."[112] (See also Chlorpromazine and Related Phenothiazine Antipsychotics.)

The TCAs, particularly amitriptyline, and riboflavin are both used clinically for migraine prophylaxis. Research into potential synergy is suggested by the available data on their mutual effects and the ability of riboflavin to counter possible adverse effects of the drug.

Note: Riboflavin is often used to monitor drug compliance with a range of medications, including TCA therapy. Riboflavin is coadministered with the medication because it is simple to assess riboflavin in urine (e.g., bright-yellow flavinuria).[113-115] Thus, a patient's noncompliance is easily detected because their urine will not exhibit riboflavin (unless the patient is taking vitamins that contain riboflavin, which would confound results). This use is not intended to function as an interaction and is mentioned only to clarify potential confusion regarding such coadministration.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing TCAs, particularly for unipolar depression, are advised to coadminister riboflavin to prevent or reverse adverse effects on nutrient bioavailability and activity and to consider further adjunctive therapy with thiamine and cyanocobalamin (B_1 and B_{12}). The aim is to achieve pharmacological synergy and enhanced therapeutic outcomes through the supportive interaction of these nutrients with riboflavin and TCAs. Although riboflavin and thiamine are considered relatively nontoxic, the coadministration of a TCA and pyridoxine (B_6) amplifies the usual admonition that close supervision and regular monitoring are warranted. Because PLP-dependent enzymes play a role in serotonin synthesis, concomitant pyridoxine may prevent or reverse depletion as well as augment clinical response to TCAs through an additive or synergistic effect. See the Vitamin B_6 monograph for further discussion.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Acetylsalicylic Acid

Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin); combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin).

Concurrent intake of aspirin and riboflavin has been reported to cause gastric intolerance in some patients. In a migraine prophylaxis pilot study involving 49 individuals administered 400 mg riboflavin and 75 mg aspirin daily, one subject withdrew from the trial after 2 weeks because of gastric intolerance.[46] Both the relatively high dose of riboflavin and the lack of corroborating evidence from other clinical trials or qualified case reports render this isolated report preliminary and speculative. No mechanism of action has been documented, and given the known adverse effects of aspirin, the role of riboflavin as the predominant aggravating factor is doubtful.

Beta-1-Adrenoreceptor Antagonists (Beta-Adrenergic Blocking Agents)

Oral forms (systemic).
Evidence: Bisoprolol (Zebeta), metoprolol (Lopressor, Toprol XL).

Extrapolated, based on similar properties: Acebutolol (Sectra), atenolol (Tenormin); combination drugs: atenolol and chlortalidone (Co-Tendione, Tenoretic); atenolol and nifedipine (Beta-Adalat, Tenif); betaxolol (Kerlone), carteolol (Cartrol), esmolol (Brevibloc), labetalol (Normodyne, Trandate); metoprolol combination drug: metoprolol and hydrochlorothiazide (Lopressor HCT); nadolol (Corgard), nebivolol (Nebilet), oxprenolol (Trasicor), penbutolol (Levatol), pindolol (Visken), propranolol (Betachron, Inderal LA, Innopran XL, Inderal); combination drug: propranolol and bendrofluazide (Inderex); sotalol (Betapace, Betapace AF, Sorine), timolol (Blocadren).

Through distinct but complementary mechanisms, coadministration of riboflavin and a beta blocker could theoretically enhance migraine prevention effects without introducing adverse effects.

Sándor et al.[116] investigated the effects of riboflavin and beta blockers on migraineurs, specifically focusing on intensity dependence of auditory-evoked cortical potentials, in 26 patients before and after 4 months of prophylaxis with metoprolol or bisoprolol (all with migraine without aura) or riboflavin (13 with migraine without aura, 2 with migraine with aura). The intensity dependence of the auditory-evoked cortical potentials was significantly decreased after the treatment with beta blockers, and this decrease correlated significantly with clinical improvement. In contrast, although most patients treated with riboflavin showed clinical improvement, they demonstrated no change in intensity dependence. Based on these findings, the authors concluded that "beta-blockers and riboflavin act on two distinct pathophysiological mechanisms" and suggested that coadministration for migraine prophylaxis "might enhance their efficacy without increasing central nervous system side effects."[116]

Bile Acid Sequestrants

Cholestyramine (Locholest, Prevalite, Questran), colesevelam (Welchol), colestipol (Colestid).

Concomitant intake of riboflavin and a bile acid sequestrant may decrease the absorption of riboflavin by binding riboflavin (and many other nutrients). The tendency of these drugs to adsorb nutrients is well established with regard to fat-soluble vitamins, although controversy remains as to the frequency, extent, and clinical significance of this probable drug-induced nutrient depletion pattern.

This interaction is cited in many reviews and derivative sources as being a known effect of hypocholesterolemic resins on riboflavin absorption.[117] Although plausible and consistent with established principles of pharmacological activity, a conclusive set of evidence derived from well-designed clinical trials and qualified case reports to confirm this possibility is not readily discoverable through standard search methodologies.

Physicians prescribing bile acid sequestrants are advised to consider coadministration of riboflavin, as well as folic acid, vitamins B_{12} and B_6, mixed tocopherols and tocotrienols, vitamin D, coenzyme Q10, magnesium, and other synergistic nutrients, within a comprehensive and individualized strategy of integrative therapeutics to prevent and treat cardiovascular disease. The relationship between riboflavin and homocysteine may be sufficient to justify increased intake of riboflavin and these complementary nutrients in patients with known cardiovascular disease or factors indicating high risk. The probable interference with absorption and bioavailability of riboflavin and other relevant nutrients by these hypocholesteremic resins further heightens the imperative for enhanced nutritional support, particularly in patients with compromised nutriture. Daily administration of a high-potency multivitamin/mineral formulation will replace the nutrients impeded by the drug, thus serving as prudent prophylaxis against potential depletion. Riboflavin (as well as other nutrients and medications) should be taken 1 hour before or 4 to 6 hours after bile acid sequestrants to reduce impairment of absorption and obtain optimal bioavailability.

Imidazole Antibiotics

Clotrimazole (Mycelex) and related imidazole antibiotics.

Flavohemoglobins metabolize nitric oxide (NO) to nitrate and protect bacteria and fungi from NO-mediated damage, growth inhibition, and attack by NO-releasing immune cells. Imidazole antibiotics inhibit the NO dioxygenase function of microbial flavohemoglobin and disruption of the riboflavin pathways.[118,119] Consequently, riboflavin supplementation theoretically could impair the antimicrobial activity of imidazole antibiotics or similar agents that rely on the greater sensitivity to riboflavin depletion in the pathogen than in the host.

Physicians prescribing imidazole antibiotics may consider it prudent to query patients about vitamin intake and to suggest temporary discontinuation of riboflavin intake during treatment. Although speculative, the mechanism of action is plausible and consistent with known pharmacological principles. Further research may be warranted to determine the occurrence and probability of this potential interaction and the circumstances under which it might be clinically significant.

Methotrexate

Methotrexate (Folex, Maxtrex, Rheumatrex).

Numerous derivative articles mention that methotrexate interferes with riboflavin absorption and may inhibit the activities of riboflavin. A few others caution that high-dose riboflavin may impair the therapeutic efficacy of methotrexate. However, evidence from the scientific literature is lacking other than a brief discussion in a 1973 review on riboflavin and cancer by Rivlin[120] and the 1990 review of nutritional deficiencies associated with chemotherapy by Dreizen et al.[57] More substantive evidence from well-designed clinical trials is necessary to establish a clear pattern of interaction between riboflavin and methotrexate and determine its probability, severity, and characteristics.

In a case report, Svahn et al.[121] describe severe lactic acidosis caused by thiamine deficiency in an 11-month-old girl with B-cell leukemia/lymphoma on total parenteral nutrition during high-dose methotrexate therapy. "Treatment with a vitamin cocktail (OH-cobalamin, pyridoxine, thiamine, riboflavine, biotin, carnitine) at pharmacologic doses rapidly improved the child's clinical and laboratory status." Such adverse effects resulting from imbalanced parenteral supplementation are widely recognized and highlight the need for appropriate nutritional support as an integral component of treatment for severe conditions, especially with medications that have a narrow therapeutic index.

Metoclopramide

Metoclopromide (Reglan).

Increased GI motility is associated with a decrease in the rate of absorption for riboflavin. Metoclopramide, a 5HT3-receptor antagonist and a dopamine antagonist, has been effective in increasing underactive GI motility toward normal and thereby treating gastric stasis, which often accompanies migraine attacks. However, by altering the rate of gastric emptying, metoclopramide tends to decrease the absorption of riboflavin.[82]

Given this observed pattern, the concurrent administration of riboflavin with metoclopramide in patients being treated for migraine appears potentially beneficial as a means of ensuring riboflavin sufficiency and providing its possible therapeutic activity.

Selegiline

Selegiline (deprenyl, L-deprenil, L-deprenyl; Atapryl, Carbex, Eldepryl, Jumex, Movergan, Selpak).

Some secondary reviews of interactions involving riboflavin mention that riboflavin may deactivate selegiline in the presence of daylight. Based on in vitro research into sensitized photodegradation of selegiline in the presence of riboflavin and light, Takacs et al.[122] asserted that such "experiments proved that in the presence of riboflavin, both daylight and the light of daylight-lamps are sufficient to significantly decompose selegiline." However, evidence is lacking to confirm such activity with coadministration in a clinical setting, based on human trials or qualified case reports. Nevertheless, pending conclusive research, prudence suggests that patients being treated with selegiline be advised to avoid riboflavin supplementation or exposure to direct sunlight or other bright lights if they use both agents concurrently. Further research may be warranted.

Thiazide Diuretics

Bendroflumethiazide (bendrofluazide; Naturetin), combination drug: bendrofluazide and propranolol (Inderex); benzthiazide (Exna), chlorothiazide (Diuril), chlorthalidone (Hygroton), cyclopenthiazide (Navidrex); combination drug: cyclopenthiazide and oxprenolol hydrochloride (Trasidrex); hydrochlorothiazide (Aquazide, Esidrix, Ezide, Hydrocot, HydroDiuril, Microzide, Oretic); combination drugs: hydrochlorothiazide and amiloride (Moduretic); hydrochlorothiazide and captopril (Acezide, Capto-Co, Captozide, Co-Zidocapt); hydrochlorothiazide and enalapril (Vaseretic); hydrochlorothiazide and lisinopril (Prinzide, Zestoretic); hydrochlorothiazide and losartan (Hyzaar); hydrochlorothiazide and metoprolol (Lopressor HCT); hydrochlorothiazide and spironolactone (Aldactazide); hydrochlorothiazide and triamterene (Dyazide, Maxzide), hydroflumethiazide (Diucardin); methyclothiazide (Enduron), metolazone (Zaroxolyn, Mykrox), polythiazide (Renese), quinethazone (Hydromox), trichlormethiazide (Naqua).

Hydrochlorothiazide and related thiazide diuretics may increase the loss of riboflavin in the urine and could contribute to a cumulative depletion over time, especially in patients with poor nutritional status. Such an adverse effect is highly plausible given general knowledge of thiazide-induced depletion affecting many nutrients. However, specific evidence from clinical trials or qualified case reports is lacking. Further research is warranted. Pending such conclusive findings, coadministration of a multivitamin may be appropriate, particularly in patients with compromised dietary intake. Supervision and monitoring are appropriate.

Trimethoprim and Trimethoprim-Sulfamethoxazole

Trimethoprim (Proloprim, Trimpex); combination drug: trimethoprim and sulfamethoxazole (cotrimoxazole, co-trimoxazole, SXT, TMP-SMX, TMP-sulfa; Bactrim, Bactrim DS, Cotrim, Septra, Septra DS, Sulfatrim, Uroplus).

Interference with the therapeutic activity of sulfa drugs by riboflavin is widely reported in derivative literature. However, specific evidence from clinical trials or qualified case reports is lacking. Conversely, long-term use of sulfa-based antibiotics may deplete riboflavin and other B vitamins, primarily through their adverse effect on the GI environment and its microbiota. See Tetracycline and Other Antibiotics for discussion and citations regarding this effect.

Note: Sulfamethazine is photodegraded in the presence of fluorescent light and FMN. This effect is not related to coadministration but does have implications for accurate laboratory assessment. Procedures for quantitating sulfa drugs and their metabolites need to be performed in subdued lighting and using amber or low-actinic vessels to prevent losses from photochemical reactions.[123]

NUTRIENT-NUTRIENT INTERACTIONS

Boron

See Boric Acid, Borate, and Boron.

Calcium

Calcium

Calcium absorption is impaired in riboflavin deficiency. Dairy products are rich sources of both nutrients.

Folate (Folic Acid)

Folate (Folic Acid)

The activities of folate and riboflavin are interdependent. Riboflavin is a cofactor for MTHFR, the FAD-dependent enzyme responsible for maintaining the specific folate coenzyme required to form methionine from homocysteine. The recycling of folate cofactors depends on riboflavin and vitamin B_6, whereas riboflavin is required for activating vitamin B_6 to PLP.[16] Thus, the regulation of homocysteine metabolism represents an activity of clinical significance dependent on the presence and activity of both nutrients.

Bates and Fuller[124] reported that the "effects of acute riboflavin deficiency on fetal development have similarities with effects of folate deficiency, possibly mediated by effects of flavins on folate metabolism." Weanling rats fed a riboflavin-deficient diet exhibited a marked reduction in activity of hepatic MTHFR.

In general, B vitamins can be most effective when administered together because of their interrelationships and interdependencies and the consequent cascade effect of functions or deficits.

Iron

Iron

Iron absorption and metabolism are impaired in riboflavin deficiency through multiple mechanisms not fully elucidated. Riboflavin deficiency may impair iron absorption, increase intestinal loss of iron, and impair iron utilization in hemoglobin synthesis. Powers[125] reported that coadministration of riboflavin and iron to individuals who are deficient in both nutrients enhances the therapeutic response to iron in iron deficiency anemia.

Psyllium, Fiber, and Related Laxatives

Methylcellulose (e.g., Citrucel), polycarbophil (e.g., FiberCon), psyllium (e.g., Metamucil).

Concomitant intake of psyllium may decrease the absorption of riboflavin.[126] Separating oral intake by at least 2 hours will usually minimize any such interference.

Vitamin B_3 (Niacin)

Vitamin B_3 (Niacin)

Kynurenine mono-oxygenase, an FAD-dependent enzyme, is necessary for the synthesis of NAD and NADP, niacin-containing coenzymes, from tryptophan. Therefore, in the presence of a low-niacin diet, riboflavin sufficiency would be necessary for endogenous synthesis of niacin from tryptophan.

Vitamin B_6 (Pyridoxine)

Vitamin B_6 (Pyridoxine)

Riboflavin and pyridoxine are intimately related, both physiologically and clinically. The clinical signs of riboflavin deficiency and pyridoxine deficiency are similar, and significant interactions between indicators of their nutritional status have been documented, notably in two studies involving elderly patients.[127,128] Riboflavin is a cofactor in the activation of vitamin B_6. Pyridoxine 5′-phosphate oxidase (PPO), an FMN-dependent enzyme, is necessary for the conversion of most naturally available vitamin B_6 (i.e., pyridoxamine phosphate and pyridoxine phosphate), to pyridoxal 5′-phosphate (PLP), its coenzyme form.[129] Correcting a riboflavin deficiency can restore normal activity to that enzyme (PPO). In general, B vitamins can be most effective when administered together because of their interrelationships and interdependencies.

Vitamin B_{12}

Vitamin B_{12}

The numerous interactions between riboflavin and B_{12} are critical to normal function in many physiological processes. For example, methionine synthase, the enzyme that converts homocysteine to methionine, depends on both 5-methyltetrahydrofolate (as a methyl donor) and vitamin B_{12}, as methylcobalamin.[130] Conversely, biosynthesis of methylcobalamin depends on flavoproteins. Riboflavin deficiency interferes with the metabolism of other nutrients, especially the other B vitamins. Nevertheless, evidence is lacking to confirm that riboflavin deficiency leads to a functional deficiency of vitamin B_{12}. In general, B vitamins can be most effective when administered together because of their interrelationships and interdependencies and the consequent cascade effect of functions or deficits.

Vitamin E

Vitamin E

Riboflavin deficiency has been associated with increased oxidative stress. Both vitamin E and riboflavin can act as antioxidants. Concomitant intake may produce a synergistic effect that potentiates this antioxidant effect. In particular, glutathione reductase requires FAD to regenerate reduced glutathione from oxidized glutathione. Thus, riboflavin may protect vitamin E from lipid peroxidation while facilitating regeneration of oxidized vitamin E through its role in production of reduced glutathione.

Zinc

Zinc

Zinc absorption is impaired in riboflavin deficiency.

The 131 citations for this monograph, as well as additional reference literature, are located under Vitamin B_2 (Riboflavin) on the CD at the back of the book.

Vitamin B_3 (Niacin)

Nutrient Names: Vitamin B3, niacin, niacinamide.
Synonyms: Niacin: Nicotinic acid, nicotinate.
Niacinamide: Nicotinamide, nicotinic acid amide, nicotinic amide.
Related Substances: Hexaniacin, inositol hexaniacinate, inositol hexanicotinate, inositol nicotinate.
Other Synonyms: 3-Pyridine carboxamide, anti-blacktongue factor, antipellagra factor, Benicot, nicamid, nicosedine, nicotylamidum, pellagra-preventing factor, vitamin G.
Trade Names include: Efacin, Endur-Acin, Enduramide, Hexopal, Niaca, Niacor, Niasafe, Niaspan, Nicalex, Nicamin, Nico-400, Nicobid, Nicolar, Nicotinex, Nico-Span, Papulex, Slo-Niacin, Tega-Span, Tri-B3, Wampocap.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Acetylsalicylic acid (ASA, aspirin) Acetaminophen Nonsteroidal anti-inflammatory drugs (NSAIDs) ☼/⊕/✗/✗✗✗	Anti-inflammatory agents, particularly aspirin, are often administered to moderate superficial adverse effects associated with niacin (e.g., flushing, pruritus) due to effect of competitive inhibition on nicotinuric acid conjugation pathway. Coadministration may also enhance benefits on cardiovascular risk.	Coadministration of aspirin or NSAID may increase tolerance of, and enhance compliance with, niacin therapy. Consider lower-dose niacin. Monitor liver enzymes.
Anticonvulsant medications ✗✗✗/⊕/✗/⊕	Concurrent niacinamide may potentiate action of anticonvulsants (particularly primidone and carbamazepine) by decreasing drug clearance. Niacinamide may also decrease conversion of primidone to phenobarbital. Further research warranted.	Niacinamide coadministration may be beneficial, but interaction can vary depending on medication. Requires clinical management.
Bile acid sequestrants ⊕⊕/⊕/✗/◇◇/◇	Concurrent use of niacin and bile acid sequestrants may produce an "additive effect" on hypolipidemic activity, particularly lipoprotein B levels, by separate, well-established mechanisms. However, simultaneous intake may interfere with absorption and bioavailability of both agents and reduce their effectiveness. Combining colestipol and niacin may reduce thyroxine-binding globulin and total serum thyroxine (T_4) levels and increase triiodothyronine (T_3) uptake ratios. Further research warranted, including use of inositol hexaniacinate.	Coadministration of niacin and bile acid sequestrant can enhance efficacy of hypolipidemic strategy. Separate intake. Monitor liver enzymes. Supplement fat-soluble nutrients and coenzyme Q10 with resin therapy. Support healthy dietary and lifestyle changes.
Gemfibrozil Fibrates ⊕⊕/⊕/✗/✗	Niacin and fibrates can elevate high-density lipoprotein cholesterol (HDL-C) levels and provide secondary beneficial effects of shifting low-density lipoprotein (LDL) particle size and lowering triglycerides. Niacin appears to exert more effect on HDL-C and fibrates on triglycerides. Thus coadministration can provide complementary cardioprotective effects and reduce risk of vascular events. Both agents, however, can cause hyperhomocysteinemia, with gemfibrozil the exception.	Coadministration can be beneficial, particularly in patients for whom low HDL-C represents the primary lipid disturbance. Coadminister B_6, B_{12}, and folic acid. Monitor liver enzyme and homocysteine levels. Support healthy dietary and lifestyle changes.
HMG-CoA reductase inhibitors (statins) ⊕⊕/⊕/✗/✗✗	Coadministration of niacin and statin therapy has been widely researched and subsumed within conventional treatment of hyperlipidemia and atherosclerosis. Although exerting a broadly additive effect, niacin exerts greater influence on HDL-C levels, whereas statins primarily reduce levels of LDL-C. Combined effect also increases risk of hepatotoxicity, myositis, and other adverse effects. Niacin also depletes methyl donors and contributes to hyperhomocysteinemia and hypocysteinemia, whereas statins interfere with biosynthesis of coenzyme Q10.	Coadministration can be particularly appropriate in patients for whom low HDL-C represents the primary lipid disturbance. Coadminister B_6, B_{12}, and folic acid. Coadminister coenzyme Q10 and consider SAMe or other methyl donors to reduce adverse effects. Monitor liver enzyme and homocysteine levels. Support healthy dietary and lifestyle changes.
Insulin, biguanides, meglitinide analogs Oral hypoglycemic agents ⊕⊕/⊕/✗/✗	Niacinamide supports pancreatic beta cells, enhances insulin secretion, and increases insulin sensitivity, potentially delaying onset or reducing symptoms of type 1 diabetes mellitus. Niacin influences glucose tolerance but may elevate glucose levels; most relevant with metabolic syndrome and dyslipidemia. Thus high-dose niacin may disrupt glycemic control, whereas niacinamide is unlikely to interfere with activity of insulin or oral hypoglycemic medications. Evidence of effects of niacin and niacinamide on glucose function and dysglycemic is mixed and inadequate; further research needed.	Coadministration of either niacinamide or low-dose niacin may be appropriate in some patients. Careful evaluation, close supervision, and regular monitoring essential. Monitor liver enzymes with niacin. Promote appropriate diet and exercise.
Isoniazid, rifampin Antituberculor agents ≈≈/☼	Isoniazid is well known for depleting niacin, primarily by interfering with the functions of vitamin B_6 and tryptophan, but also through competition in NAD. Adverse effects more severe in nutrient-	Coadminister niacin and B_6, especially with nutritionally compromised patients, and always with long-term therapy. Monitor closely for any signs of deficiency.

Continued

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
	depleted patients, especially with long-term use, but often subtle and pervasive. Coadministration of niacin and vitamin B_6 may prevent or reverse deficiency pattern without compromising therapeutic activity.	
Mercaptopurine, azathioprine, and thioguanine Thiopurines ≈≈/☼	Niacin depletion, to stage of pellagra, is a well-known effect associated with thiopurine therapy. Adverse effects are more severe in nutrient-depleted patients, especially with long-term use. Coadministration of niacin may prevent or reverse deficiency pattern without compromising therapeutic activity.	Coadminister niacin, especially with nutritionally compromised patients, and always with long-term therapy. Monitor closely for any signs of deficiency.
Tetracycline antibiotics ⊕⊕/⊕✗/◇◇/≈≈	Simultaneous intake of B_3 and other B vitamins with tetracycline antibiotics can reduce absorption and bioavailability of both/all agents. Coadministration of niacinamide with tetracycline or minocycline often effective against inflammatory skin conditions. Antibacterial effect on intestinal flora and gut ecology can produce secondary adverse effects on B vitamin status and inflammatory processes.	Separate intake if concurrent administration indicated or necessary. Administer probiotic flora after antibiotics.
Thioridazine ⊕⊕	Concomitant administration of niacin and thioridazine may cause increased therapeutic effect, through uncertain mechanism(s), possibly involving stimulation of GABA receptors by niacin. Limited but positive evidence from clinical trials.	Consider coadministration. Close supervision and regular monitoring appropriate.
Tricyclic antidepressants (TCAs) ⊕⊕/⊕✗/✗✗	Coadministration of niacinamide may support the serotonergic effects of L-tryptophan and its potentiation of therapeutic activity of TCAs. Preliminary evidence mixed; rationale plausible. Research indicates narrow therapeutic range and importance of titrating tryptophan dose, particularly in unipolar patients.	Consider coadministration of niacinamide and L-tryptophan. Effect can be very dose-dependent. Close supervision and regular monitoring critical.
Ursodeoxycholic acid Chenodeoxycholic acid ✗✗	These anticholelithogenic agents increase cholesterol saturation of bile and thus may reduce antihyperlipidemic activity of niacin. Evidence limited but treated as consensus.	Concurrent use contraindicated as incompatible.

HMG-CoA, 3-Hydroxy-3-methylglutaryl—coenzyme A; *NAD*, nicotinamide adenine dinucleotide; *SAMe*, S-adenosylmethionine; *GABA*, gamma-aminobutyric acid.

NUTRIENT DESCRIPTION

Chemistry and Forms

Niacin and niacinamide are the two principal forms of the water-soluble B-complex vitamin, B_3. Nicotinic acid and nicotinamide are alternate names for niacin and niacinamide, respectively. Niacin was initially isolated from rice bran in 1911. Later, in 1934, Warburg and Christian isolated niacinamide, the amide of niacin, when coenzyme II (NADP) was extracted from equine erythrocytes. The structure of niacinamide consists of a pyridine ring with an amide group in position three. Inositol hexaniacinate is the hexanicotinic acid ester of meso-inositol; it also called inositol hexanicotinate or inositol nicotinate.

Niacin is extremely stable to heat, light, acid, alkali, and oxidation.

Physiology and Function

Although niacin and niacinamide have divergent pharmacological activities, they share the fundamental function that identifies them as B_3, the vitamin activity that prevents pellagra. However, niacin does not meet the criteria for being defined as a vitamin in the strictest sense because it can be derived from tryptophan. However, at a 60:1 ratio for biosynthesis, this process is highly inefficient and depends on vitamins B_1, B_2, and B_6 as essential cofactors.

Niacin, as either nicotinamide or nicotinic acid, is rapidly absorbed in the proximal small intestine by facilitated diffusion (at low concentrations) and by passive diffusion (at high concentrations). A small proportion of niacinamide is metabolized to niacin, primarily through the activity of enteric flora. The pharmacokinetics of niacinamide vary significantly depending on dose, species, gender, and route of administration. In humans, peak serum concentrations of niacinamide are attained within 1 hour of oral ingestion because it is rapidly cleared from circulation and distributed. Niacin is primarily eliminated via the urine, but also appears in breast milk.

Nicotinamide adenine dinucleotide (NAD+, coenzyme I) and nicotinamide adenine dinucleotide phosphate (NADP+, coenzyme II) are the active forms of nicotinamide. The nicotinamide component of NAD and NADP plays a key role in hydrogen transfer reactions by acting as a hydride ion acceptor or donor in numerous intracellular oxidation-reduction (redox) reactions. Thus, they are required for the activity of more than 200 enzymes participating in a broad range of metabolic processes, including glycolysis, tissue respiration, and lipid, amino acid, and purine metabolism. Notably, NAD is required for the redox reactions in glycolysis and in Krebs cycle during oxidative phosphorylation, through which biological systems derive most of their energy from carbohydrates. NADPH is also involved in fatty acid and steroid synthesis as well as the pentose phosphate shunt pathway, one pathway by which ribose is synthesized. Consequently, niacin is essential to biosynthesis of hormones such as estrogen, progesterone, testosterone, and insulin, along with stress-related hormones in the adrenals. Niacinamide is known to stimulate gamma-aminobutyric acid (GABA) receptors, without binding to the receptor sites, an effect likened to that of benzodiazepines. Both NAD+ and NADP+ function as cofactors for numerous dehydrogenase enzymes (e.g., lactate and malate dehydrogenases) responsible for innumerable biochemical reactions in

the body, including detoxifying alcohol and utilizing carbohydrates, fats, and proteins. Niacin is a precursor of glucose tolerance factor, and niacinamide facilitates beta-cell regeneration in vivo and in vitro.

Nicotinamide adenine dinucleotide is the substrate for mono–adenosine diphosphate (ADP)–ribosyltransferases and poly-ADP-ribose polymerase (PARPs), two classes of enzymes that separate the niacin moiety from NAD and transfer ADP-ribose units from NAD to acceptor proteins. Although their functions are not yet well understood, PARPs also appear to play an important role in DNA replication and repair, as well as cell differentiation. Niacinamide inhibits free-radical formation and acts as an antioxidant, at least in part by preventing NAD depletion during DNA repair by inhibiting PARP. In particular, niacinamide protects pancreatic islet cell lysis (e.g., after exposure to oxygen free radicals and nitric oxide) and suppresses cytokine-mediated induction of nitric oxide synthase. Through its inhibition of PARP, niacinamide also modulates major histocompatibility complex (MHC) class II expression and exerts an anti-inflammatory action affecting neutrophil chemotaxis.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

Within conventional medical practice, vitamin B_3 usage, typically as niacinamide, is primarily framed in terms of prophylaxis and treatment of frank vitamin B_3 deficiency states, particularly pellagra. However, the most common clinical application of niacin is treatment of primary hyperlipidemia, specifically type IIa/IIb, III, IV, or V hyperlipoproteinemia, where it is a first-line therapy, often in combination with an HMG-CoA reductase inhibitor, for reducing low-density lipoprotein cholesterol (LDL-C) concentrations and triglycerides and increasing high-density lipoprotein cholesterol (HDL-C) concentrations.

Supplementation with vitamin B_3 can play an essential role in treatment of individuals with malabsorption syndromes associated with pancreatic insufficiency and diseases of the small intestine, such as celiac and tropical sprue. Diabetes mellitus, hyperthyroidism, malignant carcinoid syndrome, and other pathophysiological states can increase metabolic requirements for B_3 and carry a significant risk for B_3 deficiency. Hartnup's disease is a rare autosomal recessive tryptophan metabolism disorder wherein inborn errors of metabolism cause tryptophan absorption and transport to be impaired and tryptophan to be diverted to form 5-hydroxytryptamine, thereby impairing conversion of tryptophan to niacin and increasing risk of niacin deficiency and the need for niacin (and tryptophan) intake.

Historical/Ethnomedicine Precedent

The use of lime or other alkalinating agents in the diets and cooking practices of many traditional cultures represents an institutionalized application of the empirical observation that bound niacin in many food sources, especially maize, needs to be liberated to supply adequate dietary intake of niacin.

Possible Uses

General

Burns, human immunodeficiency virus (HIV) support, postpartum support, pregnancy, schizophrenia, skin cancer.

Niacin

Anxiety, atherosclerosis, Bell's palsy, diabetes mellitus, dysmenorrhea, Hartnup's disease, high hypercholesterolemia, hyperlipidemia, hyperlipoproteinemia (type IIa/IIb, III, IV, V), hypertriglyceridemia, hypothyroidism, intermittent claudication, hypothyroidism, migraines, multiple sclerosis, myocardial infarction (recurrence), photosensitivity, Raynaud's disease, smoking cessation, tardive dyskinesia.

Niacinamide

Acne (topical), alcohol withdrawal support, anxiety, bursitis, cataracts, dermatitis herpetiformis (with tetracycline), diabetes mellitus (type 1; prevention), Hartnup's disease, hypoglycemia, osteoarthritis, pellagra, photosensitivity, Raynaud's disease, tardive dyskinesia.

Inositol Hexaniacinate

Hypercholesterolemia, intermittent claudication, peripheral vascular disease, Raynaud's disease.

Deficiency Symptoms

Niacin deficiency manifests pervasively, affecting every cell in the body. Symptoms of mild niacin deficiency include indigestion, fatigue, canker sores, vomiting, and depression. In its classic presentation as pellagra, severe niacin deficiency is characterized by cutaneous, mucous membrane, central nervous system (CNS), and gastrointestinal (GI) symptoms, alone or in combination; a pattern commonly described as the "four Ds": dermatitis, diarrhea, dementia, and death. Nutritionally based pellagra usually involves a simultaneous tryptophan deficiency. The dermatitis caused by a niacin deficiency is characterized by cracked, thick, scaly skin forming a symmetrical, darkly pigmented rash and exacerbated by sun exposure, a phenomenon known as "mal del sol." This condition is often complicated by other B-vitamin deficiencies. Scarlet glossitis and stomatitis are characteristic of acute deficiency. The tongue and mouth become inflamed, painful with a burning sensation, and take on a bright, beefy red appearance. Diarrhea results from decreased hydrochloric acid secretion accompanied by inflammation of the GI tract. Dementia caused by a lack of niacin begins with irritability, headaches, and insomnia, followed by mental confusion, amnesia, hallucinations, and severe depression. If untreated, pellagra is ultimately fatal.

The most common causes of niacin deficiency are alcoholism and inadequate intake of niacin (and tryptophan) with sufficient bioavailability; genetic, pathophysiological, and iatrogenic factors also constitute significant risks. High dietary intake of cereals (e.g., sorghum, corn) not processed with lime, to increase tryptophan bioavailability, is a common cause of niacin deficiency in settings of poverty and poor diet. However, a broad nutritional deficit is usually required, especially involving protein, tryptophan and/or thiamine, riboflavin, and pyridoxine. Excessive leucine intake (e.g., with high millet intake, as common in India) can lead to a niacin deficiency even with normal intake because leucine blocks NAD synthesis. Diarrhea, cirrhosis, and inadequate or imbalanced nutrient infusions during postoperative recovery are common causes of secondary niacin deficiency.

Dietary Sources

Liver, poultry, meat, fish, eggs, peanuts, brewer's yeast, torula yeast, rice bran, rice polishings, and wheat bran are rich dietary

sources of vitamin B_3. Legumes, mushrooms, nuts, sunflower seeds, and wheat germ can also serve as significant nutrient sources. In general, however, although whole grains and cereal products may contain some vitamin B_3, fortification of white flour is the primary means of ensuring that commonly consumed grain products provide adequate niacin nutriture. Niacin tends to be bound to glycosides in mature cereal grains, such as corn and wheat, which significantly decreases its bioavailability. Alkali treatment of grains, such as with alkaline-cooking process using lime, may result in release of the bound niacin and increase its bioavailability; however, this has been disputed. Dietary tryptophan can be converted to niacin and can enhance available supplies, but evidence indicates that the 60:1 conversion ratio may be overly optimistic.[1]

Food sources of B_3 often also contain thiamine, riboflavin, pantothenic acid, pyridoxine, cyanocobalamin, and folic acid. B-complex vitamins (especially B_1, B_2, and B_6), vitamin C, magnesium, zinc, protein, and essential fatty acids enhance absorption of vitamin B_3, whereas alcohol, coffee, excess sugar, antibiotics, and steroids reduce niacin absorption.

Nutrient Preparations Available

Vitamin B_3 as a nutritional supplement is primarily available as niacinamide (nicotinamide) or niacin (nicotinic acid). Multivitamin formulations typically contain some form of B_3. Nicotinamide is the form of niacin most often used in nutritional supplements and in food fortification. Nicotinate and inositol hexaniacinate (the hexanicotinic acid ester of meso-inositol) are also available as nonprescription forms. Timed-release supplemental niacin (OTC) can produce fewer superficial adverse effects (e.g., flushing) but can also be more hepatotoxic. Nicotinic acid in a shorter-acting, timed-release preparation, sometimes referred to as "intermediate release" or "extended release," is available by prescription. Limited but relatively consistent evidence indicates that inositol hexaniacinate may be the best-tolerated form of niacin, with minimal incidence of skin flushing, nausea, vomiting, agitation, and hepatotoxicity.[2-4]

Within conventional medical practice the crystalline, immediate-release form (usually taken two to four times daily) and the extended-release form (once daily) are the two prescription formulations of niacin approved for treatment of dyslipidemia. The American Heart Association advises against using OTC supplemental niacin.[5]

Note: Niacin dosage values for requirements and foods are described in niacin equivalents (NE), which are calculated by combining nicotinic acid and niacinamide intake and adding an estimate for tryptophan conversion.

$$\text{Niacin (mg equivalents)} = \text{Nicotinic acid (mg)} + \text{Nicotinamide (mg)} + \text{Tryptophan (mg)}/60$$

Dosage Forms Available

Capsule, liquid, powder, tablet, effervescent tablet. Injectable forms are sometimes administered by health care professionals.

Source Materials for Nutrient Preparations

All B vitamins are predominantly synthesized, except for the "food form," in which synthesized B vitamins are added to nutrient broth for yeast, which (supposedly) incorporates higher amounts of them into the cells, which are then dried and tableted.

Dosage Range

Adult

Dietary: The U.S. dietary reference intake (DRI) for niacin is 16 mg niacin equivalents per day for men and 14 mg equivalents daily for women.[6] Pregnant or lactating women: 18 mg daily.
Supplemental/Maintenance: 100 mg daily, combined forms.
Pharmacological/Therapeutic: 500 mg three times daily.
Toxic: U.S. tolerable upper limit (UL) established for nicotinic acid in adults is 35 mg per day; this level was selected to avoid the adverse effect of flushing in the general population, even though flushing and other adverse effects from nicotinamide are significantly less common. No separate tolerable UL has been established for nicotinamide. Reports of nicotinamide overdosage are not present in the literature.
Nicotinic acid/niacin: Transient acute flushing symptoms can occur at 100 to 200 mg niacin. Elevated liver enzymes, jaundice, and other signs of hepatotoxicity have been observed at nicotinic acid intakes as low as 750 mg/day for less than 3 months. Timed-release nicotinic acid has been associated with chemical hepatitis at levels as low as 500 mg/day for 2 months, although most cases have involved significantly higher doses and longer periods of intake.
Nicotinamide/niacinamide: Low toxicity generally characterizes the safety profile of nicotinamide. Intake of 3 g/day of nicotinamide for longer than 3 months has been associated with adverse effects such as nausea, vomiting, elevated liver enzymes, and jaundice. However, rare occurrences of liver toxicity have been reported at doses in excess of 1000 mg/day.

Pediatric (<18 Years)

Dietary:

Infants, birth to 6 months: 2 mg/day (AI, adequate intake)
Infants, 7 to 12 months: 4 mg/day (AI)
Children, 1 to 3 years: 6 mg/day (RDA)
Children, 4 to 8 years: 8 mg/day (RDA)
Children, 9 to 13 years: 12 mg/day (RDA)
Adolescents, 14 to 18 years: 14 mg (females) or 16 mg (males) daily (RDA)

Supplemental/Maintenance: Usually not recommended for children under 12 years of age. Avoid extended-release forms.
Pharmacological/Therapeutic: Usually not recommended for children under 12 years of age. Niacinamide has been administered in research and clinical settings involving prevention of type 1 diabetes mellitus in "high-risk" individuals at daily doses of 150 to 300 mg per year of the child's age, or 25 mg per kilogram body weight daily. Avoid extended-release forms.
Toxic: No tolerable UL for niacin in infants has been proposed. The U.S. tolerable UL established for niacin in children age 1 to 8 years is 10 to 15 mg daily and 20 mg daily for children 9 to 13 years; for adolescents (14-18 years) it is 30 mg daily. These levels were selected to avoid the adverse effect of flushing in the general population; flushing from nicotinamide is unreported and not considered an associated effect.

Laboratory Values

Cellular NAD and NADP content: Some clinicians and researchers suggest this test may provide the most clinically relevant indicators of niacin nutritional status.[7]

Erythrocyte nicotinamide adenine nucleotide (NAD): This test can provide a sensitive indicator of niacin status.
Red blood cell (RBC) NAD/NADP ratio: A ratio of RBC NAD to RBC nicotinamide nucleotide phosphate (NADP) less than 1.0 may indicate deficiency.
Urinary 1-*N*-methyl-nicotinamide (NMN) and 2-*N*-pyridone (2-N-P): Excretion of less than 0.8 mg NMN per day and/or less than 1.0 mg 2-N-P per day indicates niacin deficiency. Although this measurement of excretion levels of major niacin metabolites can provide relatively accurate indices of niacin status, the results are often not conclusive.
Whole-blood niacin: Reference range 1.2 to 2.9 μg/mL.
Abnormal liver function studies: All individuals taking pharmacological doses of niacin should be monitored for liver function and enzyme levels; elevations in AST (SGOT) and ALT (SGPT) are common.
Lymphocytic growth response.

Niacin or nicotinic acid administration can alter findings from several laboratory tests.

Urinary catecholamine concentration measurements by fluorimetric methods may be falsely elevated by niacin.
Urine glucose determination using Benedict's reagent (cupric sulfate) may produce false-positive reactions. However, nicotinic acid may elevate blood glucose levels.
Nicotinic acid may falsely elevate blood growth hormone levels.
High-dose nicotinic acid may elevate blood uric acid levels.
Niacin may falsely elevate homocysteine (Hcy) levels (by interference with the assay). It can also truly elevate Hcy levels by consuming methyl donor nutrients in its metabolism.
Niacin may decrease high-sensitivity C-reactive protein (hsCRP).

SAFETY PROFILE

Overview

The safety profile for pharmacological preparations of vitamin B_3 varies significantly for different forms of the nutrient and exhibits a major differentiation between short-term, nonthreatening but uncomfortable adverse effects and longer-term toxicity. Evaluation of vitamin B_3 toxicity is further complicated by over 50 years of research findings and clinical observations that use varied preparations and poor methodology or that are inadequately powered, rendering contradictory and inconsistent conclusions, and that are often simply obsolete or clinically irrelevant.

Generally, adverse effects (predominantly flushing and itching) are significantly more likely with nicotinic acid than with nicotinamide, and, conversely, nicotinamide is better tolerated than nicotinic acid. Moreover, adverse reactions to niacinamide, at doses less than 1000 mg/day, are rare (and possibly linked to impure materials), and as such the nutrient is generally considered safe in most situations.[8-11] However, the possibility exists that adverse effects of niacinamide have not been adequately documented because significantly fewer clinical trials have involved niacinamide and the lack of data simply reflects a study bias. No adverse effects are associated with intake of niacin from food sources in typically consumed forms.[6] Adverse effects ranging from minor discomfort to severe toxicity are possible with nicotinic acid. Close supervision and regular monitoring are warranted when administering doses of niacin greater than 1000 mg/day.

Nutrient Adverse Effects

General Adverse Effects

Niacin often causes skin flushing with burning and tingling sensations, especially in the face, at levels more than 100 mg, although some sensitive individuals can experience flushing with as low a dose as 10 to 20 mg. These symptoms are of rapid onset and limited duration and may be accompanied by stomach distress, itching, and headache. The vasodilatory response involved constitutes a significant mechanism of action in the therapeutic action of niacin and is considered beneficial by many who self-administer niacin. However, many patients who discontinue or refuse niacin do so to avoid this unpleasant effect. These niacin-induced adverse effects typically resolve with discontinuation. Tachyphalaxis also develops with continued daily use, although tolerance may disappear with breaks of just a few days, but is usually quickly reestablished shortly after daily intake is resumed.

Nausea and GI upset are usually the first signs of toxicity with both niacin and niacinamide. Niacin is excreted as methylated pyridones, the formation of which uses *S*-adenosylmethionine (SAMe), the primary physiological methyl donor. The resulting niacin-induced interference with methionine metabolism and depletion of SAMe impairs detoxification processes and contributes to many of niacin's adverse effects, including decreased levels of vitamin B_6 and increased plasma homocysteine concentrations. Changes in hepatic transaminase enzyme levels, indicating liver inflammation, are often the second detectable sign of niacin toxicity. Prudence warrants that aspartate transaminase (AST, SGOT) and alanine transaminase (ALT, SGPT) be monitored regularly during therapy with any form of niacin. Elevated liver enzymes, jaundice, and other signs of hepatotoxicity have been observed at nicotinic acid intakes as low as 500 mg/day for less than 3 months, although doses of 1500 to 3000 mg/day are more typically associated with clinically significant adverse effects. A significant body of evidence indicates that slow-release or extended-release forms of niacin are more likely to cause adverse effects and hepatic toxicity reactions. Niacin administration needs to be discontinued or the dose significantly reduced at first indication of adverse effects on liver function. When initiating pharmacological doses of time-release niacin, beginning with 500 mg and increasing by 500 mg each month up to the target dose (usually 1.5-3.0 g) improves tolerance to the therapy.

Other symptoms rarely or infrequently associated with niacin intake include headache, dizziness, anxiety, panic attacks, hypothyroidism, abnormal cardiac rhythms, heart palpitations, difficult breathing, lactic acidosis, myopathy, elevated creatine kinase levels, tooth or gum pain, macular swelling, blurred vision, and toxic amblyopia.

In a multicenter randomized, placebo-controlled trial, Garg et al.[12] found that niacin therapy, at 1000 mg or more per day, can substantially increase plasma homocysteine levels.

Niacinamide, at high dosage levels, has been associated with nausea, heartburn, vomiting, flatulence, and diarrhea. Parenteral administration of niacinamide has been reported to cause mild headaches and dizziness.

Rare occurrences of anaphylactic shock have been reported following intravenous or oral niacin therapy.

Adverse Effects Among Specific Populations

Individual characteristics that increase susceptibility to adverse effects from excess nicotinic acid intake include abnormal liver function or a history of liver disease, active

peptic ulcer disease, alcohol abuse, diabetes, hypoglycemia, gout, cardiac arrhythmias, severe hypotension, inflammatory bowel disease, and migraine headaches.

Pregnancy and Nursing

Use of niacin supplementation during pregnancy or breastfeeding is not recommended because research on safety and effectiveness is insufficient. No problems have been reported.

Children

Use of niacin supplementation in children is not recommended because of insufficient research on safety and effectiveness and diminished hepatic detoxification capacity. No problems have been reported.

Contraindications

Vitamin B_3 is contraindicated in persons with hypersensitivity or allergy to niacin or niacin-containing substances and in children under 12 years of age, especially time-release forms.

Precautions and Warnings

Niacin should be avoided, or used only under close supervision and with appropriate monitoring, in patients with liver disease or compromised hepatic function, especially time-release forms.

Concomitant use of niacin and HMG-CoA reductase inhibitors (statins) significantly increases the risk of adverse effects, ranging from mild and reversible to severe and potentially fatal, especially in patients with compromised renal or hepatic function (see later discussion).

For decades, warnings have been voiced regarding potential risks for individuals with diabetes or hypoglycemia. Nicotinic acid can induce elevation in blood glucose and depletion of glycogen stores. Recent clinical trials found that niacin does not appear to raise blood glucose levels in patients with type 2 diabetes.[13,14] Thus, although niacin may cause significant alterations in blood sugar levels and insulin, such effects warrant clinical management rather than avoidance. (See Nutrient-Drug Interactions.)

Niacin can increase uric acid production and elevate blood uric acid concentrations. Individuals with gout, or predisposition to gout, should be administered niacin only under close supervision, preferably within the context of a comprehensive approach to dietary change and risk reduction. This adverse effect is primarily theoretical and evidence preliminary or inconsistent.

Niacin may elevate plasma homocysteine levels and should only be used under close supervision and with appropriate monitoring by patients with hyperhomocysteinemia or elevated risk of stroke or heart disease.

High-dose niacin intake can aggravate peptic ulcer and should be avoided in these patients except under close supervision and with appropriate monitoring.

Rare occurrences of leukopenia and slightly increased blood eosinophils have been reported in individuals taking niacin. Caution is advised in patients with bleeding disorders or undergoing anticoagulant therapy.

INTERACTIONS REVIEW

Strategic Considerations

With its long-standing role within standard practice of cardiovascular care, niacin is a nutrient that belies the labels of "alternative" and "conventional" and demonstrates the importance of an integrative approach to risk reduction and therapeutic intervention based on scientific evidence and clinical outcomes. The use of niacin with statins, resins, and fibrates is well established in conventional medicine. As such, niacin confirms the need for a multidisciplinary and collaborative model in both the benefits it conveys and the risks it amplifies when coadministered with various drug regimens and in the ways in which a strategic approach employing multiple nutrients can reduce adverse effects, optimize efficacy, and expand benefits.

Vitamin B_3 is among the most frequently researched nutrients in conventional medicine. However, a review of the available evidence illustrates that the combination of widespread usage and scientific research of limited character and narrow focus has resulted in an incomplete and unevenly distributed set of data characterized by many more speculative, ill-founded, or inadequately investigated "interactions" than thoroughly researched and well-documented ones.

Niacin can play an important role in a comprehensive strategy for reducing dyslipidemia and the risk of coronary disease, but low doses may be safer and just as effective as high doses. Also, there is an even greater need to coadminister vitamins B_6 and B_{12} and folate, as well as methyl donor support through nutrients such as SAMe and betaine, to counter the tendencies to hepatoxicity and hyperhomocysteinemia, especially if statins are also employed. The issue of how antioxidants, singly or as networks, may interact with niacin to impair some of its therapeutic activity deserves focused research.

Two primary issues consistently arise regarding clinical application of niacin: toxicity and glucose control. The issue of *toxicity* is inherent to the nature of niacin and manifests primarily in adverse effects on the liver and interference with B_6-tryptophan-methionine metabolism, leading to elevation of homocysteine (Hcy). The use of low-dose niacin or the alternative administration of nontoxic inositol hexaniacinate may adequately address the former. Coadministration of B_2, B_6, B_{12}, folic acid, SAMe, and possibly betaine may diffuse the adverse effect on methyl donor supply and Hcy regulation.

The issue of interference with *glucose control,* particularly the often-asserted possibility of interference with oral hypoglycemic medications, may have been resolved with recent evidence indicating a lack of clinically significant interaction; nevertheless, continued research into potential benefits, drawbacks, and clinical implementation of coadministration is needed. Regular monitoring of liver enzyme levels, specifically AST and ALT, as well as plasma Hcy, is critical whenever administering niacin, especially in conjunction with statins.

The multiple concerns with niacin-induced toxicity highlight the need for further research into the efficacy of inositol hexaniacinate, or low-dose niacin, for treatment of dyslipidemias.

Likewise, the role of niacinamide in relation to insulin sensitivity, glucose tolerance, and dysglycemia suggests the need for integrative strategies that can both prevent the progression of dysfunction to disease and evolve within a multidisciplinary treatment strategy that responds flexibly to improvement or decline in the patient's condition.

In almost all its uses, vitamin B_3 exemplifies several fundamental principles operative in the clinical practice of integrative medicine. Less may do more, or enough, for any given agent. Static monotherapy using any agent is often less effective than flexible, personalized, and synergistic polypharmacy/polynutrient strategies crafted to the individual patient and evolving with their changing condition. Moreover, the spectrum of

clinical applications for niacin and niacinamide and these agents' interactions with various drugs emphasize the importance of the guiding principles in the management of most clinically significant interactions: the centrality of physician-patient trust and dialogue, the importance of collaboration among health care professionals bringing together various perspectives and expertises, the continuum of dosage from nutrient support to pharmacological intervention, the opportunities to emphasize therapeutic actions or mitigate adverse effects through combinations and dosage manipulation, and the essential need for ongoing supervision, monitoring, and titration.

NUTRIENT-DRUG INTERACTIONS

Acetylsalicylic Acid, Acetaminophen, and Related Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

Evidence: Acetylsalicylic acid (acetosal, acetyl salicylic acid, ASA, salicylsalicylic acid; Arthritis Foundation Pain Reliever, Ascriptin, Aspergum, Asprimox, Bayer Aspirin, Bayer Buffered Aspirin, Bayer Low Adult Strength, Bufferin, Buffex, Cama Arthritis Pain Reliever, Easprin, Ecotrin, Ecotrin Low Adult Strength, Empirin, Extra Strength Adprin-B, Extra Strength Bayer Enteric 500 Aspirin, Extra Strength Bayer Plus, Halfprin 81, Heartline, Regular Strength Bayer Enteric 500 Aspirin, St. Joseph Adult Chewable Aspirin, ZORprin).
Extrapolated, based on similar properties:
ASA combination drugs: ASA and caffeine (Anacin); ASA, caffeine, and propoxyphene (Darvon Compound); ASA and carisoprodol (Soma Compound); ASA, codeine, and carisoprodol (Soma Compound with Codeine); ASA and codeine (Empirin with Codeine); ASA, codeine, butalbital, and caffeine (Fiorinal); ASA and extended-release dipyridamole (Aggrenox, Asasantin).
Acetaminophen (APAP, Paracetamol, Tylenol).
COX-1 inhibitors: Diclofenac (Cataflam, Voltaren), diclofenac and misoprostol (Arthrotec), diflunisal (Dolobid), etodolac (Lodine), fenoprofen (Dalfon), furbiprofen (Ansaid), ibuprofen (Advil, Excedrin IB, Motrin, Motrin IB, Nuprin, Pedia Care Fever Drops, Provel, Rufen); combination drug: hydrocodone and ibuprofen (Reprexain, Vicoprofen); indomethacin (indometacin; Indocin, Indocin-SR), ketoprofen (Orudis, Oruvail), ketorolac (Acular ophthalmic, Toradol), meclofenamate (Meclomen), mefenamic acid (Ponstel), meloxicam (Mobic), nabumetone (Relafen), naproxen (Anaprox, Naprosyn), oxaprozin (Daypro), piroxicam (Feldene), salsalate (salicylic acid; Amigesic, Disalcid, Marthritic, Mono Gesic, Salflex, Salsitab), sulindac (Clinoril), tolmetin (Tolectin)
COX-2 inhibitor: Celecoxib (Celebrex).

Effect and Mechanism of Action

Aspirin or other anti-inflammatory agents can be administered to reduce cutaneous flushing and other unwanted reactions associated with niacin intake. Both nicotinic acid and salicylic acid agents undergo glycine conjugation. Competitive inhibition with coadministration may reduce total nicotinic acid clearance and thereby cause saturation (and effective elimination) of the nicotinuric acid conjugation pathway.[15]

Theoretically, concomitant use of niacin and aspirin may increase the risk of bleeding.

Research

The use of aspirin or other anti-inflammatory agents to moderate niacin-induced effects is a well-known, empirically based practice among health care professionals experienced in nutritional therapeutics and self-medicating individuals. Several clinical trials have investigated and confirmed the efficacy of concomitant aspirin to relieve the adverse effects of niacin (nicotinic acid), such as flushing, headache, pruritus, tingling, and heat. As of 1992, the National Cholesterol Education Program recommended pretreatment with aspirin or another NSAID before niacin therapy as a means of enhancing compliance with niacin-based treatment of hyperlipidemia.

Ding et al.[15] conducted a pharmacokinetic study of the interaction between nicotinic acid and salicylic acid by investigating the impact of aspirin administration on nicotinic acid steady-state levels and total clearance in six healthy subjects. Nicotinic acid solutions were infused at constant rates (0.075-0.100 mg/kg/min) for 6 hours to establish steady-state concentrations. Two hours after the nicotinic acid infusion began, they orally administered 1 g aspirin. By analyzing nicotinic acid, nicotinuric acid, and salicylic acid in plasma samples, they observed an immediate marked decrease of nicotinuric acid levels and an increase in nicotinic acid concentrations after aspirin administration. The authors hypothesized that "salicylic acid causes a concentration-dependent decrease of total nicotinic acid clearance that results in the saturation (and effective elimination) of the nicotinuric acid conjugation pathway."

Whelan et al.[16] conducted the first randomized, double-blind, placebo-controlled trial to evaluate the efficacy of aspirin in reducing cutaneous reactions caused by niacin. They administered four different treatment regimens to 31 healthy subjects who had been randomized into four groups. They found that 325 mg of aspirin decreased intolerability to niacin significantly better than 80 mg aspirin. Aspirin reduced the incidence of warmth and flushing associated with niacin, but not the itching and tingling. Subsequently, in a randomized, double-blind, placebo-controlled, crossover study, Jungnickel et al.[17] compared the effects of pretreatment with two aspirin regimens and placebo on niacin-induced cutaneous reactions in 42 healthy adult subjects. Subjects received 325 mg aspirin, 650 mg aspirin, and placebo for 4 consecutive days and also ingested 500 mg immediate-release niacin 30 minutes after taking aspirin or placebo on the fourth day. They concluded that an aspirin regimen of 325 mg effectively suppressed niacin-induced cutaneous reactions, with no additional benefit derived from increasing the aspirin dose to 650 mg.[17]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The use of aspirin or other anti-inflammatory agents to reduce the discomfort of cutaneous reactions to niacin represents a viable option to offer patients during niacin therapy. A daily

dose of 325 mg aspirin per day has proved effective and is generally assumed to be safe for most patients. Close supervision may be warranted for patients at risk for bleeding given the theoretical possibility of an additive interaction between these two agents. In general, time-release niacin should generally be avoided unless supervised by an experienced health care professional.

Anticonvulsant Medications, Including Phenobarbital, Phenytoin, and Valproic Acid

Evidence: Carbamazepine (Carbatrol, Tegretol), diazepam (Valium), divalproex semisodium, divalproex sodium (Depakote), primidone (Mysoline), sodium valproate (Depacon), valproate semisodium, valproic acid (Depakene, Depakene Syrup).

Extrapolated, based on similar properties: Clonazepam (Klonopin), clorazepate (Tranxene), ethosuximide (Zarontin), ethotoin (Peganone), felbamate (Felbatol), fosphenytoin (Cerebyx, Mesantoin), levetiracetam (Keppra), mephenytoin, mephobarbital (Mebaral), methsuximide (Celontin), phenobarbital (phenobarbitone; Luminol, Solfoton), phenytoin (diphenylhydantoin, Dilantin, Dilantin-125, Dilantin Infatabs, Dilantin Kapseals, Phenytek), tiagabine (Gabitril), topiramate (Topamax), trimethadione (Tridione), zonisamide (Zonegran).

Similar properties but evidence lacking for extrapolation: Gabapentin (Neurontin), lamotrigine (Lamictal), oxcarbazepine (GP 47680, oxycarbamazepine; Trileptal), pheneturide (ethylphenacemide).

Interaction Type and Significance

✗✗✗ **Potentially Harmful or Serious Adverse Interaction—Avoid**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

⊕ **Potential or Theoretical Beneficial or Supportive Interaction, with Professional Management**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

Concomitant use of niacinamide with antiepileptic drugs (AEDs) may decrease drug clearance of AEDs, specifically carbamazepine, diazepam, and sodium valproate, through inhibition of cytochrome P450 (CYP450) and thereby potentiate the anticonvulsant action of these drugs.[18,19] Nicotinamide (niacinamide) may also decrease the conversion of primidone to phenobarbital.[18]

Research

Bourgeois et al.[18] conducted related experiments examining the effect of nicotinamide on the conversion of primidone to phenobarbital in mice and in three epileptic patients. They observed that in mice "200 mg per kilogram of nicotinamide increased the half-life of primidone by 47.6%, and the conversion to phenobarbital and phenylethylmalonamide was decreased by 32.4% and 14.5%, respectively." Similarly, nicotinamide also decreased the conversion of primidone to phenobarbital in the human patients in a dose-dependent manner. They also reported increased carbamazepine levels in two patients coadministered nicotinamide. These researchers proposed that the observed nicotinamide-induced inhibition of primidone and carbamazepine metabolism in humans "probably occurs by inhibition of cytochrome P-450 by nicotinamide."

Subsequently, Kryzhanovskii and Shandra[19] studied the effects of nicotinamide (250 mg/kg), pyridoxal 5-phosphate (B_6; 10 mg/kg), and alpha-tocopherol (100 mg/kg) with diazepam, carbamazepine, sodium valproate, and their combinations on epileptic activity in acute experiments on mice with corazole-induced seizures. This nutrient formulation "potentiated anticonvulsive action" of the AEDs studied, specifically improving their effects on "convulsive intensity and lethality." The authors concluded that their findings provided "new evidence of the advisability of using vitamins in combination with synthetic anticonvulsive drugs."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The available research findings suggest that physicians prescribing anticonvulsant medications might consider the possible therapeutic benefit of coadministering vitamin B_3, specifically as niacinamide, along with other nutrients as a means of enhancing drug activity and potentially enabling use of these drugs at reduced dosage levels. The preliminary nature of the data reviewed indicates that further research through well-designed clinical trials is warranted to determine the efficacy, safety, and clinical management of concomitant nutrient support, including niacinamide, during AED therapy. Pending conclusive research-based evidence, close supervision and regular monitoring are prudent during coadministration of niacinamide with AED therapy to ensure that the vitamin does not significantly potentiate excessive drug activity and to adjust drug doses accordingly. When nicotinamide is started or stopped, AED drug levels should be determined, and adjusted as necessary.

Bile Acid Sequestrants

Evidence: Cholestyramine (Locholest, Prevalite, Questran), colestipol (Colestid).

Extrapolated, based on similar properties: Colesevelam (Welchol).

◈◈ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

◈ **Adverse Drug Effect on Nutritional Therapeutics, Strategic Concern**

Probability: **2. Probable**

Evidence Base: ◉ **Emerging** to ● **Consensus**

Effect and Mechanism of Action

Niacin and bile acid sequestrants reduce cholesterol levels by separate, well-established mechanisms that produce an additive effect. The action of cholesterol-lowering resins is largely derived from their interference with lipid absorption, as are their primary adverse effects on bioavailability of numerous nutrients. In particular, niacin and resin agents can bind in the digestive tract and mutually interfere with absorption and bioavailability when ingested close to each other. Furthermore, by an unknown mechanism, combined colestipol and niacin can reduce thyroxine-binding globulin (TBG) and total

serum thyroxine (T_4) levels and increase triiodothyronine (T_3) uptake ratios.[20]

Research

A narrow but significant and consistent body of evidence spanning many years provides a solid base of research data supporting the coadministration of niacin and bile acid sequestrants. Starting in 1983, an evolving research team, including Blankenhorn, Nessim, Cashin-Hemphill, Azen, Hodis, and others, conducted extensive research and published numerous studies documenting the beneficial effects of combined colestipol-niacin therapy in the treatment of patients with hyperlipidemia, coronary atherosclerosis, femoral atherosclerosis, and coronary venous bypass grafts.[21-31] In a 1990 review of this body of work, Blankenhorn et al.[32] presented this overview:

> The evaluation of the results of Cholesterol Lowering Atherosclerosis Study has shown that some triglyceride-rich lipoproteins play an important role in the progression of atherosclerosis. The combined niacin-colestipol treatment resulted in a forty to fifty per cent decrease in the levels of cholesterol-rich lipoprotein B but had no effect on triglyceride-rich lipoproteins. Patients who had increased levels of [the] latter lipoproteins ... showed progression of atherosclerotic lesions [despite niacin-colestipol therapy]. On the other hand, in the Helsinki Heart Study, despite minimal reduction in the levels of LDL-cholesterol, patients with phenotypes IIB and IV had higher reduction rates in coronary end points than patients with phenotype IIA.

Furthermore, these researchers have extensively investigated, refined, and documented techniques for assessing atherosclerosis, evaluating efficacy and predicting outcomes of these and related antihyperlipidemic interventions, including innovative use of computer- and human-derived coronary angiographic endpoint measures.[23,32-34]

In a serial blood-lipid-lowering study, during routine thyroid function monitoring, these researchers unexpectedly observed that after 1 year of combined colestipol and niacin therapy, previously euthyroid patients demonstrated reduced total serum T_4 levels and increased T_3 uptake ratios, apparently as a result of reduced TBG levels.[20]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Bile acid sequestrants and niacin constitute two of the many conventional therapies used alone or in various combinations for treating hyperlipidemia, atherosclerosis, and interrelated conditions. The body of evidence strongly supports beneficial interaction on hyperlipidemia, atherosclerosis, and mortality from coronary heart disease from concomitant administration of niacin and cholesterol-lowering resins, particularly on coronary and femoral atherosclerosis, where continued regression can continue for several years. However, bile acid sequestrants and niacin may interfere with the absorption of each other if the two agents are ingested at the same time; therefore, separation of oral intake should be separated by 4 to 6 hours to avoid diminished bioavailability and obtain more effective therapeutic response.

Supervision and regular monitoring, not only of lipid levels, but more critically of liver enzymes, is essential given the known risks associated with niacin therapy. Monitoring of thyroid hormone levels is also judicious because the combined action of these two agents has been associated with adverse changes in total serum T_4 levels, T_3 uptake ratios, and TBG levels. Complementary thyroid support may be warranted. Furthermore, bile acid sequestrants can reduce absorption and bioavailability of fat-soluble nutrients (e.g., vitamins A, D, E, and K), as well as coenzyme Q10 and omega-3 fats, which are essential to healthy cardiovascular function and reducing cardiovascular risk, particularly mortality from coronary heart disease. Enhanced nutrient intake, through foods and supplements, is recommended, with intake being separated from the resin agent by at least 2 hours before and 4 hours after the medication.

The use of niacin in a less toxic form, inositol hexaniacinate, may provide a prudent option within such an integrative lipid management strategy. However, further research with well-designed, adequately powered clinical trials will be necessary to confirm efficacy and safety and establish clinical guidelines. Pending conclusive evidence, such an approach may be preferable because no available evidence indicates diminished therapeutic activity or increased probability of adverse effects compared with the use of nicotinic acid.

Gemfibrozil and Related Fibrates

Evidence: Gemfibrozil (Apo-Gemfibrozil, Lopid, Novo-Gemfibrozil).

Effect and Mechanism of Action

Achieving and maintaining increased plasma concentrations of high-density lipoprotein cholesterol (HDL-C) produces a cardioprotective effect that is increasingly being recognized as complementary to and equally important as reducing low-density lipoprotein cholesterol (LDL-C) in reducing risk of heart attack and stroke. Central to the function and activity of HDL-C is its influence and impact on reverse cholesterol transport. Among its many beneficial functions, HDL also exerts anti-inflammatory effects, reduces oxidation of LDL, and promotes fibrinolysis. Niacin is currently the most effective agent for increasing low HDL-C levels. Fibrates represent the other main class of HDL-elevating drugs. Both agents can also shift small, dense LDL particles toward larger, more buoyant particles and lower elevated triglyceride levels, thereby reducing atherogenic tendencies.[35,36]

Gemfibrozil, fenofibrate, and other fibrates are well known for their triglyceride-lowering effects, but they also raise HDL-C levels by 10% to 15%. Fibrates are classified as peroxisome proliferator-activated receptor (PPAR) agonists, even though their mechanism of action is also complex and not fully understood. Whereas PPAR agonists are located throughout the body, fibrates are known particularly to stimulate hepatic PPAR-alpha and thereby increase apolipoprotein AI and AII synthesis, decrease triglyceride synthesis, and enhance

catabolism of triglyceride-rich particles. Alone, and apparently more so together, fibrates and niacin can reduce the risk for the combined endpoint of myocardial infarction or death from coronary artery disease (CAD) in patients with CAD for whom low HDL cholesterol represents the primary lipid disturbance.

Research

Spencer et al.[37] conducted a retrospective review of 161 patients who were prescribed a combination of gemfibrozil (1200 mg/day) and niacin (1229 mg/day) for 6 to 12 months to determine the effect of the combination therapy on lipid profile. In conjunction with dietary instruction, coadministration of niacin and gemfibrozil produced marked and significant changes in lipid levels: total cholesterol and LDL decreased by 14%, HDL increased by 24%, total/HDL cholesterolratio decreased by 30%, and triglycerides decreased by 52%. This beneficial effect was most marked in patients with initial levels of HDL less than 40 mg/dL, triglycerides greater than 250 mg/dL, and LDL greater than 160 mg/dL. The authors reported no episodes of ALT elevation or symptomatic myositis.

In a placebo-controlled, angiographic regression trial involving subjects with normal or modestly elevated LDL-C and low levels of HDL-C, Andrews et al.[38] found that 30 months of treatment with gemfibrozil and (if necessary) niacin and/or cholestyramine raised HDL by 25% and lowered LDL to less than 110 mg/dL. However, despite these significant improvements in lipid profile, the treatment group exhibited no significant difference from the controls in flow-mediated dilation or nitroglycerin-induced dilation. Furthermore, subjects with a history of systemic hypertension demonstrated greatly impaired flow-mediated dilation that was not significantly improved with treatment.

In a randomized, open-label, crossover study, Zema[39] investigated the effects of nicotinic acid, gemfibrozil, and combination therapy on the lipid profile of 23 subjects with clinically well-defined atherosclerosis and isolated hypoalphalipoproteinemia (low HDL-C alone). In the 14 subjects "able to tolerate all forms of pharmacotherapy," HDL-C increased by 15% (34.5 to 39.7 mg/dL) with gemfibrozil (1200 mg/day); by 35% (to 46.5 mg/dL) with nicotinic acid (mean dose, 2250 mg/day); and by 45% (to 50.0 ± 7.5 mg/dL) with combination therapy of gemfibrozil and nicotinic acid. The authors reported statistically significant favorable alterations with LDL-C, LDL-C/HDL-C, non–HDL-C/HDL-C, apolipoprotein (apo) B and apo B/apo A-I. The author concluded that coadministration of gemfibrozil and nicotinic acid is both "feasible" and "effective" in raising HDL-C levels in "the majority of patients with clinical atherosclerotic disease and isolated hypoalphalipoproteinemia."[39]

Sakai et al.[40] found that niacin, but not gemfibrozil, selectively increases apo A-I, a cardioprotective subfraction of HDL, in patients with low HDL-C.

Whitney et al.[41] conducted a randomized, double-blind, placebo-controlled trial, involving 143 military retirees under 76 years of age with low HDL-C levels and angiographically evident coronary disease, to determine if increasing HDL-C levels would produce beneficial effects on progression of coronary heart disease and clinical events. They found that the group administered a combination of gemfibrozil, niacin and cholestyramine, along "with aggressive dietary and lifestyle intervention" involving regular exercise and low-fat diets, experienced a 20% decrease in total cholesterol level, 36% increase in HDL-C level, 26% decrease in LDL-C level, and 50% reduction in triglyceride levels, compared with placebo. Focal coronary stenosis decreased by 0.8% in the treated group, but increased by 1.4% in the placebo group. A composite cardiovascular event endpoint was reached in 26% of patients in the placebo group and 13% of those in the treated group. Notably, the treated group reported a higher incidence of adverse effects, particularly flushing and GI intolerance, but these rarely led to withdrawal from the study. These findings are limited by the small size and use of a composite clinical outcome. Furthermore, it is unknown whether the observed improvements in angiographic findings resulted from reductions in LDL-C or increases in HDL-C, or both.[41]

Most fibrates elevate plasma levels of the atherogenic amino acid homocysteine (Hcy), a known cardiovascular risk factor, at least in part through an alteration of creatine-creatinine metabolism and changes in methyl transfer. For example, fenofibrate and bezafibrate lead to a 20% to 40% elevation of plasma Hcy levels. In contrast, gemfibrozil does not increase Hcy. Niacin use has also been associated with elevations in plasma Hcy levels. Concurrent administration of folic acid and vitamins B_{12} and B_6 is often warranted to modulate plasma Hcy and prevent the fibrate and/or niacin from counteracting the desired cardiovascular protection.[42] The causal effects of Hcy are unconfirmed by single, large-scale, prospective clinical intervention trials, but the association between hyperhomocysteinemia and a range of pathophysiological processes is widely recognized, and a 2006 meta-analysis reached the conclusion that lowering Hcy levels reduces the risk of vascular events.[43]

Fibrates, particularly gemfibrozil, are known to interact with statins to increase the risk of myositis, myopathy, and rhabdomyolysis (as is niacin).[44,45] Whether such an adverse interaction is possible with concomitant use of fibrates and niacin has yet to be investigated. Further research through well-designed clinical trials is warranted to establish efficacy and safety.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians treating individuals with dyslipidemia are advised to consider the combination of niacin and a fibrate agent in patients for whom the elevation of HDL-C constitutes a principal therapeutic goal. Along with periodic evaluation of lipid levels, assessment of liver function and plasma Hcy levels may also be appropriate given the adverse effects of both agents. Concomitant folic acid and vitamins B_{12} and B_6 play an important role in a comprehensive strategy, especially when administering fenofibrate or bezafibrate. Repletion of SAMe, especially with betaine, may also moderate the hepatotoxic effects of these agents on methionine metabolism, methyl group availability, and Hcy levels. Coadministration of coenzyme Q10 may also be appropriate in enhancing cardiovascular health and reducing risk.

HMG-CoA Reductase Inhibitors (Statins)

Evidence: Atorvastatin (Lipitor), fluvastatin (Lescol, Lescol XL), lovastatin (Altocor, Altoprev, Mevacor); combination drug: lovastatin and niacin (Advicor); pravastatin (Pravachol), simvastatin (Zocor); combination drug: simvastatin and extended-release nicotinic acid (Niaspan).

Extrapolated, based on similar properties: Rosuvastatin (Crestor).

Effect and Mechanism of Action

Concomitant administration of niacin and HMG-CoA reductase inhibitors (statins) may produce additive effects that enhance the reduction of serum cholesterol levels but also increase the risk of adverse effects. As indicated by their collective name, statins limit synthesis of LDL-C by interfering with the normal cholesterol-synthesizing activity of the enzyme 3-hydroxy-3-methylglutaryl–coenzyme A (HMG-CoA) reductase in the liver. Niacin can elevate levels of HDL-C by 15% to 30% while also preferentially increasing HDL2 and LpA-I particles and slightly to moderately reducing LDL-C. Niacin's mechanisms of action are broad and complex and include selectively increasing the antiatherogenic HDL subfraction, lipoprotein (Lp) A-I (without apolipoprotein A-II), while inhibiting triglyceride synthesis, lipolysis in adipose tissue, and apo A-I catabolism. Collectively, these objectives are central to reducing hypercholesterolemia, limiting atherogenic processes and supporting cardiovascular health.[5,46-50]

All statin drugs are metabolized by the CYP450 isoform 3A4. Consequently, many drugs and other substances that share this metabolic pathway can elevate plasma levels of a statin and thereby increase the risk of myopathy and other adverse effects.

Statin drugs are associated with adverse symptoms that are typically considered insignificant but potentially severe, including elevated liver enzymes (SGOT/AST and SGPT/ALT), myositis, myopathy, and rhabdomyolysis, as well as impairment of coenzyme Q10 synthesis.[51-53] For example, HMG-CoA reductase inhibitors occasionally cause myopathy, which is manifested as muscle pain and weakness and accompanied by grossly elevated creatine kinase (>10 times ULN). Rhabdomyolysis is a relatively uncommon condition in which muscle cells are broken down, releasing myoglobin, muscle enzymes, and electrolytes into the blood, sometimes resulting in kidney failure. The risk of statin-induced myopathy and other adverse effects appears to be increased by high levels of HMG-CoA reductase inhibitory activity in plasma. The severity and probability of such reactions vary considerably among individuals and may be based on genetic factors influencing hepatic function and statin metabolism, such as CYP3A genotype.[54] The reported incidence of elevated hepatic transaminases and myopathy with lovastatin use over 4 years is 1.3% and 0.1% of cases, respectively; however, safety at 5 years appears predominant, but long-term data (≥20 years) on adverse effects is still not available.[53,55-57]

Niacin is also associated with adverse effects on the liver, including elevating hepatic transaminases, depleting methyl donors and increasing homocysteine levels. Niacin can lower plasma levels of vitamin B6 and interfere with the metabolism of methionine, leading to hyperhomocysteinemia and hypocysteinemia with attendant increase of cardiovascular risks.[58-60] Specifically, elevated levels of niacin (e.g., >1 g/day) can deplete SAMe because niacin is excreted as methylated pyridones, the formation of which uses SAMe as the methyl donor. SAMe is formed by the adenylation of methionine via *S*-adenosylmethionine synthase and acts as the methyl donor in virtually all known biological methylations. Thus, depletion of SAMe impairs detoxification processes and may account for many of niacin's adverse effects. The concomitant use of niacin and a statin drug increases the risk of many adverse effects, including development of toxicity symptoms, such as myopathy and rhabdomyolysis, in patients previously stable when treated with a single agent.

Research

The therapeutic benefits of coadministering niacin with statin agents, generally, have been well documented, as have the potential risks. The body of scientific literature demonstrating this interaction and its clinical implications is sufficiently well known to establish it as a standard therapy within the armamentarium of conventional medical practice. Consequently, rather than provide an exhaustive review of pertinent literature, this section focuses on landmark research as well as studies that illustrate issues of particular clinical significance, suggest parameters of therapeutic application, or raise questions of safety and patient variability. Furthermore, although the research beginning with Altschul et al. and continuing through the Coronary Drug Project on the efficacy of niacin therapy in the treatment of hyperlipidemia, especially with low HDL-C, deserves mention, a review and analysis of the research on niacin monotherapy is beyond the scope of this section. However, broadly viewed, the available evidence from clinical trials more consistently supports the use of niacin in conjunction with statins, resins, or other antihyperlipidemic agents, rather than as niacin monotherapy, for decreasing cholesterol levels and slowing the progression of atherosclerotic plaque formation in individuals being treated for atherosclerosis. Lastly, the limited duration of many studies restricts use of the resultant data in conclusively assessing adverse effects associated with usage over years or decades on a diverse patient population.

Efficacy. Malloy et al.[61] conducted an open sequential study involving 22 patients with clinical characteristics of familial hypercholesterolemia to compare serum lipoprotein responses to three interventions: diet alone, colestipol and niacin with diet, and colestipol, niacin, and lovastatin with diet. The respective characteristics of the treatment components were diet: less than 200 mg/day of cholesterol and less than 8% of total calories from saturated fat; colestipol: 30 g/day; lovastatin: 40 to 60 mg/day; and niacin: 1.5 to 7.5 g/day. These researchers reported significantly improved responses, as measured by lower mean total serum cholesterol and LDL-C levels and elevated HDL-C levels, with the multiple intervention than with any binary combination. They concluded that "colestipol, lovastatin, and niacin are mutually complementary in treating hypercholesterolemia" and noted that "this regimen produces reductions in serum cholesterol levels similar to those associated with regression of atheromatous plaques in animal studies." Adverse effects were not reported among the study participants.[61]

In 1994, Davignon et al.[62] conducted a study comparing the effects of placebo, nicotinic acid extended-release capsules (0.5-1.0 g twice daily), pravastatin (40 mg at bedtime), or the combination for 8 weeks in 158 patients with type IIa or IIb primary hypercholesterolemia. They observed greater declines in LDL-C levels and increases in HDL-C levels, relative to baseline, with the niacin and pravastatin combination than

with either agent alone; all three treatments were significantly more effective than placebo.

Jacobson et al.[63] conducted a randomized, double-blind trial involving 74 hypercholesterolemic patients to investigate gender differences in efficacy of fluvastatin and niacin in the treatment of hypercholesterolemia. After an initial 6 weeks in which subjects received fluvastatin or placebo, open-label niacin, to a maximum of 3 g daily, was added to each treatment for the next 9 weeks. In the initial phase of 3 to 6 weeks of treatment, the reduction in LDL-C was significantly greater with fluvastatin (20.8%) compared with placebo. At the end of 12 to 15 weeks, the addition of niacin potentiated the response to 43.7% in those administered the fluvastatin and niacin combination and to 26.5% in those receiving placebo plus niacin. Notably, these researchers reported significant gender differences in the LDL-C response to the fluvastatin and niacin combination. Women demonstrated LDL-C reductions of 54.6%, whereas men exhibited LDL-C reductions of 38.2%. Female subjects also tended to experience greater LDL-C reductions with the placebo plus niacin combination than did male subjects. At the end of 12 to 15 weeks, HDL-C increased by 33.1%, whereas triglyceride levels declined by 32.3%.[63] These variable responses based on gender deserve further research, as do other factors that shape interindividual variability in clinical response, adverse effects, lifestyle influences, compliance, and other relevant characteristics.

In a randomized trial involving 65 patients with low HDL levels and hypertriglyceridemia, O'Keefe et al.[64] (1995) compared pravastatin in combination with niacin, magnesium, and placebo. They found that, after 18 weeks, subjects in the pravastatin plus niacin group had a −41% change in the total cholesterol/HDL-C ratio, whereas those in the pravastatin plus magnesium and pravastatin plus placebo arms demonstrated −13% and −16% changes, respectively. Furthermore, the HDL2 and HDL3 subfractions, as well as the apolipoprotein A-I levels, were increased significantly and postprandial lipemia diminished significantly (−32% change in the remnant particle triglyceride concentration and decreased very-low-density lipoprotein (VLDL) remnant levels) only in the pravastatin/niacin arm. Additionally, the levels of small dense LDL3 cholesterol were decreased to a greater extent in the pravastatin plus niacin group than in the other groups. The authors concluded that the pravastatin and niacin combination produced significant and more numerous benefits than those produced by a pravastatin-magnesium combination (or placebo), and that such effects were clinically important in "patients with clustered risk factors."[64]

In a randomized, open-label trial, Jokubaitis[65] administered fluvastatin (20 mg/day) or placebo for six weeks and noted that fluvastatin produced a 20.8% reduction in LDL-C levels from baseline. Then, starting at six weeks, open-label niacin was administered to all patients and titrated to a final dose of 3 g/day. Subjects treated with both niacin and fluvastatin exhibited a 43.7% reduction in LDL-C levels at the week 15 endpoint, in contrast to a 26.5% reduction seen with niacin monotherapy. The author concluded by recommending that "use of combination therapies may result in optimal management of patients with moderately severe hypercholesterolaemia and mixed dyslipidaemic profiles."

In a 14-week, prospective, open-label trial involving 16 diabetic patients with LDL-C concentrations of at least 150 mg/dL after dietary therapy, Gardner et al.[66] found that coadministration of niacin (titrated to a maximum of 500 mg three times daily) and "low-dose" pravastatin (20 mg/day) produced favorable results on lipid profiles, including significant lowering of LDL cholesterol, compared with pravastatin monotherapy. Notably, only five of these diabetic subjects required minor alterations (three increased, two decreased) in their hypoglycemic regimens to maintain glycemic control; most were treated without compromising glycemic control.

Guyton et al.[67] conducted a multicenter, open-label study involving 269 hypercholesterolemic adult subjects to determine the long-term safety and efficacy of an extended-release once-a-night niacin preparation, Niaspan, in the treatment of hypercholesterolemia. After 48 weeks of treatment, the extended-release niacin alone (median dose, 2000 mg) reduced LDL cholesterol (18%), apolipoprotein (apo) B (15%), total cholesterol (11%), triglycerides (24%), and lipoprotein Lp(a) (36%), and increased HDL-C (29%). However, the extended-release niacin plus a statin lowered LDL-C (32%), apo B (26%), total cholesterol (23%), triglycerides (30%), and lipoprotein Lp(a) (19%), and increased HDL cholesterol (26%). Notably, 2.6% of patients exhibited reversible elevations of aspartate aminotransferase or alanine aminotransferase more than twice the normal range. A pair of trials conducted by Goldberg and associates arrived at similar conclusions.[68,69]

McKenney et al.[70] conducted a multicenter, randomized, open-label, parallel-design study to assess the effect of niacin and atorvastatin on lipoprotein subclasses in patients with atherogenic dyslipidemia. At baseline, all subjects demonstrated total cholesterol greater than 200 mg/dL, triglycerides between 200 and 800 mg/dL, and apo B greater than 110 mg/dL, as measured by nuclear magnetic resonance spectroscopy. After a low-fat diet stabilization period, subjects were randomly assigned to atorvastatin (10 mg) or immediate-release niacin (3000 mg) daily for 12 weeks. The authors reported that both atorvastatin and niacin significantly reduced the concentrations of VLDL particles (−31% and −29%, respectively) and small LDL particles (−44% and −35%). Niacin increased the concentration of large LDL (+75%), "shifted the LDL subclass distribution toward the larger particles, more effectively converted patients from LDL phenotype B to phenotype A, and increased levels of the larger and perhaps more cardioprotective high-density lipoprotein particles." In contrast, atorvastatin reduced the number of LDL particles more than niacin (31% vs. 14%), "preferentially lowered the concentration of small LDL particles without increasing levels of large LDL, and more effectively, reduced LDL particle numbers." Thus, these two agents exhibited their strengths and respective contributions to potential synergistic use with atorvastatin showing a preferred LDL effect and niacin a preferred HDL effect.[70]

In a three-year, randomized, controlled, double-blind trial involving 160 patients with documented coronary heart disease (CHD), low HDL-C levels, and normal LDL-C levels, Brown, Zhao, et al.[71] found that a combination of simvastatin and niacin increased HDL2 levels, inhibited the progression of coronary artery stenosis, and decreased the frequency of occurrence of a first cardiovascular event, such as myocardial infarction, stroke, death, or revascularization. Other findings from this study, indicating that protective increase in HDL2 with simvastatin plus niacin was attenuated by concurrent therapy with antioxidants, were widely interpreted as indicating a negative interaction between antioxidants and statins.[72] However, a closer analysis more likely shows a blunting effect of the antioxidants on the rise of HDL cholesterol, more associated with niacin, rather than a direct effect on the statin therapy.

In a 52-week, multicenter, open-label study involving a total of 814 men and women (mean age, 59 years) with

dyslipidemia, Kashyap et al.[73] administered niacin-lovastatin combination in four escalating doses: 500 mg niacin plus 10 mg lovastatin for the first month, 1000 mg niacin plus 20 mg lovastatin for the second, 1500 mg niacin plus 30 mg lovastatin for the third, and 2000 mg niacin plus 40 mg lovastatin for the fourth month through week 52. They observed dose-dependent effects for all major lipid parameters. At week 16, mean LDL-C and triglycerides were reduced by 47% and 41%, respectively, and LDL/HDL cholesterol and total/HDL cholesterol ratios were also decreased by 58% and 48%, respectively; these effects persisted through week 52. Mean HDL cholesterol was increased by 30% by the sixteenth week but slowed to attain an increase to 41% at the end of 1 year. Lipoprotein Lp(a) and C-reactive protein also decreased in a dose-related manner by 25% and 24%, respectively, at 2000 mg niacin plus 40 mg lovastatin.[73] In a randomized, double-blind trial involving 39 patients undergoing stable statin therapy, published that same month (March 2002), Wink et al.[74] demonstrated that coadministration of very-low-dose niacin (50 mg orally twice daily) for 3 months increased the mean HDL-C by 2.1 mg/dL, compared with statin therapy and placebo, while avoiding the adverse effects (and dropout rates) associated with niacin therapy at higher dosage levels.

Taylor et al.[75] have conducted various phases of the Arterial Biology for the Investigation of the Treatment Effects of Reducing Cholesterol (ARBITER) study over an extended period. In the ARBITER 2 study, these researchers found that statins alone are not enough to halt the progression of atherosclerosis, as measured by carotid intima media thickness (CIMT), even when the LDL-C target is achieved. In that study, investigators demonstrated that the combination extended-release nicotinic acid 1000 mg daily (Niaspan) and a statin (usually simvastatin 40 mg daily) halted the progression of atherosclerosis while the atherosclerotic process continued in patients treated with statin alone.[76] At the Scientific Sessions of the American Heart Association (2005), Taylor et al.[77] presented findings from the ARBITER 3 study, involving 148 patients, demonstrating that a further 12 months of treatment with prolonged-release nicotinic acid 1000 mg daily (Niaspan) and a statin (usually simvastatin 40 mg daily) achieved regression of atherosclerosis, including among patients with diabetes mellitus or the metabolic syndrome. This significant reduction in CIMT was associated with a 23.7% increase in HDL-C, leading to a reduction of approximately 5% in atherosclerotic plaque in the carotid arteries of patients.

In related research, a retrospective analysis of 44,351 patients with a mean follow-up of 30 ± 12 months found that raising HDL-C, in addition to lowering LDL-C and triglycerides, significantly improves outcomes in a wide spectrum of patients. After categorizing patients by primary or secondary prevention, gender, and the presence or absence of diabetes mellitus, Stanek and associates observed that achieving optimal lipid values for HDL-C in addition to LDL-C and triglycerides resulted in a significant 30% reduction in cardiovascular event risk, overall and across all subgroups.[78] Research comparing a Niaspan-simvastatin combination versus simvastatin alone is continuing through the Atherothrombosis Intervention in Metabolic Syndrome with Low HDL-C/High Triglyceride and Impact on Global Health Outcomes (AIM-HIGH) studies.

Safety. In a rat model, Basu and Mann[58] found that niacin administration can lower plasma levels of vitamin B_6 and interfere with the metabolism of methionine, leading to hyperhomocysteinemia and hypocysteinemia. Coadministration of B_6 normalized Hcy levels without compromising niacin's therapeutic effects on dyslipidemia.

Subsequent to the reports of myotoxicity in individuals treated with lovastatin and niacin concomitantly, other researchers investigated the potential for increased adverse effects with other statin agents.[79,80] Davignon et al.[62] reported no significant differences regarding adverse events or laboratory parameters in both placebo and pravastatin groups at 8 and 88 weeks. However, compared with placebo, treatment with nicotinic acid resulted in significant increases in aspartate and alanine transaminase (ALT). Thus the adverse effects associated with niacin alone or niacin-pravastatin together were both greater than with niacin alone. Jokubaitis[65] studied the coadministration of niacin with fluvastatin to examine the possibility of similar adverse effect from this alternative combination. He reported that fluvastatin (20 mg/day) with niacin (titrated to final dosage of 3 g/day) was "well tolerated, with no reports of myopathy or of significant elevations in creatine kinase or liver transaminase levels," over 6 weeks. Guyton et al.[67] found that adverse hepatic effects from the combination of a statin and an extended-release, once-a-night niacin preparation (0.5-3.0 g/day) were "minor and occurred at rates similar to those reported for statin therapy." In the study previously mentioned, Kashyap et al.[73] noted that treatment with escalating doses of a niacin-lovastatin combination was "generally well tolerated" and that "drug-induced myopathy did not occur in any patient." Flushing was the most common adverse event, causing 10% of subjects to withdraw, while the "incidence of elevated liver enzymes to >3 times the upper limit of normal was 0.5%." Secondary compendiums consistently state that increased adverse effects have not been reported with the combination of niacin and pravastatin.

In a retrospective case-control study, Wilke et al.[54] found that CYP3A genotype was associated with increased severity of atorvastatin-induced muscle damage, but not an increased risk for development of such adverse effects, as indicated by elevated serum creatine kinase (CK) levels. Thus, individuals who were homozygous for CYP3A5*3 demonstrated greater serum CK levels than patients heterozygous for CYP3A5*3, when concomitant lipid-lowering agents (gemfibrozil with or without niacin) were sequentially removed from the analysis. Consequently, individuals who have a genetic problem with metabolizing statins might have a larger depletion of coenzyme Q10 (due to a higher level of the statin drug) and thus a greater incidence of adverse effects; conversely, individuals who tolerate statins better may be metabolizing them more rapidly and thus depleting coenzyme Q10 to lesser degree.[81]

Reports

Reaven and Witztum[79] reported the case of a patient on lovastatin therapy who developed rhabdomyolysis subsequent to the introduction of nicotinic acid, 2.5 g daily, and briefly discussed a case of myositis in another patient concurrently taking lovastatin and nicotinic acid. Even though such events are consistent with known pharmacological effects of both agents, Stockley[82] commented on these data: "These adverse reports are therefore isolated and it is by no means certain that the addition of nicotinic acid was responsible for what happened."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The coordinated administration of niacin with statin drugs represents a constructive application of drug-nutrient interactions that has been fully integrated into conventional

medical practice. Niacin therapy has generally been found to be most effective in patients with the highest total cholesterol levels and is particularly indicated in patients with low HDL-C levels. However, the National Cholesterol Education Program (NCEP) guidelines suggest combination niacin/statin therapy only when diet and single-drug therapy are not effective. The importance of this broad approach cannot be emphasized enough in educating patients to adopt a proactive and comprehensive approach to enhancing cardiovascular health rather than just reducing risk by focusing on any single indicator of pathophysiological processes. Thus, pharmacotherapy, even when complemented by coordinated use of niacin and synergistic nutrients within an integrative strategy, can never take the place of patient initiative in adopting healthy dietary habits, maintaining a consistent exercise regimen, minimizing stress, and cultivating a supportive social network.

The clinical efficacy, potential for beneficial interaction, and risk of adverse reactions from coadministration of niacin vary among the statin agents. A wide range of substances and conditions alter the pharmacokinetics of and clinical response to statin therapy, and the various HMG-CoA reductase inhibitors have different potentials for interactions. Hepatic dysfunction may influence the pharmacokinetics of pravastatin; all HMG-CoA reductase inhibitors are contraindicated in patients with liver disease or unexplained elevations in serum transaminases. The pharmacokinetics of pravastatin, simvastatin, and fluvastatin are only minimally altered by renal dysfunction, but modification of lovastatin dosage may be necessary in patients with severe renal insufficiency; nevertheless, caution is warranted in all such patients. This interindividual variability and the broad range of factors influencing cardiovascular health and risk highlight the importance of individualized and flexible prescribing practices characterized by close monitoring and attention to signs of clinical response to the medication program.

Both statins and niacin possess problematic safety profiles, and their concomitant use can increase the risk of adverse effects just as it offers increased potency for therapeutic benefit. Close supervision and regular monitoring of hepatic transaminases (AST, ALT) and CK (for myositis) are appropriate, in addition to standard lipid profiles. Patients need to be educated about potential adverse effects of antihyperlipidemic pharmacotherapy and advised to observe for unexplained muscle pain, tenderness, weakness, cramps, or stiffness and immediately report any such untoward developments. Particular caution is warranted if the patient is being treated with another agent that can affect CYP3A4 metabolism.

A range of nutritional therapies can play important roles within an integrative strategy of comprehensive medical care for individuals with hyperlipidemia. The use of niacin in a less toxic form (inositol hexaniacinate) may provide a prudent option within such an integrative lipid management strategy. However, further research with well-designed, adequately powered clinical trials will be necessary to confirm efficacy and safety and establish clinical guidelines. Pending such conclusive evidence, such an approach may be preferable because no available evidence indicates diminished therapeutic activity or increased probability of adverse effects compared with the use of nicotinic acid. Additionally, coadministration of coenzyme Q10 (100 mg three times daily) and methyl donors may mitigate some adverse effects of statins and niacin, respectively, while supporting the strategic goals of reducing cardiovascular risk and enhancing cardiovascular, specifically myocardial, function. In particular, repletion of SAMe, especially with vitamin B_6 and betaine, may also moderate the hepatotoxic effects of these agents on methionine metabolism, methyl group availability, and Hcy levels. As discussed later, supplemental chromium can enhance the activity of niacin in lipid management (thereby allowing lower niacin dosage levels) as well as directly decrease triglycerides and total cholesterol and increase HDL-C. More broadly, folic acid and vitamin B_{12} can complement this nutrient support by helping to moderate tendencies to hyperhomocysteinemia and reducing the risk of vascular events.

Insulin, Biguanides, Meglitinide Analog Oral Hypoglycemics

Insulin: Animal-source insulin (Iletin); human analog insulin (Humanlog); human insulin (Humulin, Novolin, NovoRapid, Oralin).
Biguanides: Buformin (Andromaco Gliporal, Buformina), metformin (Dianben, Glucophage, Glucophage XR), phenformin (Debeone, Fenformin).
Sulfonylureas: Acetohexamide (Dymelor), chlorpropamide (Diabinese), glimepiride (Amaryl), glyburide (glibenclamide; Diabeta, Glynase Prestab, Glynase, Micronase, Pres Tab), glipizide (Glucotrol; Glucotrol XL), tolazamide (Tolinase), tolbutamide (Orinase; Tol-Tab).
Combination drugs: Glipizide and metformin (Metaglip), glyburide and metformin (Glucovance).
Extrapolated, based on similar properties:
Alpha-glucosidase inhibitors: Acarbose (Glucobay, Precose).
Meglitinide analogs: Nateglinide (Starlix), repaglinide (Prandin).
Thiazolidinediones (Glitazones): Pioglitazone (Actos), rosiglitazone (Avandia).

Effect and Mechanism of Action

The activity and mechanisms (as well as use and interactions) of niacin and niacinamide are distinct in regard to the effects of vitamin B_3 on glycemic control.

Agents in the meglitinide class of antidiabetic drugs work by stimulating the beta cells to produce and release insulin in the presence of glucose postprandially.

Acute use of nicotinic acid (niacin) inhibits lipolysis in adipose tissue and thus suppresses circulating nonesterfied fatty acid (NEFA) levels. However, NEFA levels increase above baseline once the niacin effect abates.[83] With this increased NEFA availability, NEFA oxidation occurs at the expense of glucose oxidation, and according to the Randle cycle hypothesis, the resultant reduction in glucose uptake by skeletal muscle is associated with an increase in blood glucose levels.[84] Niacin administration, in large doses, could interfere with the therapeutic activity of medications designed to lower blood glucose levels. Thus, theoretically, hyperglycemia may occur with concomitant intake of niacin and sulfonylureas. However, niacin has also been identified as a constituent of the glucose tolerance factor in yeast that enhances insulin response.

Chronic administration of nicotinic acid can disrupt glycemic control in diabetic patients being treated with insulin or hypoglycemic medications.

Niacinamide may enhance insulin secretion and increase insulin sensitivity, at least in part by protecting and preserving pancreatic beta–islet cell function. The activation of poly-ADP-ribose polymerase (PARP), as an adaptive response to minimize oxidative damage to DNA, appears to deplete cellular NAD+ and cause beta–islet cell death.[85] Therefore, repletion of cellular NAD+ levels through administration of niacinamide, would prevent cell death and preserve beta–islet cell function and sustain insulin response and may be beneficial in the prevention and delay of type 1 diabetes mellitus. Niacinamide has been shown to have no effect on insulin secretion or glucose kinetics and is generally considered unlikely that concomitant niacinamide, at typical dosages, would interfere with the activity of insulin or oral hypoglycemic medications.

Research

Niacinamide (Nicotinamide). Treatment with high-dose niacinamide, at doses ranging from 200 mg to 3 g per day, appears to exert protective effects on beta-cell function in animals and humans, particularly patients with newly diagnosed diabetes mellitus (type 1) and children at high risk.[86-91] Subsequently, a recent meta-analysis of 10 randomized, controlled trials involving 158 niacinamide-treated and 129 control patients with recent-onset type 1 diabetes revealed significantly better preservation of basal C-peptide secretion (a stable indicator of insulin secretion) in the niacinamide-receiving cohort after 1 year. Subanalysis of the five placebo-controlled trials yielded the same result.

Elliott and Chase[92] conducted a controlled but nonrandomized and unblinded trial involving 22 high-risk children (<16 years of age) to investigate the efficacy of oral nicotinamide in preventing the onset of diabetes mellitus. They concluded that "all of eight untreated control subjects have developed diabetes, whereas only one of fourteen treated children has diabetes to date." Likewise, in an experiment involving nine adult volunteers, Paul et al.[93] reported that niacinamide, at a dose of 1.2 g/m^2 for 7 days, caused no significant differences from baseline in insulin sensitivity, glucose disappearance rate, or acute insulin response to glucose.

Conversely, the findings from one large, well-designed and adequately powered trial and a small case series strongly suggest the limitations of niacinamide in effectively preventing type 1 diabetes.[94,95]

Greenbaum et al.[95a] investigated the effects of short-term administration of nicotinamide on glucose metabolism in subjects at high risk of developing insulin-dependent diabetes mellitus (IDDM), specifically to determine if such intake might cause insulin resistance in such subjects. They observed a 23.6% decrease in insulin sensitivity after administering nicotinamide (2 g/day) to eight islet cell antibody–positive (ICA+) relatives of IDDM patients for 2 weeks.

Thus, overall, niacinamide monotherapy, outside the context of dietary changes and complementary pharmacological support (pharmaceutical, nutritional, or botanical) is unlikely to forestall the onset of type 1 diabetes in most individuals, especially in those with strong genetic susceptibility, or to provide effective treatment for such patients once the disease process has progressed. However, the research directed toward investigating the interactions between niacinamide and antidiabetic therapies suggests that the pharmacological activity of this nutrient can be beneficial for some patients given appropriate dosage levels and proper monitoring and supervision.

Bingley et al.[96] performed intravenous tolerance tests in 10 healthy adult subjects before and after 14 days of treatment with nicotinamide (25 mg/kg/day) and concluded that "nicotinamide does not affect insulin secretion and glucose kinetics in normal subjects."

Polo et al.[97] conducted a 6-month, single-blind study involving 18 patients with "non-insulin-dependent (type 2) diabetes mellitus of normal body weight without signs of autoimmunity, i.e., negative for islet cell antibodies, with secondary failure of sulphonylureas, defined as persistent hyperglycaemia in spite of maximal doses of sulphonylureas." The subjects were randomly assigned to one of three treatments: (1) insulin plus nicotinamide (0.5 g three times daily), (2) insulin plus placebo (three times daily), or (3) current sulphonylureas plus nicotinamide (0.5 g three times daily). At baseline and after 6 months, all subjects were evaluated for C-peptide release under basal conditions and 6 minutes after intravenous glucagon, for glycosylated hemoglobin (HbA_{1c}), and for fasting and mean daily blood glucose levels. Compared with insulin plus placebo group, C-peptide release increased in both groups receiving nicotinamide, and HbA_{1c}, fasting, and mean daily blood glucose levels improved in the three groups to the same extent. Applying multiple-regression analysis, they determined that "nicotinamide administration was the only significant factor for the improvement of C-peptide release." The authors concluded that "nicotinamide improves C-peptide release in type 2 diabetic patients with secondary failure of sulphonylureas, leading to a metabolic control similar to patients treated with insulin."[97]

Niacin (Nicotinic Acid). Many secondary sources, reviews, and derivative reference works have stated, with varying degrees of certainty, that niacin administration could impair insulin activity, significantly elevate blood glucose concentrations, and cause glucose intolerance and insulin resistance, and that such effects could produce adverse effects on glycemic control in patients receiving insulin or oral hypoglycemic agents. Many studies have produced findings that support, or have been interpreted as supporting, such a conclusion, particularly in the context of dyslipidemia.[68,69,98-114] Consequently, standard treatment guidelines for years recommended against the use of niacin in patients with diabetes. Over time these preliminary cautionary notes have failed to achieve confirmation through well-designed clinical trials, and countervailing evidence has emerged. However, even if confirmed, this potentially beneficial effect of niacin intake would more accurately be characterized as a convergence of patient communication, case management, and drug titration issues rather simply than as an adverse effect or interaction. At this time, the trend in the evidence supports the position that coadministration of niacin, at low to moderate doses and with proper medical supervision, does not interfere with the therapeutic efficacy of oral hypoglycemic therapy and may provide strategic benefit in individuals with dyslipidemia, especially proportionately low HDL-C concentrations.

Elam et al.[114a] conducted a prospective, randomized, placebo-controlled clinical trial involving 468 participants, including 125 with diabetes, who had diagnosed peripheral arterial disease, to investigate the efficacy and safety of relatively high, lipid-modifying dosages of niacin in diabetic patients. After an active run-in period, subjects were randomly assigned to receive immediate-release niacin (crystalline nicotinic acid), 3000 mg/day (or maximum tolerated dosage), or placebo for up to 60 weeks (including 48-week double-blind phase). Glucose levels were modestly increased by niacin, 8.7 and 6.3mg/dL, in participants with and without

diabetes,respectively. Furthermore, niacin use significantly increased HDL-C by 29% and 29%, decreased triglycerides by 23% and 28%, and reduced LDL-C by 8% and 9%, respectively, in subjects with and without diabetes. There were "no significant differences in niacin discontinuation, niacin dosage, or hypoglycemic therapy in participants with diabetes assigned to niacin vs placebo." The authors concluded that their "study suggests that lipid-modifying dosages of niacin can be safely used in patients with diabetes and that niacin therapy may be considered as an alternative to statin drugs or fibrates for patients with diabetes in whom these agents are not tolerated or fail to sufficiently correct hypertriglyceridemia or low HDL-C levels."[114a]

In a 16-week, double-blind, placebo-controlled trial, Grundy et al.[115] evaluated the efficacy and safety of 1000-mg or 1500-mg, once-daily extended-release (ER) niacin in 148 patients with diabetic dyslipidemia. Sixty-nine patients (47%) were also receiving concomitant therapy with statins. In addition to dose-dependent increases in HDL-C levels for both niacin doses (vs. placebo) and reductions in triglyceride levels for the 1500-mg ER niacin (vs. placebo), baseline and week 16 values for glycosylated hemoglobin levels were 7.13% and 7.11%, respectively, in the placebo group; 7.28% and 7.35%, respectively, in the 1000-mg ER niacin group (vs. placebo); and 7.2% and 7.5%, respectively, in the 1500-mg ER niacin group. Four subjects discontinued participation because of inadequate glucose control, whereas four others (including one given placebo) quit because of flushing. No significant adverse effects were observed, including myopathy or hepatoxic effects. Thus, low doses of ER niacin (1000 or 1500 mg/day) provide "a treatment option for dyslipidemia in patients with type 2 diabetes" that is unlikely to produce significant adverse effects or disrupt glycemic control in most patients.[115]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing oral hypoglycemic agents, especially an initial course of treatment or change in medication dosage, are advised to ask the patient about vitamin B_3 intake, in all forms, including within multivitamin formulations. Niacinamide may enhance insulin secretion and increase insulin sensitivity, whereas niacin may alter the action of insulin and levels of blood glucose in some individuals.

Whether prescribed or self-administered, the potential effect of either nutrient must be factored into dosing and monitoring schedules. Coadministration of niacin or niacinamide in patients on insulin therapy may warrant reduced insulin dose in those with type 1 diabetes or reduced oral hypoglycemic dose in those with type 2 diabetes, respectively. In particular, dosage may need to be adjusted when high-dose niacin (nicotinic acid) appears to antagonize the medication's antidiabetic activity. Similar cautions may be appropriate in patients with hypoglycemia or metabolic syndrome.

The concomitant administration of niacin and such medications may provide a significant beneficial synergistic effect, especially in patients with comorbid dyslipidemia and type 2 diabetes or metabolic syndrome. Monitoring of liver enzymes becomes more critical in such patients, especially with concurrent statin therapy.

Thus, although the balance of the available evidence indicates that concomitant use of niacin or niacinamide with insulin or oral hypoglycemic agents may not result in an adverse interaction, such coadministration requires an open and trusting therapeutic relationship, patient awareness, and professional supervision and regular monitoring if clinically beneficial outcomes are to be obtained. In some patients, if niacinamide therapy is particularly effective, insulin requirements will either decline or it may no longer be required.

Isoniazid, Rifampin, and Related Antitubercular Agents

Isoniazid (isonicotinic acid hydrazide; INH, Laniazid, Nydrazid), rifampicin (Rifadin, Rifadin IV).

Extrapolated, based on similar properties: Ethambutol (Myambutol), pyrazinamide (PZA); combination drugs: isoniazid and rifampicin (Rifamate, Rimactane); isoniazid, pyrazinamide, and rifampicin (Rifater).

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability: **3. Possible** or **2. Probable**

Evidence Base: ● **Consensus**

Effect and Mechanism of Action

Pellagra and peripheral neuropathy are recognized complications of isoniazid therapy, especially with long-term treatment. This important antitubercular drug is a hydrazide derivative of isonicotinic acid that acts as a niacin and pyridoxine antagonist. The mechanisms of this interaction are complex and have yet to be fully elucidated. Isoniazid significantly inhibits the activity of kynurenine aminotransferase in the conversion of tryptophan to niacin. However, it appears that this direct interference is the prime factor in isoniazid-induced depletion of niacin.[116,117] Isoniazid's well-established interference with vitamin B_6 appears to be the more significant cause of impaired conversion of tryptophan to niacin. Moreover, as a form of isonicotinic acid, isoniazid replaces niacinamide in nicotinamide adenine dinucleotide (NAD). Consequently, isoniazid may deplete levels of niacin and cause a niacin deficiency, particularly in poorly nourished patients. Enhanced intake of vitamin B_6 may reduce this adverse effect, but dose levels need to reach an adequate threshold.[118,119] Niacin administration can prevent or reverse this drug-induced deficiency pattern.

Research

Isoniazid-induced vitamin B_3 deficiency has been recognized within the pharmacological literature since 1967.[120,121]

Shibata et al.[117] used rats fed a niacin-free diet to investigate in vivo inhibition of kynurenine aminotransferase activity by isoniazid. A diet containing INH and an injection of INH significantly inhibited kynurenine aminotransferase activity, and this inhibition was sufficient to reduce the urinary excretion of xanthurenic acid, the side-reaction product of the conversion pathway of tryptophan to niacin, to a level "below the limit of detection." However, the conversion ratio of tryptophan to niacin was "no different between the control and INH groups."

Reports

Bjornstad[122] and Harrington[123] have also reported cases of pellagra induced by isoniazid therapy in 1972 and 1977, respectively.

Comaish et al.[124] reported a case in which topical administration of niacinamide produced a positive response in a patient with tuberculous meningitis who had developed a pellagra-like skin eruption after treatment with isoniazid. In addition to the "almost complete resolution of the rash..., there was noticeable improvement in the patient's depression and apathy" subsequent to the "percutaneous absorption of niacinamide."

Ishii and Nishihara[116] investigated 106 necropsy cases of tuberculosis and diagnosed eight cases of pellagra, on the grounds of neuropathological findings and retrospective study of clinical data. None of these patients had been diagnosed as niacin deficient, even though pellagra symptoms had developed during isoniazid therapy in every case. These patients died 4 to 16 weeks after manifesting pellagra symptoms. The authors concluded: "Pellagra should be suspected whenever tuberculous patients under treatment with isoniazid develop mental, neurological or gastrointestinal symptoms, even in the absence of typical pellagra dermatitis."

Darvay et al.[119] reported a case of isoniazid-induced pellagra that occurred despite pyridoxine (10 mg daily) supplementation. Drug withdrawal and administration of niacin "led to a rapid and sustained clinical improvement."

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Although coadministration of pyridoxine with INH has become routine, niacin coadministration is also recommended during long-term treatment of tuberculosis with isoniazid. A daily dosage of 200 mg niacin is typical in most cases. Depletion of vitamin B_3, even to the level of frank deficiency manifested as pellagra, is a well-known adverse effect of isoniazid therapy. In some individuals such depletion is of limited significance, especially with short-term use in well-nourished populations. However, the diagnosis of vitamin B_3 deficiency is often overlooked or delayed, even with overt dermatological, mental, neurological, and gastrointestinal (GI) symptoms. In particular, pellagra lacking skin lesions may develop in patients with minimal sun exposure (e.g., bedridden); thus the condition known as *pelle sine pelle agra* (i.e., pellagra psychosis without skin lesions) can develop with significant GI symptoms, neurological pathology, and even psychosis without obvious signs of typical pellagra-induced dermatitis. Close monitoring and attention to the broad spectrum of the clinical presentation of niacin depletion is critical to clinical management of patients undergoing isoniazid therapy.

Mercaptopurine, Azathioprine, and Thioguanine (Thiopurines)

Mercaptopurine (6-Mercaptopurine, 6-MP, NSC 755; Purinethol), azathioprine (asathioprine; Azamun, Imuran, Thioprine), thioguanine (6-thioguanine, 6-TG, 2-amino-6-mercaptopurine; Lanvis, Tabloid).

Interaction Type and Significance

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

☼ **Prevention or Reduction of Drug Adverse Effect**

Probability:

3. Possible or **2. Probable**

Evidence Base:

● **Consensus**

Effect and Mechanism of Action

Mercaptopurine, azathioprine, and thioguanine are cytotoxic antimetabolites used in the treatment of irritable bowel syndrome, leukemia, and some cancers. The mechanisms involved in their therapeutic activity have not been fully elucidated. Thiopurine *S*-methyltransferase (TPMT) catalyzes the *S*-methylation of all three drugs. Mercaptopurine requires intracellular anabolism by hypoxanthine guanine phosphoribosyl transferase (HGPTPT or HGPRT) to become cytotoxic. Likewise, azathioprine is an immunosuppressive prodrug, the *S*-imidazole precursor of 6-MP, converted to 6-mercaptopurine in the liver by TPMT. Intracellular activation of thioguanine, a 6-thiopurine analog of the naturally occurring purine bases hypoxanthine and guanine, results in incorporation into DNA as a false purine base.

Pellagra is a recognized adverse effect of treatment with mercaptopurine, azathioprine, and thioguanine. Coadministration of vitamin B_3 can prevent or reverse this drug-induced deficiency pattern.

Research

Thiopurine-induced vitamin B_3 deficiency has been recognized within the pharmacological literature.

Reports

In a case report, Jarrett et al.[125] described two patients who developed pellagra during treatment with azathioprine for inflammatory bowel disease.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Niacin coadministration is recommended during treatment with thiopurines. Depletion of vitamin B_3, even to the level of frank deficiency manifested as pellagra, is a well-known adverse effect of thiopurine therapy. In some individuals such depletion is of limited significance, especially with short-term use in well-nourished populations. Concomitant folic acid is also usually warranted to prevent or reverse depletion. Close monitoring and attention to the clinical presentation of niacin depletion is critical to clinical management of patients undergoing thiopurine therapy.

Tetracycline Antibiotics

Demeclocycline (Declomycin), doxycycline (Atridox, Doryx, Doxy, Monodox, Periostat, Vibramycin, Vibra-Tabs), minocycline (Dynacin, Minocin, Vectrin), oxytetracycline (Terramycin), tetracycline (Achromycin, Actisite, Apo-Tetra, Economycin, Novo-Tetra, Nu-Tetra, Sumycin, Tetrachel, Tetracyn); combination drugs: chlortetracycline, demeclocycline, and tetracycline (Deteclo); bismuth, metronidazole, and tetracycline (Helidac).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

◇◇ **Impaired Drug Absorption and Bioavailability, Precautions Appropriate**

≈≈ **Drug-Induced Nutrient Depletion, Supplementation Therapeutic, with Professional Management**

Probability:

2. Probable

Evidence Base:

◉ **Emerging to**
● **Consensus**

Effect and Mechanism of Action

B-vitamin supplements, including B_3, may interfere with tetracycline pharmacokinetics, impairing absorption and bioavailability; such an interaction would also impair bioavailability of the vitamin. Separation of intake timing can mitigate this possible unintended effect.

Extended use of tetracycline antibiotics could adversely affect bioavailability and function of vitamin B_3 and other B-complex nutrients, both directly and indirectly. Apart from the two-way pharmacokinetic issues, the destructive impact of antimicrobial agents on gut microflora can impair production of B vitamins (as well as vitamin K) and potentially contribute

to systemic inflammatory processes and depressed immune system function.[126-135]

High doses of niacinamide can exert significant anti-inflammatory effects. The coadministration of niacinamide with tetracycline or minocycline may be effective against several types of dermatological pathologies, particularly blistering skin diseases such as bullous pemphigoid and dermatitis herpetiformis.[136]

Research

In an investigation of the effects of various nutrients on the pharmacokinetics of tetracycline hydrochloride in healthy subjects, researchers observed a significant impairment of drug bioavailability associated with concomitant oral administration of a B-complex vitamin supplement.[137]

Some small studies and a number of cases have been published in which the combination of niacinamide and tetracycline or minocycline has found to be efficacious in the treatment of bullous pemphigoid, cicatricial pemphigoid, pemphigus vegetans, dermatitis herpetiformis, and similar dermatoses.[138-148]

Clinical Implications and Adaptations

Physicians prescribing tetracycline or related antibiotic medications should advise patients regularly supplementing with B_3, alone or within a B-complex vitamin formulation, to take the nutrient(s) and the medication at least 4 hours apart.

Concomitant use of niacinamide and a tetracycline-class antibacterial may be effective in the treatment of dermatological conditions, whether infectious or autoimmune, under proper medical supervision.

Prudence suggests that individuals treated with oral tetracyclines or other broad-spectrum antibiotics for an extended time be administered a course of probiotic flora for an equivalent duration to restore intestinal microbiota. Short-term use of tetracyclines is unlikely to lead to clinically significant alterations in the GI ecology, as is use of topical preparations.

Thioridazine and Related Phenothiazines

Evidence: Thioridazine (Mellaril).
Extrapolated, based on similar properties: Acetophenazine (Tindal), chlorpromazine (Largactil, Thorazine), fluphenazine (Modecate, Permitil, Prolixin, Prolixin Decanoate, Prolixin Enanthate), mesoridazine (Serentil), methotrimeprazine (levomepromazine; Nozinan), pericyazine (Neuleptil), perphenazine (Trilafon); combination drug: perphenazine and amitriptyline (Etrafon, Triavil, Triptazine); prochlorperazine (Compazine, Stemetil), promazine (Sparine), promethazine (Phenergan, Promacot, Promethegan), propiomazine (Largon), thiethylperazine (Torecan), thioproperazine (Majeptil), trifluoperazine (Stelazine), triflupromazine (Vesprin).
See also Antipsychotics in Theoretical, Speculative, and Preliminary Interactions Research.

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

Probability: 4. Plausible

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

The concurrent administration of niacin and thioridazine appears to exert an additive or synergistic beneficial effect based on one or more unknown mechanisms.

Niacinamide appears to stimulate gamma-aminobutyric acid (GABA) receptors without binding to receptor sites.[149,150]

Research

In a much-cited study, Mohler et al.[150] found that niacinamide exerts benzodiazepine-like actions capable of producing an anxiolytic effect equivalent to a potent benzodiazepine.

Saxena, Lehmann, and colleagues investigated the coadministration of niacin and thioridazine in a series of clinical trials involving geriatric patients conducted during the early 1970s.[151,152] In one controlled trial, addition of niacin (300-1500 mg/day) to the thioridazine (and fluoxymesterone) regimen of elderly patients being treated for psychosis produced higher levels of cooperation and decreased tendency to withdraw from other people.[153]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians prescribing thioridazine or related phenothiazine antipsychotic agents might consider the potential benefits of concomitant niacin, as suggested by this preliminary research. Prudence and close supervision are warranted given the limited scope and size of the available evidence. Further research may be warranted.

Tricyclic Antidepressants (TCAs)

Evidence: Imipramine (Janimine, Tofranil).
Extrapolated, based on similar properties: Clomipramine (Anafranil).
Similar properties but evidence lacking for extrapolation: Amitriptyline (Elavil); combination drug: amitriptyline and perphenazine (Etrafon, Triavil, Triptazine), amoxapine (Asendin), desipramine (Norpramin, Pertofrane), doxepin (Adapin, Sinequan), nortriptyline (Aventyl, Pamelor), protriptyline (Vivactil), trimipramine (Surmontil).

Interaction Type and Significance

⊕⊕ **Beneficial or Supportive Interaction, with Professional Management**

⊕✗ **Bimodal or Variable Interaction, with Professional Management**

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

Probability: **4. Plausible**

Evidence Base: ○ **Preliminary**

Effect and Mechanism of Action

L-Tryptophan supplementation can potentiate the action of tricyclic antidepressants (TCAs) through its serotonergic effects. The coadministration of niacinamide appears to support this synergistic interaction by reducing peripheral breakdown of tryptophan.[154]

Research

In a 4-week, double-blind, controlled study, Chouinard et al.[154] randomly assigned 25 newly admitted, severely depressed patients to receive tryptophan-nicotinamide, imipramine, or tryptophan-nicotinamide-imipramine combination. They observed that "there were no substantial differences between the three treatments," but that the efficacy of tryptophan-nicotinamide combination tended to decline after 2 weeks when the nutrient doses were increased: tryptophan from 4 to 6 g per day and nicotinamide from 1.0 to 1.5 g per day. Notably, the "therapeutic response of patients treated with tryptophan-nicotinamide was significantly correlated

with the rise in plasma tryptophan." In contrast, the therapeutic response and rise in plasma tryptophan were negatively correlated within the tryptophan-nicotinamide-imipramine group, "implying that tryptophan levels were too high in some patients." The authors concluded that their findings "suggest that tryptophan-nicotinamide may be as effective as imipramine in unipolar patients providing the dose is kept within the therapeutic window, and that at low doses it could also potentiate the action of tricyclic antidepressants." They also noted that "bipolar patients seem to require higher doses of tryptophan than unipolar patients."[154]

Subsequent research investigated the pivotal role of tryptophan in potentiating the antidepressant action of TCAs and confirmed that the dose level of tryptophan was critical to obtaining a beneficial outcome.[155,156] However, other research into the interaction between L-tryptophan and TCAs failed to produce findings of efficacy.[155,157]

Nutritional Therapeutics, Clinical Concerns, and Adaptations

Physicians treating individuals diagnosed with depressive disorders using TCAs can reasonably consider the potential benefits of coadministering L-tryptophan and niacinamide within the context of an integrative therapeutic strategy. The ability of such nutrients to potentiate TCAs is notably dose dependent and requires close supervision and regular monitoring. Pretreatment tryptophan depletion status and carefully calibrated dosages of L-tryptophan (typically 4 g/day) and niacinamide (1.0 g/day) appear to be primary factors in determining probability of an optimal effect. Once stabilization occurs, reduction of antidepressant medication levels can be considered if consistent with the expressed patient treatment goals, particularly in patients with a history of adverse effects attributable to the antidepressant medication. Evolving personalized treatment protocols coordinated by health care professionals trained and experienced in both nutritional therapeutics and conventional psychopharmacology offer opportunities for deriving clinical benefits greater than what might be achieved by conventional antidepressant medications alone.

Ursodeoxycholic Acid and Chenodeoxycholic Acid

Chenodeoxycholic acid (CDCA, chenodiol; Chenix).
Ursodeoxycholic acid (UDCA, ursodiol; Actigall, Destolit, Urdox, Urso, Ursofalk, Ursogal).

Interaction Type and Significance

✗✗ **Minimal to Mild Adverse Interaction—Vigilance Necessary**

Probability:
4. Plausible to
2. Probable

Evidence Base:
● **Consensus** but
☐ **Inadequate**

Effect and Mechanism of Action

Cholesterol makes up only 5% of bile, but approximately 75% of the gallstones found in the U.S. population are formed from cholesterol. Ursodiol and chenodiol are anticholelithogenic agents that contain bile acids and are sometimes used for dissolution of cholesterol-based stones less than 1.5 cm in diameter. Chenodiol and ursodiol are considered equally effective as cholesterol gallstone solubilizing agents. Both ursodeoxycholic acid (ursodiol) and chenodeoxycholic acid (chenodiol) undergo 7-dehydroxylation to form lithocholic acid, with chenodiol being more efficiently 7-dehydroxylated than ursodiol. However, ursodiol is generally preferred over chenodiol because of its lower incidence of diarrhea and hepatotoxicity. Some portion of ursodeoxycholic acid is epimerized to chenodeoxycholic acid via a 7-oxo intermediate.

Among conventional pharmacologic agents administered in the treatment of cholelithiasis, only niacin and the statins do not contribute to the formation of gallstones.

Because of their tendency to increase cholesterol saturation of bile, concomitant use of ursodiol or chenodiol may reduce the antihyperlipidemic activity of niacin.[158,159]

Research

The information on these interactions is derived from literature distributed by the manufacturers of proprietary products. Specific research derived from clinical trials or animal research may be extant but was not accessible to multiple searches conducted using standard resources.

Nutritional Therapeutics, Clinical Concerns, and Adaptations

The concomitant use of ursodeoxycholic acid (ursodiol) or chenodeoxycholic acid (chenodiol) with niacin appears to be incompatible and inappropriate as complementary therapies within a strategy for treatment of hyperlipidemia. Coadministration is generally not recommended unless otherwise indicated and then only under close supervision.

Associated Therapies

Radiotherapy

Administration of niacinamide may enhance the efficacy of radiotherapy in the treatment of cancer. Using a rat model, Agote et al. observed that concomitant nicotinamide with radioactive iodine treatment enhanced the radiosensitivity of normal and goitrous thyroid in the rat and increased effectiveness of radiation at lower doses.[160] In a 1997 review of preclinical and clinical studies, Denekamp and Fowler[161] found that niacinamide increased tissue sensitivity to radiation in cancer therapy.

Physicians and other health care professionals may consider reviewing the potential for such synergistic therapies with appropriate patients and provide referral information to centers specializing in such integrative approaches. Further research is warranted.

THEORETICAL, SPECULATIVE, AND PRELIMINARY INTERACTIONS RESEARCH, INCLUDING OVERSTATED INTERACTIONS CLAIMS

Adrenoreceptor Antagonists (Systemic)

Alpha-1-adrenoreceptor antagonists (alpha-1-adrenergic blocking agents): Doxazosin (Cardura), guanabenz (Wytensin), prazosin (Minipress).

Beta-1-adrenergic antagonists (beta-1-adrenergic blocking agents): Oral forms (systemic): Acebutolol (Sectral), atenolol (Tenormin); combination drugs: atenolol and chlortalidone (Co-Tendione, Tenoretic); atenolol and nifedipine (Beta-Adalat, Tenif); betaxolol (Kerlone), bisoprolol (Zebeta), carteolol (Cartrol), esmolol (Brevibloc), labetalol (Normodyne, Trandate), metoprolol (Lopressor, Toprol XL); combination drug: metoprolol and hydrochlorothiazide (Lopressor HCT); nadolol (Corgard), nebivolol (Nebilet), oxprenolol (Trasicor), penbutolol (Levatol), pindolol (Visken), propranolol (Betachron, Inderal LA, Innopran XL, Inderal); combination drug: propranolol and bendrofluazide (Inderex); sotalol (Betapace, Betapace AF, Sorine), timolol (Blocadren).

Related but evidence against extrapolation: **Beta-adrenergic blocking eyedrops (ophthalmic forms):** Betaxolol (Betoptic), carteolol (Cartrol, Ocupress), levobunolol (AKBeta, Betagan), metipranolol (OptiPranolol), timolol (Timoptic).

Both niacin and adrenergic blocking agents can produce vasodilation and lower blood pressure; the concomitant use of such agents could theoretically induce an additive effect resulting in postural hypotension. Even though the pharmacological principles of this potential interaction appear plausible, if not self-evident, substantive evidence from well-designed controlled trials is lacking. Pending such research, physicians prescribing these medications should ask patients about any prescribed or self-administered use of niacin, advise patients to be watchful for such effects, and closely monitor for excessive changes in blood pressure.

Atypical Antipsychotics

Aripiprazole (Abilify, Abilitat), clozapine (Clozaril), olanzapine (Symbyax, Zyprexa), quetiapine (Seroquel), risperidone (Risperdal), ziprasidone (Geodon).
Extrapolated, based on similar properties: Haloperidol (Haldol).
See also Thioridazine and Related Phenothiazines and Benztropine sections.

Since the 1940s, Hoffer and others have investigated the management of schizophrenia and related psychiatric disorders using orthomolecular therapy emphasizing megadose niacin and niacinamide as means of elevating levels of NAD, their biologically active form. In early double-blind trials, a doubling of the recovery rate, a 50% reduction in hospitalization rates, and dramatic reductions in suicide rates were reported with treatment using 3 g of niacin daily. Based on years of clinical practice and research involving more than 1000 patients treated with either niacinamide or niacin (1.5-6.0 g/day) for 3 months to 5 years, Hoffer and others have concluded that B_3 monotherapy is most efficacious with early and acute schizophrenia. However, they have cautioned that B_3 monotherapy is usually relatively ineffective in the treatment of individuals with chronic schizophrenia, although multinutrient megadose therapy is reported to be beneficial in some chronic cases.[8,149,162-165]

Green[166] and others have suggested that some of the reported success with individuals diagnosed as schizophrenic may be the result of misdiagnosis and that such patients were actually suffering from subclinical pellagra. Thus, the perceptual changes, neurasthenia, and other characteristic deficiency symptoms would be expected to respond significantly to high doses of B_3 in any form.

This controversial research has been debated for decades, and evidence from double-blind clinical trials is mixed and generally limited by study size, duration, and design. In some studies, patients were also being treated with psychoactive medications, potentially limiting therapeutic response and confounding findings.[167-171]

Nevertheless, such usage suggests the possibility of an additive or synergistic interaction with coadministration of niacin or niacinamide and an antipsychotic medication. No clinical trials have applied coadministration to investigate this plausible interaction directly, nor has any substantive evidence emerged to suggest any pattern for an adverse or beneficial outcome. Pending conclusive research, physicians prescribing benzodiazepines are advised to query patients about vitamin intake and closely supervise and regularly monitor patients initiating or making any changes in therapeutic regimen, particularly involving megadose intake of vitamins.

Benzodiazepines

Alprazolam (Xanax), bromazepam (Lexotan), chlordiazepoxide (Librium), clonazepam (Klonopin, Rivotril), clorazepate (Gen-Xene, Tranxene), diazepam (Valium), estazolam (ProSom), flurazepam (Dalmane), lorazepam (Ativan), medazepam (Nobrium), midazolam (Hypnovel, Versed), oxazepam (Serax), prazepam (Centrax), quazepam (Doral), temazepam (Restoril), triazolam (Halcion).

The therapeutic activity of benzodiazepines derives from their potentiating the activity of GABA. Specifically, benzodiazepines bind to a receptor on the GABA A receptor complex, which facilitates the binding of GABA to its specific receptor site. This binding by benzodiazepines causes increased frequency of opening of the chloride channel complexed with the GABA A receptor. Such opening of the chloride channel results in membrane hyperpolarization and subsequent inhibition of cellular excitation.

Mohler et al.[150] found that niacinamide exerts benzodiazepine-like actions capable of producing an anxiolytic effect equivalent to a potent benzodiazepine.

Niacinamide appears to stimulate GABA receptors without binding to receptor sites.[149,150] Thus, the concomitant administration of niacinamide and a benzodiazepine could theoretically produce an additive effect with potential for an excessive sedative-hypnotic response. Furthermore, because benzodiazepines are metabolized predominantly in the liver by oxidation and conjugation, any adverse effects on the liver caused by vitamin B_3 could theoretically impair drug metabolism and elevate blood levels.

Substantive evidence from well-designed clinical trials or qualified case reports is lacking to confirm these hypothetical interactions and to suggest any pattern for an adverse or beneficial outcome. Pending such research, physicians prescribing benzodiazepines are advised to query patients about vitamin intake and closely supervise and regularly monitor patients initiating or making any changes in therapeutic regimen, particularly involving megadose intake of vitamins.

Benztropine

Benztropine (Cogentin).

Benztropine is used to treat Parkinson's disease and to mitigate akathisia and other adverse reactions to neuroleptics and other antipsychotic drugs. Kramer et al.[172] reported in a letter that coadministration of 4000 mg of L-tryptophan and 25 mg niacin per day taken with benztropine enhances the treatment of akathisia. Further research in such potentially beneficial interactions is warranted.

Carbidopa and Related Antiparkinsonian Agents

Carbidopa (Lodosyn), levodopa (L-dopa; Dopar, Larodopa); combination drugs: levodopa and benserazide (co-beneldopa; Madopar); levodopa and carbidopa (Atamet, Parcopa, Sinemet, Sinemet CR); levodopa, carbidopa, and entacapone (Stalevo).

In animal models, Bender and Smith[173] found that benserazide, carbidopa, and other aromatic hydrazine derivatives can induce subclinical iatrogenic niacin deficiency by inhibiting kynurenine hydrolase, an enzyme involved in niacin synthesis. Subsequently, Bender et al.[174] reported niacin depletion in parkinsonian patients treated with L-dopa, benserazide, and carbidopa.

These preliminary findings suggest the need for close monitoring of vitamin B_3 status in patients using antiparkinsonian medications, looking for indications of depletion rather than waiting for signs of frank deficiency. Moreover, well-designed

clinical trials are warranted to determine potential benefits and risks of B_3 coadministration.

Fluorouracil (5-FU)

Fluorouracil (5-FU; Adrucil, Efudex, Efudix, Fluoroplex).

Pellagra has been reported in patients with long-term administration of 5-FU.[175-178] Monitoring of vitamin B_3 and general nutrient status is always important during chemotherapy. Concurrent administration of appropriate nutrient support may be appropriate and is usually best provided within the context of coordinated care by health care professionals trained and experienced in both conventional oncology and nutritional therapeutics.

Ganglionic Blocking Agents

Mecamylamine hydrochloride (Inversine), trimethaphan camsylate (Arfonad).

Some derivative publications have proposed a potential adverse interaction between niacin and ganglionic blocking agents based on the known direct vasodilator action of these medications and the possibility of an additive interaction potentiating hypotensive effects. Although theoretically plausible, such assertions may be overstated given the lack of substantive evidence from well-designed clinical trials or qualified case reports, and of minimal relevance given that these drugs are not currently in clinical use because of toxicity and the difficulty of titrating their hypotensive effects. Nevertheless, pending such research, physicians administering these drugs are advised to query patients about vitamin intake and closely supervise and regularly monitor patients initiating or making any changes in therapeutic regimen, particularly involving intake of niacin in pharmacological doses.

Griseofulvin

Griseofulvin (Fulvicin, Grifulvin, Gris-PEG, Grisactin, Gristatin).

Rasool et al.[179] conducted in vitro research that indicates griseofulvin solubility increases in a nonlinear fashion as a function of nicotinamide concentration. They studied two aliphatic analogs of nicotinamide (nipecotamide and *N,N*-dimethylacetamide) as ligands with griseofulvin and found that they increased the solubilities of the drug in a linear fashion.

Thus, theoretically, the simultaneous administration of niacinamide and griseofulvin could result in increased levels of the drug, a potentially adverse reaction of clinical significance if induced unintentionally. However, use of nicotinamide might enable use of lower dosages of griseofulvin to achieve the same level of therapeutic effect while reducing effects from the drug. Physicians prescribing griseofulvin are advised to query patients regarding vitamin intake and to consider potential benefits of coadministration under supervision. Further research is warranted into parameters of effects and, on confirmation, as a basis for developing guidelines for enhancing benefits and minimizing risk of adverse effects.

Guanethidine

Guanethidine (Apo-guanethidine; Ismelin).

Guanethidine lowers blood pressure by blocking norepinephrine release from adrenergic synapses; in the process it can deplete norepinephrine over time. Niacin may theoretically increase guanethidine effect, but a clear mechanism has not been established, nor has substantive clinical research been published. Pursuit of such research is improbable given the minimal use of guanethidine in clinical practice.

Neomycin

Neomycin (Mycifradin, Myciguent, Neo-Fradin, NeoTab, Nivemycin).

Niacin and neomycin have both been shown to reduce serum lipoprotein Lp(a) levels in patients with hyperlipidemia. Thus, for example, in an experiment involving 14 type II hyperlipoproteinemic subjects, Gurakar et al.[180] observed that concomitant treatment with neomycin (2 g/day) and niacin (3 g/day) "induced a 48% decline in low density lipoprotein cholesterol levels and a 45% reduction in the concentration of lipoprotein Lp(a)." However, the primary value of such findings is not in their direct clinical application; rather, such observations elucidate the ways in which "lipoprotein Lp(a) concentrations can be altered pharmacologically and that the progression of cardiovascular disease may be altered through changes in lipoprotein (a) levels."

Thus, although such an interactive effect might be interpreted to suggest that coadministration of neomycin with niacin might enhance the cholesterol-lowering effects of niacin, such use is inadvisable because of the numerous adverse effects of extended neomycin administration, especially the well-documented depletion of numerous key nutrients. Pharmacologic dose niacin is also well documented to lower Lp(a) levels by itself, but it is unclear whether or not this effect is enhanced by coadministration of neomycin.

Nicotine Transdermal Patches

Nicotine (Habitrol, NicoDerm CQ, Nicotrol).

The relationship between nicotine and niacin is often confused in secondary literature, especially when using the nicotinic acid nomenclature. Fundamentally, niacin is a vasodilator, whereas nicotine is a vasoconstrictor. Nicotine clearly binds to and stimulates nicotinic acetylcholine receptors, which are divided into two types: nicotinic and muscarinic.

Using a rat model, Turenne et al.[181] observed that "neither acute (0.25mg/kg) or chronic (0.5mg/kg/day for 14 days) administration of nicotine... had any significant effect" on the normal vasodilatory response to ingestion of nicotinic acid.

Notably, tobacco can decrease vitamin B3 absorption.

In a letter published in *The Lancet* (1980), Clarkes[182] suggested an intriguing approach to the relationship between niacin and nicotine in the context of tobacco addiction, as follows:

> Morphine works by tricking the endorphin receptors— might not nicotine similarly dupe the niacin (vitamin B_3) receptors of the CNS?... Is it not possible, then, that nicotine fills niacin receptor sites and creates a deficiency of a nutrient required by the CNS? Perhaps this is why some say they need a cigarette to "calm their nerves."
>
> If this hypothesis is valid, it might be possible to wean some smokers off their nicotine addiction by administering nicotinic acid (niacin).[182]

Subsequently, a few letters in professional publications have discussed the possibility that the concomitant use of supplemental niacin and transdermal nicotine could result in increased adverse effects associated with the vitamin, particularly flushing.[183,184] Since then, several secondary articles and lay publications have reiterated these concerns as if they had been proved. In the absence of well-designed clinical trials or qualified case reports, this purported interaction may simply be an example of overuse of inadequately examined citations.

Overall, a clinically significant effect on blood pressure is improbable from concurrent use of transdermal nicotine

(or tobacco smoking) and oral niacin given limited available knowledge of this interaction. Further research using well-designed clinical trials may be appropriate to determine the probability and characterization of a clinically significant interaction.

Oral Contraceptives: Monophasic, Biphasic, and Triphasic Estrogen Preparations (Synthetic Estrogen and Progesterone Analogs)

Ethinyl estradiol and desogestrel (Desogen, Ortho-TriCyclen).
Ethinyl estradiol and ethynodiol (Demulen 1/35, Demulen 1/50, Nelulen 1/25, Nelulen 1/50, Zovia).
Ethinyl estradiol and levonorgestrel (Alesse, Levlen, Levlite, Levora 0.15/30, Nordette, Tri-Levlen, Triphasil, Trivora).

Ethinyl estradiol and norethindrone/norethisterone (Brevicon, Estrostep, Genora 1/35, GenCep 1/35, Jenest-28, Loestrin 1.5/30, Loestrin1/20, Modicon, Necon 1/25, Necon 10/11, Necon 0.5/30, Necon 1/50, Nelova 1/35, Nelova 10/11, Norinyl 1/35, Norlestin 1/50, Ortho Novum 1/35, Ortho Novum 10/11, Ortho Novum 7/7/7, Ovcon-35, Ovcon-50, Tri-Norinyl, Trinovum).
Ethinyl estradiol and norgestrel (Lo/Ovral, Ovral).
Mestranol and norethindrone (Genora 1/50, Nelova 1/50, Norethin 1/50, Ortho-Novum 1/50).
Related, internal application: Etonogestrel/ethinyl estradiol vaginal ring (Nuvaring).

Norethindrone Enanthate

Norethindrone, injectable (NET EN; Noristerat).
Related progestin injectable: Medroxyprogesterone (depot medroxyprogesterone acetate, DMPA; Depo-Provera, Depo-subQ Provera 104).
Related progestin and estrogen injectable: Estradiol cypionate and medroxyprogesterone acetate (Cyclofem, Lunelle); norethisterone enanthate and estradiol valerate (Mesigyna).
See also Vitamin B_6 monograph.

The use of oral contraceptives (OCs) has been associated with both elevated and decreased levels of vitamin B_3. Pyroxidine, as the coenzyme pyridoxal phosphate, is involved in conversion of tryptophan to niacin, and tryptophan load tests have shown that certain metabolites of B_6 have increased secretion when OCs are used, with compromised B_6 status a frequent outcome.[185-194] Resulting deficiencies of vitamin B_6 caused by OC use could lead to a subsequent decrease in the formation of niacin from tryptophan and an increased risk of niacin deficiency. Furthermore, OC formulations with a high progestin/progestogen content can induce tryptophan pyrrolase, thereby diverting pyridoxine for niacin synthesis to the detriment of 5-hydroxytryptamine (serotonin) formation and contributing to tendencies to premenstrual syndrome and depression. In such patients, supplementation with vitamin B_6 (pyridoxine), at levels of 25 mg two or three times daily, may mitigate such adverse effects. Conversely, with estrogen-containing formulations (and/or in different individuals), OC use might decrease the need for niacin intake by increasing the efficiency of niacin synthesis from tryptophan.[195]

The clinical implications of this potential interaction are uncertain at this time and are likely to vary depending on patient characteristics as well as specific medication and dosage. Further research with well-designed clinical trials of adequate power are warranted to clarify these outstanding issues and to provide guidelines for understanding the variable influences of diverse OC formulations on individuals of differing genetic and metabolic constitutions as well as dietary, lifestyle, and economic characteristics.

In a related study of a long-acting, low-dose injectable OC, norethisterone enanthate (20 mg monthly), Bamji et al.[196] reported a peculiar aberration in the tryptophan-niacin pathway, as indicated by increased kynurenic acid excretion after tryptophan load was observed.

Nutritional counseling should be an ongoing part of any comprehensive patient education program. Health care professionals prescribing OCs are advised to encourage patients to adopt healthy dietary patterns and an increased understanding of how eating well directly influences both their feeling of well-being and their long-term health. The levels of niacin, 10 to 25 mg, found in most B-complex or multivitamin formulations are probably adequate to compensate for any potential deficiency caused by OC use, particularly in women from high-risk groups. In general, increased intake of the entire B-vitamin complex appears warranted in women taking hormonal OCs.

Pargyline

Pargyline (Eutonyl).

Pargyline (hydrochloride) is a selective monoamine oxidase inhibitor. The concomitant use of pargyline and niacin could theoretically cause an excessive drop in blood pressure. Substantive evidence of such interaction-induced hypotension is lacking, but caution and medical supervision are advisable when introducing a new agent or changing dosages in an ongoing therapeutic regimen.

Pyrazinamide

Pyrazinamide (PZA; Tebrazid); combination drug: isoniazid, pyrazinamide, and rifampicin (Rifater).

Using a rat model, Shibata et al.[197] observed that pyrazinamide, an antituberculosis agent, may elevate niacin levels by altering the metabolism of tryptophan to niacin and of tryptophan to serotonin. Substantive evidence of this potential interaction occurring in humans is lacking.

Notably, both niacin and pyrazinamide are known to cause hyperuricemia and increase the risk for gout. Prudence suggests the avoidance of any concurrent use outside the context of close supervision and regular monitoring by a qualified health care professional.

Selective Serotonin Reuptake Inhibitor and Serotonin-Norepinephrine Reuptake Inhibitor (SSRI and SSRI/SNRI) Antidepressants

Citalopram (Celexa), duloxetine (Cymbalta), escitalopram (S-citalopram; Lexapro), fluoxetine (Prozac, Sarafem), fluvoxamine (Faurin, Luvox), paroxetine (Aropax, Deroxat, Paxil, Seroxat), sertraline (Zoloft), venlafaxine (Effexor).

Vitamin B_3 saturation might theoretically encourage diversion of tryptophan to serotonin synthesis and provoke excessive serotonin levels in individuals being treated with serotonin reuptake inhibitors. However, evidence is lacking to confirm such a phenomenon. Should this interaction be confirmed by well-designed clinical trials, such an effect could be characterized as a "potential synergistic opportunity" or a "potential adverse effect," depending primarily on communication, coordination, and clinical management.

Sulfinpyrazone and Probenecid

Sulfinpyrazone (Anturane), probenecid (Benemid, Parbenem, Probalan).

The use of niacin at higher dosage levels could potentially interfere with the uricosuric effects of sulfinpyrazone or probenecid by impairing uric acid excretion and thereby elevating uric acid levels. Although the mechanism of this

potential interaction is plausible, substantive evidence of its occurrence in humans and well-defined characterization of its clinical significance are lacking. Nevertheless, individuals diagnosed with gout should avoid supplementing with niacin outside the context of close supervision and regular monitoring by a qualified health care professional.

Warfarin and Other Anticoagulants

Primary: Warfarin (Coumadin, Dicumarol, Marevan).
Related medications: Anisindione (Miradon), dicumarol, ethyl biscoumacetate (Tromexan), nicoumalone (acenocoumarol; Acitrom, Sintrom), phenindione (Dindevan), phenprocoumon (Jarsin, Marcumar).
Similar properties but evidence lacking for extrapolation: Antiplatelet thromboprophylactics: Acetylsalicylic acid, cilostazol (Pletal), clopidogrel (Plavix), dipyridamole (Permole, Persantine), ticlopidine (Ticlid); combination drug: ASA and extended-release dipyridamole (Aggrenox, Asasantin); heparin (Calciparine, Hepalean, Heparin Leo, Minihep Calcium, Minihep, Monoparin Calcium, Monoparin, Multiparin, Pump-Hep, Umihep, Uniparin Calcium, Uniparin Forte).

The derivative literature frequently asserts that niacin may increase the risk of bleeding when used concurrently with anticoagulants or antiplatelet drugs. Evidence from clinical trials or well-qualified case reports is lacking to substantiate claims of probable risk of clinically significant adverse effects from concomitant use in typical doses under proper medical supervision.

Coagulopathy is a well-known complication of severe niacin-induced hepatotoxic reactions, primarily associated with sustained-release niacin preparations. Based on the available case reports, such effects are possible even in patients with minimal transaminase level elevations; however, the frequency of such events appears to be rare. "Deficiency in protein synthesis, including coagulation factors, and coagulopathy are unrecognized complications of sustained-release niacin therapy." In the cases described, "protein deficiency, coagulopathy, and aminotransferase level elevation resolved promptly after withdrawal of niacin therapy."[198,199]

Notably, niacin improves prothrombotic tendencies by reducing plasminogen activator inhibitor-1 (PAI-1), fibrinogen, and alpha-2 antiplasmin. Coagulation parameters are altered in peripheral arterial disease (PAD), and altered coagulation may play a critical role in the susceptibility to cardiovascular complications in PAD. In a randomized trial, Philipp et al.[200] found that niacin decreases plasma fibrinogen and LDL cholesterol in patients with PAD. They observed that changes in fibrinogen levels were "highly correlated with changes in low-density lipoprotein cholesterol in subjects taking niacin." Likewise, in a multicenter, randomized, placebo-controlled trial, Chesney et al.[201] found that niacin "favorably modifies fibrinogen and plasma F1.2." Such a decrease in F1.2 suggests that niacin reduces the production of thrombin from prothrombin, although the mechanism and parameters of occurrence of such a phenomenon have yet to be fully elucidated. This beneficial effect on abnormal procoagulation factors indicates the possibility of a strategic "interaction" of clinical significance given proper dosing, medical supervision, and regular monitoring.

The probability of a clinically significant interaction between niacin and anticoagulants appears to be low, based on presently available evidence. Although niacin and such agents can both affect related metabolic functions, a direct interaction would be considered as "confirmed" only if niacin altered prothrombin times in patients previously stabilized on warfarin. In general, it is prudent to monitor the international normalized ratio (INR) when altering any pharmacological treatment given with oral anticoagulants, especially warfarin. Furthermore, periodic monitoring of liver enzymes in patients being treated with niacin is advisable, especially sustained-release forms. Moreover, the previous cases indicate the need to measure prothrombin times routinely in patients who develop even mild transaminase level elevation while receiving niacin therapy. The niacin should be discontinued if such abnormalities develop.

NUTRIENT-NUTRIENT INTERACTIONS

Antioxidants

Antioxidants

Odetti et al.[202] found that concomitant administration of niacin and retinol, along with tocopherols, produced more marked effects on plasma cholesterol levels did than niacin alone. Likewise, serial coronary angiographic evidence developed by Hodis et al.[203] demonstrated that the combination of niacin, colestipol, and vitamin E reduces progression of coronary atherosclerotic lesions.

However, recent evidence emerging in the context of the interaction between vitamin E and other antioxidants and niacin-statin combinations has raised serious questions about the efficacy of antioxidants supplements in preventing cardiovascular disease, especially in patients being treated with conventional hypolipidemic agents. In particular, antioxidants may blunt the therapeutic activity of niacin on cholesterol levels, possibly by interfering with niacin's effects on proteins involved with the formation of high-density lipoproteins (HDLs).[204] As part of the HDL Atherosclerosis Treatment Study (HATS), Brown, Cheung, and associates investigated the respective and collective roles of statins, niacin, and antioxidants (vitamins E and C, beta-carotene, and selenium) in cardiovascular protection in patients with coronary artery disease and low HDL cholesterol. They found that simvastatin-niacin substantially improved HDL parameters, but that these favorable responses were blunted by the antioxidants, especially with regard to Lp(A-I).[205] In an accompanying paper, focusing on coronary atherosclerotic plaques and the occurrence of a first cardiovascular event, the niacin-simvastatin combination was significantly superior to placebo with regard to average stenosis progression (0.4% and 3.6%, respectively), but in participants also receiving antioxidants, this benefit was reduced to 0.7% average stenosis progression, a finding interpreted as possible interference by antioxidants.[71] When surrogate markers of cholesterol absorption and synthesis were later measured in a subset of HATS participants, at 24 months (on treatment) and 38 months (off treatment), treatment with simvastatin-niacin continued to be associated with favorable changes in cholesterol metabolism and stenosis.[206] These findings were subsequently interpreted in many quarters as suggesting that antioxidant supplementation was contraindicated in the treatment of hyperlipidemia and prevention of cardiovascular disease.[72,207]

A more critical analysis of the data suggests that the primary observed adverse interaction is between niacin and antioxidants, not statins and antioxidants. The affected HDL increases that occurred were probably attributable to the niacin therapy because low-dose simvastatin monotherapy has only limited effects in raising the levels of HDL cholesterol and apolipoprotein (apo) A-I. Thus, one or more of the antioxidants might be interfering with niacin's ability to alter the expression ofproteins responsible for the formation of HDL.

Further, the findings derived from the population studied may have limited general relevance to individuals who have only elevated LDL cholesterol levels (and normal HDL levels) and to women, who made up only 13% of the cohort. Also, with regard to HDL status, there was no detriment to the antioxidants alone (i.e., given to a group without simvastatin/niacin), and actually a slight benefit, which, if involving thousands of patients as with the previous statin and the thrombolytic trials, might have become a trend, or even statistically significant. Lastly, the composition of the antioxidant nutrient formulation used has been questioned. Given that niacin depletes the liver of methyl donors, thereby raising homocysteine levels and contributing significantly to the vitamin's hepatotoxicity, researchers might have obtained different results if they had included methyl donor–relevant nutrients with the antioxidants, such as folic acid, choline/betaine, and possibly coenzyme Q10, the synthesis of which is inhibited by statins.

Betaine

Betaine

The hepatotoxicity of niacin reflects, to a significant degree, the high demand for methyl groups imposed by niacin catabolism, leading to a reduction in hepatic levels of *S*-adenosylmethionine (SAMe). Such depletion of SAMe by niacin is likely to play a major role in the elevation of plasma homocysteine and other adverse effects associated with high-dose niacin intake.[60] Coadministration of equimolar doses of betaine may alleviate the hepatotoxic risk associated with niacin therapy.[208] Well-designed and adequately powered clinical trials are warranted to determine the efficacy of such coadministration.

Chromium

Chromium

A potential interaction between niacin and chromium has been discussed, but only preliminary evidence is available as to its clinical implications. Niacin plays an essential role in the physiological activity of chromium, particularly glucose regulation.[209-214] Therefore, many chromium formulations contain niacin, most directly as chromium polynicotinate, a niacin-bound form of chromium, but also as glucose tolerance factor (GTF), a complex of chromium and nicotinic acid believed to facilitate insulin binding.[210] Concomitant intake may improve glucose tolerance, particularly in individuals whose diet provides inadequate levels of dietary nicotinic acid and chromium.

Urberg and Zemel[209] investigated the possibility that inconsistent response to chromium might result from inadequate levels of dietary nicotinic acid to serve as substrate for GTF synthesis. They randomly divided 16 healthy elderly volunteers into three groups and administered 200 μg chromium, 100 mg nicotinic acid, or 200 μg chromium plus 100 mg nicotinic acid daily for 28 days, with evaluation at onset and on day 28. Fasting glucose and glucose tolerance were unaffected by either chromium or nicotinic acid alone, but the group receiving the chromium–nicotinic acid combination demonstrated a 15% decrease in a glucose area integrated total (AUC) and a 7% decrease in fasting glucose. Notably, none of the treatments exerted any effect on fasting or 1-hour insulin levels. The authors interpreted their findings as suggesting that "the inability to respond to chromium supplementation may result from suboptimal levels of dietary nicotinic acid."[209] In contrast, in a double-blind crossover study involving 14 healthy adults and five adults with non-insulin-dependent diabetes mellitus (NIDDM), Thomas and Gropper[215] found that daily supplemental chromium (200 μg) complexed with 1.8 mg nicotinic acid produced no statistically significant effects on plasma insulin, glucose, or lipid concentrations. However, chromium–nicotinic acid administration slightly lowered fasting plasma total and LDL cholesterol, triglyceride, and glucose concentrations and 90-minute postprandial glucose concentrations in individuals with NIDDM.

A variety of sources indicate that the synergistic effect from coadministration of niacin and chromium may be most significant in individuals with insulin resistance and a predisposition for type 2 diabetes mellitus.[216,217] Such coadministration also can produce an enhanced effect in reducing triglycerides and elevating HDL cholesterol, often allowing for efficacy of niacin at a reduced dose.[200] Moreover, low-dose niacin can be effective in reducing plasma fibrinogen levels (elevated levels being associated with thrombotic risk) in subjects with peripheral vascular disease.[200,201]

Individuals who do not respond to administration of chromium may have inadequate levels of vitamin B_3. Coadministration may be beneficial. However, inadvertent, excessive, or unsupervised coadministration might theoretically induce a hypoglycemic state in patients taking prescription diabetes medications. This largely unexplored territory is further confounded by the possibility that niacin in larger doses may contribute to insulin resistance. Patient caution, and possibly supervision by a health care professional experienced in nutritional therapeutics, may be appropriate in the unlikely event (in the absence of prescription antidiabetic medication) that such supplementation induces hypoglycemia.

Phytosterols

Phytosterols

Yeganeh et al.[218] investigated the effects on lipid profile and atherosclerosis of combining dietary phytosterols with niacin or fenofibrate in apolipoprotein E–knockout mice. In contrast to fenofibrate, "niacin caused an increase of 150% in HDL-cholesterol concentrations and a decrease of 22% in total cholesterol levels which were associated with significant reductions in atherosclerotic lesion size as compared to controls."

Policosanol

Policosanol

Policosanol, a mixture of long-chain (13- to 24-carbon) fatty alcohols derived from sugarcane, brown rice, or beeswax, may exert many of the same therapeutic effects as statin drugs without the associated risks, especially the known adverse effect on coenzyme Q10 synthesis.[219-223] Research on policosanol as a monotherapy has thus far not lived up to earlier claims.[224] Well-designed and adequately powered clinical trials of extended duration are warranted to determine whether coadministration of policosanol and low-dose niacin or inositol hexaniacinate might produce the effects on intermittent claudication, dyslipidemias, coronary disease, and cardiovascular mortality demonstrated by statins, with or without niacin.

S-Adenosylmethionine (SAMe)

S-Adenosylmethionine (SAMe)

The hepatotoxicity of niacin reflects, to a significant degree, the high demand for methyl groups imposed by niacin catabolism, leading to a reduction in hepatic levels of SAMe. The depletion of the hepatic SAMe pool plays a role in decreased detoxification activity and is similar to hepatotoxic effects of ethanol, methotrexate, and niacinamide. Such depletion of SAMe by niacin is likely to play a major role in the

elevation of plasma homocysteine and other adverse effects associated with high-dose niacin intake.[60] Coadministration of SAMe may decrease adverse effects associated with niacin. Well-designed and adequately powered clinical trials are warranted to determine the efficacy of such a therapeutic approach.

Vitamin B_6 (Pyridoxine)

Vitamin B_6 (Pyridoxine)

Pharmacological doses of niacin can interfere with the metabolism of methionine, leading to hyperhomocysteinemia and hypocysteinemia. Coadministration of vitamin B_6 with niacin could reasonably be expected to mitigate such effects. Basu and Mann[58] found that vitamin B_6 can normalize the homocysteine-altered sulfur amino acid status of rats fed diets containing pharmacological levels of niacin, without reducing niacin's hypolipidemic effects.

For several decades a number of clinicians have reported that vitamin B_6 and niacin have been effective in managing patients diagnosed with schizophrenia and related psychiatric conditions; research findings, however, have been mixed. Such use has led to suggestions that coadministration of vitamin B_6 and niacin might produce a beneficial additive or synergistic effect that could enhance therapeutic outcomes.[225,226] In a 48-week study, conducted as part of the Canadian Mental Health Association Collaborative Study, Petrie et al.[227] found that coadministration of both nicotinic acid and pyridoxine with conventional neuroleptic treatment did not produce the significant therapeutic changes that resulted from coadministration of either nutrient (nicotinic acid or pyridoxine).

Zinc

Zinc

Enhanced zinc intake appears to cause activation of niacin metabolism and increase the excretion of niacin metabolites N'methylnicotinamide (N'MN) and N'methyl-2-pyridone-5-carboxamide (2-PYR), especially in a context of nutrient depletion. In a series of experiments involving niacin-depleted rats and then human subjects with alcoholic pellagra, Vannucchi et al.[228,229] found that zinc interacts with niacin metabolism through a probable mediation by vitamin B_6.

The 231 citations for this monograph, as well as additional reference literature, are located under Vitamin B_3 (Niacin) on the CD at the back of the book.

Vitamin B_6

Nutrient Name: Vitamin B_6.
Synonyms: Adermine hydrochloride, pyridoxal (PL), pyridoxine (PN), pyridoxamine (PM), and their phosphate derivatives: pyridoxal 5′-phosphate (PLP or P5P), pyridoxine 5′-phosphate (PNP), pyridoxamine, pyridoxamine 5′-phospate (PNP), pyridoxine hydrochloride.
Related Substance: Pyritinol.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
Amiodarone ☼/⊕X/X	Amiodarone typically causes cutaneous photosensitivity with increased risk of sunburn. This effect, which usually is slow to resolve even after drug discontinuation, is most likely due to drug-induced oxidative stress on erythrocyte membranes. Coadministration of B_6 may ameliorate this adverse effect without impairing therapeutic activity of amiodarone.	Pyridoxine may be beneficial in preventing or reversing inflammatory reaction due to amiodarone.
Anticonvulsant medications Barbiturates XX/XXX/⊕X/⊕⊕/☼/◇≈≈/◇	Anticonvulsant medications, especially carbamazepine and valproic acid, may displace pyridoxal 5′-phosphate (PLP), interfere with activity of pyridoxine-related coenzymes, and deplete these B_6 and interdependent nutrients. However, phenobarbital and phenytoin may elevate levels of B_6 (and B_{12}). Anticonvulsants can cause or aggravate hyperhomocysteinemia. Coadministration can mitigate adverse effects and may enhance therapeutic effect (e.g., valproic acid, phenobarbital). Potential for accelerated drug metabolism (and decreased circulating levels), but substantive and consistent evidence lacking, and probably only with high-dose pyridoxine. Vitamin B_6 is a known anticonvulsant. Further research needed.	Low-dose coadministration of pyridoxine (with B_{12}, riboflavin, and folate) may be beneficial, but interaction can vary depending on medication; anticonvulsant polytherapy known for greater adverse effects. Assess homocysteine and consider testing for MTHFR SNPs. Coadministration requires clinical management with regular monitoring.
Chemotherapy ☼/⊕X/X	Vitamin B_6 may mitigate certain drug-induced adverse effects but can impair therapeutic activity of some agents. Pyridoxine coadministration can reduce or reverse palmar-plantar erythrodysesthesia (hand-foot) syndrome associated with 5-fluorouracil, docetaxel, and doxorubicin HCl liposome injection without impairing drug activity. However, while B_6 may significantly reduce altretamine-associated neurotoxicity, it may also adversely affect response duration in a cisplatin (CDDP)—hexamethylmelamine regimen. Limited data suggest that further research warranted.	Coadministration can be beneficial but may impair drug activity of some agents. Watch for drug-induced adverse effects. Supervise closely and monitor regularly. Use with altretamine generally contraindicated.
Doxylamine ⊕⊕	Vitamin B_6 is effective for many women with nausea and vomiting of pregnancy and is generally considered safe. Combination of doxylamine and pyridoxine is effective in reducing the severity of such symptoms. Claims of adverse effects largely disproved. Available by prescription in some countries; Diclectin in Canada.	Consider doxylamine prescription for women with nausea and vomiting of pregnancy. Supportive dialogue and informed decision making especially important. Monitor as always during pregnancy. Ginger may also be beneficial.
Erythropoiesis-stimulating agents ≈≈/◇⊕⊕/☼/⊕⊕	EPO therapy increases hemoglobin synthesis, which can decrease erythrocyte pyridoxine status and increase nutritional requirements. Further, vitamin B_6 deficiency is common in patients with chronic renal failure, during dialysis, and with furosemide. Even absent signs of deficiency, administration of B_6 can prevent or reverse adverse effects, as well as sequelae of accompanying hemodialysis, such as peripheral polyneuropathy. Nutrient support is unlikely to impair EPO efficacy. Continued research warranted.	Coadministration of low-dose to moderate-dose vitamin B_6 can be beneficial, especially with folic acid. Supervise closely and monitor regularly, especially with renal failure.
Furosemide Loop diuretics ≈≈/☼	Furosemide acutely increases urinary excretion of B_6 (as well as vitamin C) in chronic renal failure; accompanying excretion of oxalic acid may mitigate tendency to accumulate oxalic acid.	Coadministration can be beneficial, especially with renal failure and/or dialysis. Monitor levels of vitamins B_6 and C. Supervise closely.
Gentamicin Aminoglycoside antibiotics ☼/◇≈≈/≈≈/⊕≈	Gentamicin and PLP tend to complex. This can interfere with B_6 metabolism, particularly renal PLP, and contribute to B_6 depletion. Concomitant B_6 appears to prevent gentamicin-induced adverse effects, particularly nephrotoxicity, without reducing drug efficacy. However, even though administration of PLP may reduce severity of symptoms, it may not prevent nephrotoxicity. Clinical trials needed to confirm limited but consistent findings from animal experiments.	Coadministration of vitamin B_6 may be beneficial and, at low dose, safe. No adverse effects probable.
Haloperidol Neuroleptic agents ◇≈≈/☼	Haloperidol and related neuroleptics can cause tardive dyskinesia, dystonia and other parkinsonian symptoms, most likely due to oxidative stress and lipid peroxidation. Concomitant B_6 can prevent or reduce such drug-induced extrapyramidal symptoms, even in the absence of deficiency signs, but may not enhance therapeutic outcomes. Nutrient support is not likely to impair drug efficacy. Further research warranted.	Coadminister pyridoxine, especially with long-term therapy. High-dose B_6 may be necessary and will require close supervision. Monitor for signs of deficiency or excess; standard assays may not reveal CNS levels.
Hydralazine ≈≈/◇≈≈/⊕X/◇◇	Hydralazine and B_6 can bind to form inactive complex excreted in urine. This pharmacokinetic interaction may decrease hydralazine availability, deplete pyridoxine, and impair B_6-related functions. Preliminary evidence suggests	Coadministration of vitamin B_6 may be beneficial, but moderate-level doses warrant supervision and regular monitoring. Separate intake. Impairment of drug efficacy improbable.

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
	that pyridoxine-deficiency neuropathy and other well-known hydralazine-induced adverse effects are caused by its action as a B_6 antagonist, but evidence is lacking to prove benefits of B_6 coadministration. Clinical trials needed to confirm limited but consistent findings from animal experiments.	
Isoniazid, rifampin Antitubercular agents ◈≈≈/≈≈/☼/⊕✗/✗	Isoniazid and cycloserine are pyridoxine antagonists that produce a functional vitamin B_6 deficiency. Thus, antitubercular drugs can cause adverse effects, such as anemia or peripheral neuropathies, which may be prevented or reduced by B_6 (as well as B_3 and folic acid). Further, B_6 depletion is common among at-risk populations, and disease process of tuberculosis may aggravate deficiency. In some cases, pyridoxine has been inadequate to reverse toxic drug effects such as seizures. Routine coadministration of B_6 remains controversial despite a history of effective clinical application, evidence of benefit, and lack of evidence demonstrating adverse effects.	Coadministration of vitamin B_6 (and niacin and folic acid) may be beneficial. Separate intake. Low risk of adverse effects from B_6 at typical doses. Impairment of drug efficacy improbable. High-dose pyridoxine, often intravenously, may be necessary in severe cases. Supervise closely and monitor regularly. Discontinue medication if signs of hepatotoxicity.
Levodopa, carbidopa, benserazide Antiparkinsonian medications ✗✗/◈≈≈/☼	PLP acts as a cofactor in conversion of levodopa to dopamine. Thus, high levels of pyridoxine intake can accelerate peripheral metabolism of levodopa to dopamine, reduce the availability of dopa for conversion to dopamine, and impair the therapeutic activity of levodopa. A dopa-decarboxylase inhibitor (DDI; e.g., carbidopa, benserazide) can reduce excessive metabolism of levodopa and increase amounts available to the CNS. Conversely, as a B_6 antagonist, levodopa can increase metabolic requirements for pyridoxine. Concomitant low-dose B_6, in the presence of a DDI, can prevent or reverse nutrient depletion and adverse sequelae.	Avoid supplemental intake of vitamin B with levodopa monotherapy. No contraindication with carbidopa or benserazide. Coadministration of vitamin B_6 may prevent or reduce B_6 deficiency. Supervise closely and monitor regularly.
Methotrexate ◈≈≈	Methotrexate is known to elevate homocysteine levels by interfering with B_{12}- and folate-dependent reactions and may thereby increase risks of vascular disease. Vitamin B_6 is depleted by inflammation and tends to be particularly depleted in individuals with rheumatoid arthritis. Concomitant B_6 may reduce adverse effects without impairing drug activity in treatment of rheumatoid arthritis. Further research warranted, especially with regard to genomic variability.	Coadministration of vitamin B_6 and folic acid may be beneficial. Impairment of drug efficacy improbable at low to moderate doses and in nononcological settings. Consider genomic assessment. Supervise and monitor.
Neomycin ≈≈≈☼	Neomycin may interfere with activity of B_6, directly and through its effects on interdependent nutrients. Evidence is limited and dated but suggests that neomycin for longer than 2 weeks may have adverse effects on B_6 status, particularly in the presence of compromised nutritional status, other medications, and comorbid conditions. Further research warranted.	Coadministration of vitamin B_6 and broad range of nutrients, plus probiotics, may be beneficial, especially with extended neomycin therapy.
Oral contraceptives (OCs) ☼/⊕⊕⊕	OCs can impair 5-hydroxytryptophan decarboxylase in the tryptophan to niacinamide pathway and thus decrease serotonin levels. Higher estrogen doses may aggravate symptoms in some cases. Vitamin B_6 may reduce OC-related adverse effects, especially in women with compromised nutritional status, but often also in those with no measurable B_6 deficiency. Evidence is mixed but appears inadequate to confirm the necessity of routine nutrient support. Further research warranted.	Coadministration of vitamin B_6, preferably with folic acid, may prevent or reduce adverse effects. No adverse effects probable at typical doses, but higher doses may be indicated, and monitoring would be appropriate.
Penicillamine ◈◈/≈≈/☼	Penicillamine is a pyridoxine antagonist that reacts with PLP to form a metabolically inactive thiazolidine. Vitamin B_6 activity can be impaired and, over time, a deficiency may develop. Concomitant vitamin B_6 may counteract potential adverse effects such as anemia and peripheral neuritis. Separating intake can avoid any decrease in either agent's activity.	Coadministration of vitamin B_6 may be beneficial. Separate intake. Low risk of adverse effects from B_6 at typical doses. Impairment of drug efficacy improbable.
Phenelzine Monoamine oxidase-B inhibitors ◈◈/⊕✗/≈≈/☼	Phenelzine may act as pyridoxine antagonist by reacting with PLP to form metabolically inactive hydrazone compound and could reduce blood levels of vitamin B_6. Administration of B_6 reported to reverse drug-induced effects such as neuropathy. Separating intake would reduce risk of any decrease in either agent's activity. Evidence limited but consistent with accepted pharmacological knowledge.	Coadministration of vitamin B_6 may be prevent depletion and reverse adverse drug effects. Separate intake. Low risk of adverse effects from B_6 at typical doses. Supervise and monitor.
Tetracycline antibiotics ⊕⊕/⊕✗/◈◈/≈≈	Simultaneous intake of pyridoxine and other B vitamins with tetracycline-class antibiotics can reduce absorption and bioavailability of both/all agents. Antibacterial effect on intestinal flora and gut ecology can produce secondary adverse effects on B-vitamin status and inflammatory processes. Evidence limited but consistent with accepted pharmacological knowledge.	Separate intake if concurrent administration indicated or necessary. Probiotic flora beneficial after high-dose and/or extended antibiotics.
Theophylline, aminophylline ◈≈≈/≈≈/☼/⊕	Theophylline can cause seizures, hand tremor, and other adverse effects by acting as potent, noncompetitive inhibitor of pyridoxal kinase and by inducing pyridoxal kinase activity. Consequently, circulating PLP concentrations may be depressed and body stores of pyridoxine depleted, but circulating pyridoxal levels may remain unchanged. Vitamin B_6 administration can counter increased intake requirements and may reduce drug-	Coadministration of vitamin B_6 may prevent depletion and reverse adverse drug effects. Low risk of adverse effects from B_6 at typical doses. Supervise and monitor.

Continued

Summary

Drug/Class Interaction Type	Mechanism and Significance	Management
	induced adverse effects without impairing the therapeutic activity of theophylline.	
Tricyclic antidepressants (TCAs) ⊕⊕	PLP-dependent enzymes play a role in serotonin synthesis. Deficiency of vitamin B_6 more common in depressed individuals than in general population. Coadministration may prevent or reverse depletion as well as augment clinical response to TCAs through an additive or synergistic effect. Evidence is consistent but limited; continued research warranted.	Coadministration of B_6 can be supportive and may enhance clinical response, especially with deficiency. Consider B_1, B_2, B_{12}, and folic acid. Supervise closely and monitor regularly. Counsel exercise and healthier dietary choices.

NUTRIENT DESCRIPTION

Chemistry and Forms

Vitamin B_6 is a water-soluble vitamin that was first isolated in the 1930s by Paul Gyorgy. Catalyzed by pyridoxal kinase, an adenosine triphosphate (ATP)–dependent enzyme, pyridoxal, pyridoxamine, and pyridoxine are converted to pyridoxal 5′-phosphate, the active coenzyme form, which plays the most significant role in human metabolism. Thus, "vitamin B_6" is a generic term used to collectively describe the six related compounds that exhibit the biological activity of pyridoxine: pyridoxal (PL), pyridoxine (PN), pyridoxamine (PM), and their phosphate derivatives: pyridoxal 5′-phosphate (PLP or P5P), pyridoxine 5′-phosphate (PNP), and pyridoxamine 5′-phospate (PNP).

In addition to being water soluble, pyridoxine is stable in heat, especially in acid media, but unstable in alkaline solutions and very unstable to light.

Physiology and Function

Humans cannot synthesize vitamin B_6, so dietary intake is necessary. Pyridoxine and its vitamers are absorbed in the upper small intestine by simple diffusion. The more acidic the environment, the greater is the absorption. After being transported to the liver, pyridoxine and pyridoxal (oxidized by pyridoxine oxidase) are phosphorylated by pyridoxal kinase to form pyridoxine 5′-phosphate and pyridoxal 5′-phosphate (PLP, the active coenzyme), which is then exported from the liver bound to albumin. Tissue uptake is through extracellular dephosphorylation, followed by metabolic trapping intracellularly as PLP.

Through a variety of reactions involving transamination, deamination, desulfuration, decarboxylation, side-chain cleavage, and one-carbon metabolism, pyridoxine and approximately 100 PLP-dependent enzymes are involved in amino acid metabolism; glycogen release and blood glucose regulation; hemoglobin synthesis and oxygen transport; synthesis of niacin and a variety of lipids, hormones, and neurotransmitters; cysteine metabolism and homocysteine regulation; and formation of alpha-aminolevulinic acid, sphingolipids, and intrinsic factor.

Vitamin B_6 plays a central role in the metabolism of amino acids through the transfer of NH_2 to form keto acids and enable oxidation (i.e., transamination) and the removal of amino groups from certain amino acids (i.e., deamination), both reactions enabling their use as sources for energy. Similarly, transfer of the sulfhydryl group from methionine to serine (i.e., desulfuration or trans-sulfuration) enables the formation of cysteine and regulation of homocysteine. The removal of COOH groups from certain amino acids to yield amines (i.e., decarboxylation) is central to the synthesis of neurotransmitters such as serotonin, norepinephrine, and histamine from tryptophan, tyrosine, and histidine, respectively, and the conversion of phosphatidylserine to phosphatidylethanolamine in phospholipid synthesis. Relatedly, PLP is a coenzyme in the synthesis of niacin from tryptophan, thereby supplementing niacin intake from the diet. Dopamine and gamma-aminobutyric acid (GABA) are likewise depen-dent on B_6 coenzymes, as is the formation of sphingolipids involved in the development of the myelin sheath surrounding nerve cells. Notably, PLP can be highly concentrated in the brain even when blood levels are low, and dementia may be associated with reduced transport. Pyridoxal 5′-phosphate–dependent enzymes catalyze these and many other essential metabolic transformations.

Equally important is the role of B_6, as well as folic acid, B_{12}, and B_2, as the source of coenzymes which participate in one-carbon metabolism. Thus, the freely reversible interconversion of serine and glycine is catalyzed by serine hydroxymethyltransferase (SHMT), a reaction that is both folate dependent and PLP dependent. This mobilization of folate-linked single-carbon functional groups enables the biosynthesis of purines and 2′-deoxythymidine 5′-monophosphate and the remethylation of homocysteine to methionine.

A significant portion of the PLP in the human body is bound to glycogen phosphorylase in muscle tissue and in the liver. PLP functions as a coenzyme in the phosphorolytic cleavage of glycogen as glucose-1-phosphate; it also serves as a coenzyme in gluconeogenesis, where amino acids are used to produce glucose. Vitamin B_6 nutriture may have a beneficial effect on glucose tolerance by activating apokynureninase or kynureninase that has been inactivated by undergoing transamination, particularly under the influence of elevated estrogen levels.

Pyridoxal 5′-phosphate functions as a coenzyme in the formation of alpha-aminolevulinic acid, which is a precursor of heme. Heme is a component of hemoglobin and thus is critical to the formation of erythrocytes and function of transport oxygen. Both pyridoxal and PLP are able to bind to the hemoglobin molecule.

Vitamin B_6 plays a role in modulating the activities of several major hormones. PLP can bind to steroid hormone receptors and decrease the effects of estrogen, testosterone, and other steroid receptors through competitive inhibition. Notably, exogenous estrogens (i.e., oral contraceptives) may deplete vitamin B_6 levels, possibly through inhibition of kynureninase by estrogen metabolites and induction of tryptophan oxidase, causing increased oxidative metabolism of tryptophan.

NUTRIENT IN CLINICAL PRACTICE

Known or Potential Therapeutic Uses

The role of vitamin B_6 in conventional medicine is controversial but evolving. Other than prevention and treatment of

vitamin B_6 deficiency, standard practice primarily limits the application of B_6 to intravenous administration for pyridoxine-dependent seizures in infants and adjunctive treatment of acute toxicity from cycloserine, hydralazine, or isoniazid overdose. Furthermore, warnings of potential adverse effects from supplemental use of pyridoxine appear abundantly within conventional medical literature and press releases. Nevertheless, for decades practitioners of nutritional therapeutics have reported significant efficacy in the treatment of individuals with premenstrual syndrome, estrogen overload, adverse effects of oral contraceptives, nausea and vomiting in pregnancy, depression, carpal tunnel syndrome, and asthma. Enhancement of cognitive function and immune system activity, as well as prevention of kidney stones, have also been proposed by numerous researchers and clinicians. The role of B_6, independently or in conjunction with folate, riboflavin, and vitamin B_{12}, in regulating hyperhomocysteinemia and reducing the risk of and improving outcomes in vascular disease and heart attacks remains inconclusive. Well-designed, long-term clinical trials investigating both primary and secondary prevention and integrative therapeutics are warranted.

Low circulating vitamin B_6 is associated with elevation of the inflammation marker C-reactive protein independently of plasma homocysteine levels. Furthermore, inflammation appears to induce a tissue-specific depletion of vitamin B_6 as vitamin B_6 coenzymes are used to meet the higher demands of certain tissues during inflammation and the circulating concentration of PLP declines.

Historical/Ethnomedicine Precedent

Vitamin B_6 has not been used historically as an isolated nutrient.

Possible Uses

Acne, age-related cognitive decline, alcohol withdrawal support, Alzheimer's disease, amenorrhea, anemia (if deficient, and for genetic vitamin B_6–responsive anemia), aphthous ulcers, asthma, atherosclerosis, attention deficit disorder, autism, bulimia, burns, carpal tunnel syndrome, celiac disease, childhood intelligence (for deficiency), colorectal cancer (risk reduction), coronary artery disease (risk reduction), dementia, depression, diabetic neuropathy, fibrocystic breast disease, gestational diabetes, human immunodeficiency virus (HIV) support, hyperhomocysteinemia, hypoglycemia, immune response enhancement (critically ill patients), infant seizures (inborn error in B_6 metabolism), iron-resistant anemia, low back pain, monosodium glutamate (MSG) sensitivity or poisoning, myocardial infarction, nausea and vomiting of pregnancy, nephrolithiasis, Osgood-Schlatter disease, Parkinson's disease, photosensitivity, presurgery and postsurgery support, preeclampsia, pregnancy and postpartum support, premenstrual syndrome, retinopathy, rheumatoid arthritis, schizophrenia, seborrheic dermatitis, sickle cell anemia, sideroblastic anemia, stroke prevention, tardive dyskinesia, toxemia of pregnancy, vertigo.

Deficiency Symptoms

Vitamin B_6 deficiency can manifest as impaired immunity, irritability, depression, confusion, skin lesions, inflammation of the tongue, sores or ulcers of the mouth, and ulcers of the skin at the corners of the mouth. Inflammation appears to induce a tissue-specific depletion of vitamin B_6. Adults given deoxypyridoxine, a B_6 antagonist, developed depression, nausea, vomiting, mucous membrane lesions, seborrheic dermatitis, peripheral neuritis, and a range of neurological effects, including ataxia, hyperacusis, hyperirritability, altered mobility and alertness, abnormal head movements, and convulsions.

Although frank deficiencies are considered rare, marginal vitamin B_6 status may be relatively common.[1] Deficiencies of vitamin B_6 are usually related to an overall deficiency of all the B vitamins. The risk of B_6 deficiency or insufficiency is greatest in alcoholics, women using oral contraceptives, individuals suffering from depression, and patients with chronic fatigue syndrome and kidney failure. However, several surveys have found that daily intake of B_6 is less than the recommended dietary allowance (RDA) for a significant proportion of the population. In the United States, 90% of women and 71% of men reportedly have diets deficient in B_6, with dietary intake of vitamin B_6 averaging approximately 1.5 mg and 2 mg daily for women and men, respectively.[2] In industrialized societies, children and the elderly experience B_6 deficiency more than any other B vitamin, with men and women over 60 years of age consuming an average of approximately 1.2 mg/day and 1.0 mg/day, respectively.[3,4] The milling of grain, which removes 40% to 90 % of naturally occurring B_6, and exposure to medications and environmental pollutants that act as B_6 antagonists constitute the greatest causes of vitamin B_6 deficiency or increased metabolic requirement; food fortification may mitigate some of these losses. Other factors associated with increased risk of deficiency or insufficiency and increased metabolic need include life stages characterized by rapid growth, such as pregnancy and lactation, childhood, and adolescence; increased dietary protein intake; high alcohol and coffee intake; institutionalization; tobacco smoking; chronic digestive and malabsorption disorders, including irritable bowel syndrome, diarrhea, liver disease; and chronic diseases, including asthma, diabetes, heart disease, and rheumatoid arthritis. Some individuals on a very restricted vegetarian diet may be at increased risk of insufficient B_6 intake.

Dietary Sources

Calf liver, turkey, tuna, spinach, banana, lentils, and potatoes are among the dietary sources relatively rich in vitamin B_6. Other foods containing B_6 include organ meats, pork, poultry, milk, egg yolks, fish, corn, legumes, seeds, grains, wheat, wheat germ, wheat bran, brewer's yeast, green leafy vegetables, green beans, avocados, cantaloupe, cabbage, green peppers, carrots, soybeans, blackstrap molasses, walnuts, peanuts, and pecans.

Vitamin B_6 in food sources appears as pyridoxine, pyridoxal, and pyridoxamine. Not all forms of dietary B_6 are equally bioavailable. In a mixed diet, approximately 75% of vitamin B_6 present is bioavailable. Pyridoxine glucoside, found in certain plant foods, exhibits only 50% the bioavailability as vitamin B_6 from other food sources or supplements. Furthermore, cooking and food processing can destroy a significant portion of vitamin B_6 originally present in foods. Freezing of vegetables decreases B_6 content by 20%, canning by 54%, and processing of grains by 40% to 90%.

The dietary requirement for vitamin B_6 is proportional to the level of protein consumption, ranging from 1.4 to 2.0 mg daily for a normal adult. The requirement for vitamin B_6 during pregnancy and lactation increases approximately by 0.6 mg daily.

Nutrient Preparations Available

Pyridoxine hydrochloride and pyridoxal 5'-phosphate (PLP) are the more commonly available forms, with pyridoxal and pyridoxamine also being available as supplements. Pyridoxine hydrochloride is the form most widely used in conventional medicine and typical supplements and has the advantage of efficient transport through cell membranes and the ability to cross the blood-brain barrier. However, many practitioners experienced in nutritional therapeutics frequently administer PLP because it is the activated form and is particularly important in patients with conditions characterized by impaired conversion of pyridoxine hydrochloride to PLP, such as liver disease and zinc or magnesium deficiency. Some sources maintain that PLP is better absorbed, but these claims are contentious.

Dosage Forms Available

Capsules, liquids, liposomal sprays, lozenges, softgels, tablets, effervescent tablets, and enteric-coated tablets. Vitamin B_6 is usually contained in multivitamins or B-complex formulations, including chewable tablets and liquid drops for children.

Supplemental B_6 is best taken between or with meals, preferably with doses divided throughout the day. Individuals who experience alterations in sleep patterns with B_6 may benefit from emphasizing morning intake.

Dosage Range

Adult

Dietary:

Men and women: 1.3 to 1.7 mg/day, increasing with age
Pregnant women: 1.9 mg/day
Lactating women: 2.0 mg/day

Note: Vitamin B_6 requirements rise with increased dietary protein intake. Before 1998 the U.S. RDA for vitamin B_6 was expressed in terms of protein intake. However, when the Food and Nutrition Board (FNB) of the Institute of Medicine revised the RDA for vitamin B_6 in 1998, they factored in protein intake but established fixed RDA levels.

Supplemental/Maintenance: 10 to 40 mg/day.

Optimal daily intake: Women: 50 mg/day; men: 35 mg/day.

Pharmacological/Therapeutic: 50 to 200 mg/day, occasionally as high as 500 mg daily; typically safe at levels of 200 to 300 mg daily; even so, individuals using more than 100 to 200 mg daily for more than 2 months should be supervised by a nutritionally trained health care professional.
